Intercurrent catarrh of the stomach may sooner or later become a troublesome feature, and in combating it lavage is frequently our most effective measure.

PNEUMOTHORAX

(*Seropneumothorax*; *Pyopneumothorax*)

Definition.—A collection of air in the pleural cavity. Since the latter, as a rule, contains at the same time serum or pus, the terms sero- and pyopneumothorax are frequently employed to describe the same condition. It is an uncommon condition.

Pathology.—When the pleural sac is punctured air usually escapes, accompanied sometimes by an audible hissing sound. The pleural sac in pure pneumothorax is greatly distended, and the lung is impacted against the spinal column. Other organs (spleen, heart) are also displaced owing to positive intrathoracic pressure. The heart is not rotated, however, and the relation of its parts is maintained much as in the normal condition (Osler). The air may occupy but a portion of the pleural cavity on account of previous firm adhesions (*circumscribed pneumothorax*). The point of perforation, as a rule, can be easily found, and frequently corresponds to the seat of rupture of the tuberculous cavity or superficial caseous mass. In other instances the cause of pneumothorax cannot be discovered. Inflation of the lung under water may reveal the aperture, which is usually small, by the escape of air-bubbles at the seat of puncture. Occasionally a fistulous connection between the pleural sac and the bronchi can be traced.

Simple pneumothorax is, however, of rare occurrence. The air that gains admission into the pleural sac is laden with micro-organisms (*vide* Bacteriology, p. 545), which set up various forms of inflammation, accompanied by equally various exudations. Hence the cavity is usually filled, in part, with an effusion that is purulent or seropurulent, as a rule, and rarely serous or serofibrinous. The *gas* in cases of pneumothorax may be of bacterial origin; this contains substances not found in air, such as H, H₂S, or marsh gas.

Etiology.—The *predisposing* influences are: (a) *age*—the condition occurring in adults, as a rule, though instances are also observed in young children; (b) *sex*—males suffer more than females; (c) the left side is affected nearly twice as often as the right; (d) *emphysema*, in which the superficial

air-sacs are dilated and atrophied, and so rendered liable to rupture from excessive muscular exertion.

The **exciting causes** are: (1) *Perforation of the lung and pulmonary pleura* (the most frequent cause), arising in one or other of three ways: (a) From the rupture of a tuberculous cavity into the pleural cavity. This accident rarely occurs at the apex of the lung, but commonly near the upper border of the lower or middle lobe; less frequently near the lower border of the upper lobe. A caseous focus immediately beneath the pleura may also, during the process of softening, puncture the pleural sac and invite the entrance of air during the early stages. It cannot occur, however, except in cases in which previous adhesions have failed to form at the point of perforation. At least 70 per cent. of the cases of pneumothorax are tuberculous (Morse).¹ (b) As the result of necrotic processes, in connection with certain other lung affections, as gangrene, bronchopneumonia, suppurating bronchial glands, abscess, and echinococcus cysts. (c) From rupture of the normal air-sacs in consequence of severe muscular effort (S. West, DeH. Hall). This accident is sometimes ascribable to the violent paroxysms of cough in pertussis.

(2) Some cases of *empyema*, by perforating the visceral pleura, the lungs, and bronchi.

(3) Perforations of the pleura in *malignant disease* and *abscess of the esophagus*.

(4) A *peripheral bronchiectasis* may open the pleural space.

(5) Pyopneumothorax may be of *subdiaphragmatic origin*, consecutive to *perforation by malignant disease* or *ulcer of the stomach or colon*.

(6) Pneumothorax may be occasioned by *gases* resulting from the action of a gas-forming bacterium on the pleural exudate.

(7) *Wounds* causing direct or indirect perforative lesions of the lungs. Fractures of the ribs may produce laceration of the visceral pleura, and allow the air to enter the pleural sac.

(8) English and French authors and, more recently, Americans as well have emphasized the occurrence of a benign spontaneous, non-tuberculous pneumothorax, "occurring in apparently healthy individuals without ascribable cause, resulting in no infection of the pleura and, therefore, unaccompanied by constitutional symptoms and healing rapidly and completely in a few weeks" (Hamman¹).

Symptoms.—The earliest symptoms vary according to the cause or causes that produce the condition. When it develops, as it does so often in the course of pulmonary tuberculosis, the *onset* is sudden, marked by agonizing *pain* in the side, by intense *dyspnea*, and frequently *cyanosis*. The dyspnea is often accompanied by a sense of impending suffocation. The severity of the pain and the degree of oppression depend largely, however, upon the amount of air that gains entrance into the pleural sac or is formed from the exudate, the rapidity with which it enters, and the presence or absence of previous pleuritic adhesions. If the orifice be large and valvular, the air cannot escape, but rapidly accumulates and forces all the air out of the lung by compression; the patient then sinks rapidly into collapse from shock and sudden death ensues. Fortunately, the *open* form is commoner, especially in non-tuberculous pulmonary affections. The *respirations* are frequent; the *pulse* is also frequent and feeble, sometimes reduced to a thread; and cold sweats are not uncommon. The *temperature* at first is apt to fall one or two degrees below the normal, owing to sudden collapse; *fever*, however, follows almost invariably, and frequently is of the *hectic* type. Its cause is pleuritis, often purulent, and if this be the case, the dyspnea may be due in part to the increasing effusion.

¹ *Amer. Jour. Med. Sci.*, May, 1900.

² *Ibid.*, 1916, cli, 229.

The patient now also suffers from the grave symptoms of empyema above described. Edema of the hand of the affected side is sometimes present as an early manifestation; it rapidly disappears (Weil). When pneumothorax develops in the last stages of phthisis acute symptoms may be entirely absent.

Pepper,¹ among others, has called attention to the frequency with which a pneumothorax may develop without acute symptoms, insidiously. The pulmonary symptoms are characteristically mild and there is an absence of constitutional symptoms. The physical signs are the typical ones of the usual pneumothorax.

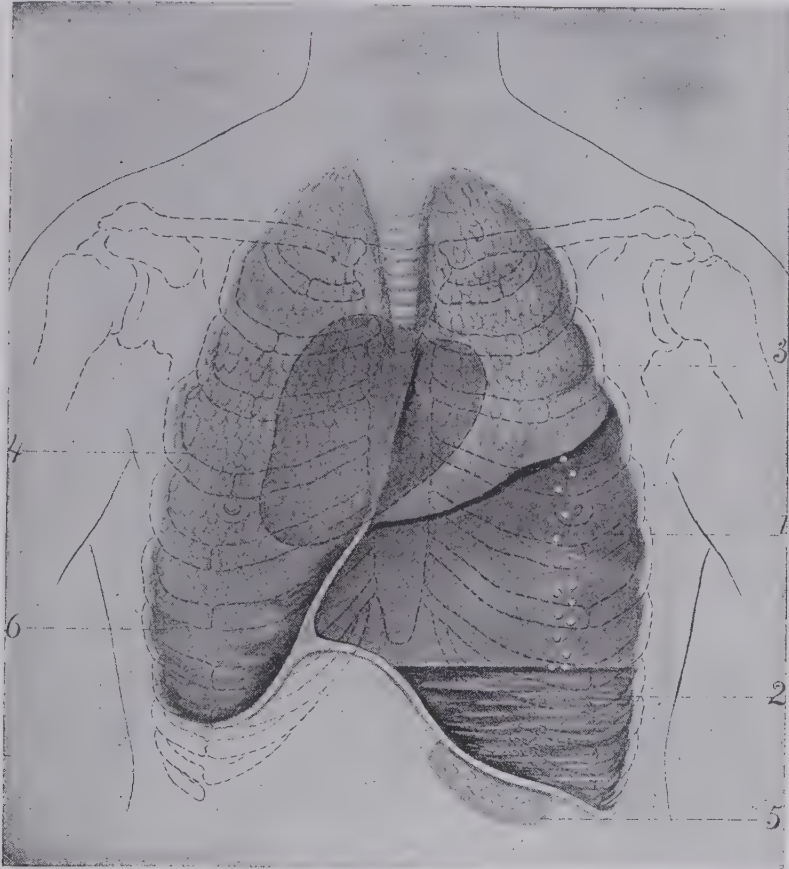

Fig. 48.—1, Air in the pleural sac; 2, fluid exudate at base of pleural sac; 3, compressed portion of lung; 4, displaced heart; 5, depressed spleen; 6, mediastinum pushed toward the right.

Physical Signs.—These are marked (see Fig. 48), although rarely they may be in abeyance for several days (masked pneumothorax). *Inspection* shows marked distention and immobility of the affected side; also some degree of distention with unnatural mobility of the healthy side.

Palpation shows the tactile fremitus to be diminished above and greatly diminished or wholly absent over the effusion below. Edema of the chest wall can frequently be made out. The impulse-beat of the heart is found to be feeble and displaced.

¹ *Amer. Jour. Med. Sci.*, 1911, cxlii, 522.

On *percussion* a deep and full or modified tympanitic note (*bell tympany*) can usually be elicited over the area corresponding to the contained air, and the excessive tension in the pleural sac, due to the enormous amount of air it contains, may cause an elevation in the pitch of the note even to dulness. The "cracked-pot" sound is audible when the air in the pleural cavity freely communicates with the external air. Wintrich's sign, or a change in the pitch of the percussion sound when the mouth is open or closed (being lowered when the mouth is closed and raised when open), may also be observed. In pyopneumothorax a flat note is elicited from the base upward as far as the fluid extends, and change of posture causes a more marked temporary variation in the upper level of flatness than occurs in pleurisy. Modifications in the pitch of the percussion sound result from an alteration in the form as well as in the dimensions of the air space. Owing to displacement of the heart there is, as a rule, resonance over the normal cardiac region, and particularly when the patient assumes a recumbent posture. The pulmonary resonance on the affected side is stationary and extends as low as resonance on the opposite side upon deep inspiration. There is no respiratory variation (Hamman). The liver and spleen, according to the side affected, are displaced downward to a greater degree than in simple pleuritic exudates.

Auscultation discloses a greatly weakened or altogether suppressed respiratory murmur when collapse of the lung is incomplete. Amphoric breathing is audible in cases of *open* pneumothorax, and bronchial râles possessing a metallic quality are sometimes heard, as well as metallic tinkling on deep inspiration or on coughing. The metallic tinkling is caused frequently by drops of fluid falling from above upon the surface of the effusion; less frequently by a re-echoing of vibrations of moist bronchial râles communicated to the air in the pleural chamber. The vocal resonance is enfeebled, as a rule, and evinces the same metallic quality. The so-called coin-test is a pathognomonic sign, and is elicited in the following manner: An assistant places one coin on the front of the chest and taps it with another while the ear of the examiner is placed on the thorax posteriorly, where will be heard the intensified echo of the coin sound thus produced. Another most characteristic sign is the so-called Hippocratic succussion, which is elicited by placing one ear upon the patient's chest while the latter's body is shaken, when a distinct splashing sound is heard.

Diagnosis.—When the attack is of ordinary severity pneumothorax is diagnosed by the history of one or other of the causal factors, together with certain physical signs that do not belong to any other affection (*coin sound, succussion-splash*). The sputum test and also bacteriologic study of the aspirated purulent exudate with a view to determining the special etiologic variety present in a given case is of the greatest importance. Spontaneous pneumothorax yields a sterile exudate, if any. It is only when the air and fluid in the pleural sac are encapsulated that it may become difficult to eliminate without the aid of the roentgen ray (*a*) a large pulmonary cavity; (*b*) excessive gaseous distention of the stomach; (*c*) an abscess below the diaphragm into which air has entered (*pyopneumothorax subphrenicus*); (*d*) a diaphragmatic hernia; (*e*) emphysema, and (*f*) pleurisy with effusion.

(*a*) *A Large Pulmonary Cavity.*—The "cracked-pot sound" and Wintrich's sign are more frequent in cavity than in pneumothorax, and the former condition does not tend to dislocate the adjacent organs. There is an absence of the succussion-splash, and, except in rare instances of the coin-test, these signs are often present, even in circumscribed pyopneumothorax. Tabulated, these points of difference are—

PYOPNEUMOTHORAX

Immobility and bulging of the interspaces. The apex-beat is usually displaced.

Diminished vocal fremitus

Percussion-note deep and full. The effusion sinks to the base, and yields flatness, the outline of which changes with the posture of the patient.

Respiratory murmur and vocal resonance usually absent. Amphoric breathing may be heard if the opening in the lung is patulous. The coin-sound and Hippocratic succussion-splash are noted.

LARGE PULMONARY CAVITY

Immobility, flattening of the chest, and depression of the interspaces. Apex-beat not displaced.

Fremitus usually increased.

Percussion gives tympany or a "cracked-pot sound," and Wintrich's change of sound as a rule.

Bronchial breathing is heard, and the vocal resonance is increased. Crackling, gurgling râles, cavernous or amphoric breathing, and pectoriloquy may be present. Absence of bell-tympany (generally) and succussion-splash.

(b) *Excessive gaseous distention of the stomach* is to be eliminated by the history of the case and by the results of the application of the therapeutic test, evacuation of the stomach and bowels.

(c) *Subphrenic Abscess Containing Air*.—This is exceedingly rare, and occurs relatively oftener on the right than on the left side (Leyden). Its leading causes are ulcers of the stomach or duodenum, followed by circumscribed peritonitis, perforation, and abscess, the latter occupying a position immediately beneath the diaphragm and above the liver. The gases that gain admission to the abscess sac from the intestines force the diaphragm upward, and thus cause retraction or even compression of the lung. The symptoms are now identical with those of circumscribed pyopneumothorax, limited to the base. A knowledge of the steps in the production of subphrenic abscess; the absence of cough and expectoration, and of marked displacement of the heart; and the presence of bulging of the hypochondrium, of striking depression of the liver, and of Pfuhl's sign (*q. v.*), are indications favoring subphrenic abscess.

(d) *Diaphragmatic Hernia*.—This either results from a severe injury or is congenital, and the most valuable point of difference between hernia of the diaphragm and pneumothorax is the peculiar cause of the former. The next most valuable point is the fact that the hernial protrusion may return suddenly to its normal position, whereupon the patient will be relieved; the condition may then reappear not less suddenly. The third distinctive feature is the presence of rumbling sounds in the protruded bowel. All other signs and symptoms of one affection may have their counterparts in those of the other.

(e) Pneumothorax may be confounded with *emphysema* by the careless observer; but the latter affection is slow in onset, free from serious shock, is bilateral as a rule, and does not exhibit the distinctive physical signs of pneumothorax (metallic tinkling, coin-sound, succussion-splash).

(f) In *pleurisy with effusion* hyperresonance may be noted above the fluid, but it lacks the bell-like tympany of pneumothorax. Over the same area there is diffuse, distant, bronchial breathing (at times slightly amphoric), while the metallic tinkling, coin-sound, and succussion-splash are totally wanting.

Prognosis.—This depends largely upon the cause. Spontaneous pneumothorax often heals rapidly. The cases attributed to advanced phthisis usually reach a fatal issue in the course of one, two, or more weeks, and rarely they run a very rapid and fatal course. On the other hand, the pulmonary condition is at times favorably influenced by its occurrence. Following empyema, or when due to trauma or abscess of lung, pneumothorax sometimes takes a favorable course. It is fraught with especial danger when it is the resultant condition of some acute lung disease (gangrene, bronchopneumonia). The prognosis is worse in right-sided pneumothorax.

Treatment.—The leading indication is the alleviation of the patient's sufferings by a prompt resort to morphin, and it often becomes necessary to administer it hypodermically. If the patient's previous strength has been moderately good, the question of operative intervention should be seriously considered, the nature of the surgical procedure then depending upon the character of the effusion. If this be serofibrinous, aspiration, as in simple pleurisy, must be performed to relieve the urgent dyspnea; if purulent, permanent drainage should be procured for the same indication. A costal resection may be advisable. When pneumothorax develops late in phthisis radical measures are not to be thought of, and the physician must rely upon aspiration (when necessary) to relieve urgent symptoms. We may also tap the air-chamber above the fluid with a fine needle, with a view to lessening the excessive tension. Unverricht has recently reported good results from a somewhat novel mode of treatment. When there is a pulmonary fistula present he inserts a tube into the pleural sac. This allows free entrance of air, the lung collapses completely, and the fistula has a chance to heal. Pisani¹ used counter-pressure from injected nitrogen in spontaneous pneumothorax, the perforation in the lung tissue being closed. For the dyspnea, atropin administered hypodermically is valuable; for the feeble cardiac action, alcoholic stimulants, aromatic spirits of ammonia, strychnin, ether, and other stimulants should be employed. Locally, cutaneous irritants may be applied (turpentine stupes, mustard pastes).

HYDROTHORAX

(*Dropsy of the Pleura; Thoracic Dropsy*)

Definition.—A collection of transuded serum in the pleural cavity.

Pathology.—Hydrothorax is generally a bilateral condition. The transudate is a clear, amber-colored liquid that is free from fibrin, but may contain cholesterin and a few endothelial cells. It has an alkaline reaction, a comparatively low specific gravity (1009 to 1012), and is non-inflammatory. The pleural surfaces are usually smooth, though sometimes decidedly pale and edematous. The mechanical effects of hydrothorax upon the lungs and other thoracic and abdominal viscera are similar to those of the exudates that accompany inflammation of the pleura, though they are rarely so marked as in serofibrinous pleurisy.

Etiology.—Hydrothorax is a secondary affection, and is usually connected with one or other of the various forms of general dropsy (hemic, renal, cardiac). The condition may develop at a comparatively early stage of arteriosclerosis and of chronic valvulitis, especially aortic incompetency, without external dropsy. Of 608 cases of hydrothorax, 294, or 48.3 per cent., were of cardiac origin. Again, of these 294 cases, 190, or 64.6 per cent., were associated with myocardial, and 107, or 35.4 per cent., with valvular heart disease. In 162, or 85.3 per cent., of the myocardial cases marked sclerosis of the vessels coexisted, while in 28, or 14.7 per cent., a slight grade of arteriosclerosis was associated. In nearly all of the myocardial cases evidence of chronic interstitial nephritis was also present (Anders²). The cases that are due to blood impoverishment are more numerous than is generally indicated by writers upon the subject, and not infrequently is hydrothorax secondary to either chronic

¹ *Gazzetta degli Ospedali e delle Cliniche*, Rome, March 23, 1916.

² "A Statistical Study of Hydrothorax; Its Diagnosis and Treatment," *Pennsylvania Med. Jour.*, February, 1914.

dysentery, chronic diarrhea, leukemia, pernicious anemia, carcinoma, malaria, syphilis, or scurvy. Strictly local causes may also induce it, as carcinoma of the pleura, or compression of the superior vena cava or of the thoracic duct by a tumor. Fetterolf and Landis have demonstrated that the fluid comes from the visceral, and not the parietal pleura, including the azygos veins.

Symptoms.—The *subjective symptoms* are attributed to the mechanical effects of the fluid, and may be quite in common with those of the causal affection; there are *dyspnea* (often culminating in orthopnea), *cyanosis*, *asthmatic seizures*, *irritative cough*, and a *feeble circulation*. The *general symptoms* arise from the primary affection.

The **physical signs** are much the same as in pleurisy with effusion—with this difference, that they are more often bilateral. Hydrothorax is often unilateral, however (59, or 31 per cent., of 190 cases—Anders), and an enlarged right auricle may be the cause of this condition in some instances. The right side is the one usually affected. I have also observed that quite frequently the two sides of the chest exhibit great variations as to the relative amount of fluid contained.¹

Diagnosis.—While this rests almost exclusively on the physical signs, these must be carefully noted, or otherwise the condition will sometimes escape detection. The diagnosis should embrace the particular etiologic variety so far as practicable, *e. g.*, if cardiac. With respect to myocardial hydrothorax, the principal error in diagnosis is in the assumption "that the condition is not to be suspected in cases in which the signs of chronic valvulitis and external edema are absent" (Anders²). In this variety such clinical features as arrhythmia and more or less hypertension may also be present.

Prognosis.—This depends upon the nature of the primary disorder that causes the dropsical transudation.

The **treatment** of hydrothorax has intimate relations with the indications presented by the underlying affection. If the measures directed toward the removal of the general dropsy (*anasarca*), of which hydrothorax is a part, are unsuccessful, and the amount of transudation in the pleural sac interferes with the functions of the heart and lungs, then aspiration must not be too long delayed, and must be repeated as often as occasion demands. Experience teaches that aspiration should precede the use of cardiac stimulants in hydrothorax, since the latter tend to aggravate the dyspnea when considerable serous fluid is present in the pleural sacs. In double hydrothorax it is wise to aspirate both sacs at one and the same sitting, since unilateral tapping affords insufficient relief.

CHYLOTHORAX

Definition.—Chylothorax is an accumulation of chyle within the pleural cavity. Baldwin has collected 47 cases and Lewin has recently reported an instructive case.

Etiology.—It may be caused by rupture of the thoracic duct or its radicles, due to chest injury, or to some diseased condition of their walls permitting of transudation into the pleural sac. It is not infrequently secondary to new growths, either without or in the duct.

The **symptoms** and signs are those of hydrothorax (*vide ante*), although a few patients complain of pain in the affected side if the condition is unilateral.

¹ For the differential diagnosis between pleurisy and hydrothorax, see Pleurisy, p. 556.

² "Myocardial Hydrothorax," *Amer. Jour. Med. Sci.*, July, 1913.

The **diagnosis** depends wholly upon the chylous nature and appearance of the transudate.

The **prognosis** is unfavorable, although the condition is by no means always fatal.

The **treatment** of chylothorax is governed by the special cause in the given case. "In those cases due to chronic obstruction, aspiration, rest in bed, and nourishing food are indicated" (Levin). Not all of the fluid should be removed at once in cases which demand paracentesis.

NEW GROWTHS OF THE PLEURA

Almost all instances of new growths developing in the pleura are secondary to primary carcinoma of the lung, the pleura being invaded by the direct extension of the neoplasm. It may also arise by metastasis from carcinoma of the lung, mammary glands, etc. The pleura presents circumscribed areas of thickening, or the growth takes the form of papular projections from its surface, becoming pedunculated as they enlarge. Their size varies from that of a pea to that of an orange. The adjacent pleura is inflamed, often adherent, and much thickened, and an effusion into the pleural cavity is often observed.

Primary carcinoma of the pleura is very rare indeed, and E. Wagner, who first described it, called it endothelial carcinoma. Most pathologists of today, however, look upon endothelioma as a variety of *sarcoma*. It owes its origin to a proliferation of the endothelial cells of the connective tissue and the lymph apparatus of the pleura. This invariably assumes the diffuse form, and by metastasis we have involvement of the other organs (lungs, lymphatics, liver). Spindle-cell sarcoma and the round-cell variety are occasionally met with.

Symptoms.—The subjective symptoms are slight in cases in which there is a single circumscribed carcinomatous mass in the pleura; but they are quite severe in the diffuse form, particularly when, as commonly occurs, it is of a secondary nature. The symptoms are now those of plastic or serofibrinous pleurisy, in addition to those of primary carcinoma of the lung, and the former may oftentimes more or less completely overshadow the latter.

Diagnosis.—The circumstances under which the condition arises often throw the strongest light upon its nature. The symptoms of slowly developing pleurisy, either plastic or serofibrinous, following carcinoma of the lung or the breast, and accompanied by the cancerous cachexia, would point strongly to the existence of *carcinoma of the pleura*. Characteristic cancerous elements may also be found by microscopic examination of the usually hemorrhagic fluid obtained on aspiration. The exudate contains fatty endothelial cells. Mitotic figures in cells of serous exudates are of confirmatory diagnostic value.

The difficulties surrounding the diagnosis of primary carcinoma of the pleura are great and usually insurmountable. The cases are very similar in their clinical manifestations to *chronic pleurisy with or without effusion*. Pain is always a more prominent symptom, however, than in simple chronic pleurisy, and this fact, when combined with evidences of a cancerous cachexia, should excite strong suspicions. The prognosis is wholly unfavorable and the treatment merely palliative.

DISEASES OF THE MEDIASTINUM

The affections of the mediastinum may be divided into three classes: (a) Inflammation, (b) Tumors, and (c) Mediastinal hemorrhage.

(a) **INFLAMMATION.**—This may affect (1) the glands or (2) the connective tissue. **Lymphadenitis** of moderate grade is found in association with bronchopneumonia and the various forms of bronchitis. The condition appears in its most pronounced form in the bronchitis of measles, influenza, and whooping-cough, and De Mussy held that enlargement of the glands in the posterior mediastinum is potent in exciting paroxysms of whooping-cough. According to De Mussy and Guit  ras, these glands when greatly enlarged give rise to dulness in the upper part of the interscapular region or down to the fourth dorsal vertebra in cases of influenza and whooping-cough. I have been able to confirm this dictum in cases of influenza, while other writers consider it questionable. Tuberculous lymphadenitis is elsewhere described (*vide* Tuberculosis, page 231). The mediastinal lymph-glands may undergo supuration in consequence of local specific infection, and though not recognizable during life, the condition may lead to perforation into either the esophagus or a bronchus, with serious results. In other instances spontaneous absorption occurs, leaving behind inspissated contents that undergo calcareous change. *Syphilitic mediastinitis* calls for treatment with soluble mercurial salts, especially the cyanid, by the intravenous method, or salvarsan.

Abscess of the Mediastinum.—This is of rare occurrence, its most frequent seat being the anterior mediastinum. Of the commoner causes may be mentioned traumatism and the infectious diseases—erysipelas, rheumatism, measles, and small-pox in particular. It may also be the result of an extension of a suppurative process from neighboring structures. Pulmonary tuberculosis is the most potent factor in producing chronic abscess in this situation.

Symptoms.—*Acute Abscess.*—Pain and tenderness in the sternum are the most prominent features, the pain being acute and often of a throbbing character. Cough and dyspnea are usually present. The general features are fever, frequently accompanied by rigors, profuse sweats, and prostration. The chief physical sign is dulness upon *percussion*, usually found anteriorly and increasing gradually with the development of the abscess. Later, the tumor may reach the surface of the body, and rarely the sternum is eroded. *Palpation* now detects pulsation and fluctuation. The abscess may either find its way downward into the abdomen, or it may perforate the trachea or the esophagus.

In *chronic abscess* the symptoms bear a close similarity to those of solid tumors. Fortunately, chronic abscess often results in spontaneous cure, in which case it is in part absorbed, and the remainder of its contents become inspissated.

Diagnosis.—*Acute abscess* must be differentiated from solid mediastinal tumors and aneurysm. The more acute onset and general symptoms of the suppurative process (hectic type of fever, chills, sweats) and the more rapid course will serve to distinguish abscess from *aneurysm* on the one hand, and *solid tumors* on the other. Further, the absence of strong expansile pulsation, diastolic shock, and the aneurysmal bruit aid materially in eliminating *aneurysm of the arch*. In obscure cases an exploratory puncture with a small needle may be safely practised, and, as a rule, with definite results.

The **treatment** is mainly surgical.

(b) **TUMORS OF THE MEDIASTINUM.**—Two forms only demand practical consideration—carcinoma and sarcoma. Hare's analysis of 520 cases gave

the following ratio: of carcinoma, 134; sarcoma, 98; lymphoma, 21; fibroma, 7; dermoid cyst, 11; hydatid cyst, 8; and fewer cases of echondroma, lipoma, and gumma. In 48 of the cases of carcinoma and in 33 of sarcoma the tumor occupied only the anterior mediastinum. It is quite probable, however, that sarcoma, and not carcinoma, is the commoner neoplasm of this region. The clinical term "cancer" was formerly used promiscuously by many authors, and the pathologic diagnosis was then difficult, so that statistics are scarcely trustworthy. Upon investigating 25 of the older reports of "cancer," Pepper and Stengel found in 13 unquestionable evidence that the growth was sarcoma, while in the remaining 12 they could not, for the greater part, decide to which form the disease belonged. Primary sarcoma may spring from the remnant of the thymus gland, from the lymphatic glands, the pleura, or lungs, or from the fibrous tissues of the mediastinum. Primary carcinoma may originate in the esophagus, bronchi, lungs, or rarely in the thymus gland. Secondary mediastinal tumors are apt to have their seat in the lymphatic glands. Carcinoma is less frequently primary than sarcoma. Among *predisposing causes* are sex and age—males being more prone to the affection than females, and the period of chief liability is between the thirtieth and fortieth years.

Symptoms.—The earlier symptoms are vague (slight substernal pains, dyspnea, languor). Later, pressure-symptoms gradually arise.

The *pain* may or may not be severe, but is invariably accompanied by a feeling of oppression. Its chief seat is in the upper sternal region, but it may radiate to the sides of the chest and even down the arms (due to pressure on the brachial plexus). *Dyspnea* appears early, is constant, and may become intense. It is caused by pressure either upon the trachea, upon a primary bronchus, or upon a recurrent laryngeal nerve. *Asthmatic seizures* may occur before there is constant dyspnea and before the tumor has reached notable size. There is *cough*, which may be paroxysmal and of a brazen character. Aphonia may be present. There may be *dysphagia* from pressure upon the esophagus, though this is rare. If there is an inflammation of the vagus or sympathetic nerve, the rate of the pulse may be either slowed or markedly quickened. Owing to implication of the sympathetic there may be local hyperemias and pupillary inequalities.

Compression of the superior vena cava or of the subclavian vein may be followed by cyanosis and edema of the parts drained by these vessels. The early occurrence of venous occlusion and dilatation of the superficial veins is quite characteristic. Collateral circulation may be rarely established. Less frequently the inferior cava may also be compressed.

Physical Signs.—*Inspection.*—In advanced cases a swelling, usually somewhat irregular and often diffuse, appears in the sternal region. The tumor may cause erosion of the sternum, and a little later occupy a position immediately beneath the skin. I saw a case in which the perforation occurred at the right edge of the sternum where aneurysms of the ascending arch appear. In the early stages, however, this prominence is not present. *Palpation.*—When a tumor is present it may pulsate distinctly, and the heart's apical impulse may be detected in various abnormal positions. Tactile fremitus is feeble or absent over the seat of the growth.

On *percussion*, dulness is noted, and this is true even in many instances that do not present a visible swelling. The dull area varies in outline with the size and position of the tumor. *Auscultation* usually reveals no sounds over the dull area except a bruit in rare instances. The heart-sounds are inaudible over the tumor site as a rule, and the breath-sounds and vocal resonance are feeble or absent. To the above physical signs are frequently added those of pleural effusion.

The **diagnosis** of mediastinal growths is made, if at all, principally by exclusion. *Aneurysm* is differentiated from solid mediastinal tumors with only slight success in many instances. Aneurysm, however, runs a longer course, on the average, than mediastinal tumor. The tumor when due to aneurysm communicates a strong, heaving, expansile pulsation—a characteristic that is absent or only feebly manifested in the case of solid mediastinal growths. The severe diastolic shock, noted on both palpation and auscultation in cases of aneurysm, is also absent in solid tumor. Kassabian has shown that new growths can be early recognized by a roentgen ray examination. On the other hand, shadows situated in the anterior portion of the chest and to the right of the median line are generally produced by aneurysms.

The *duration* of the disease varies from six to eighteen months.

The **prognosis** is absolutely hopeless, except in the case of benign tumors, which may be removed in some instances.

The **treatment** is directed toward the relief of the most urgent symptoms. Anodynes are required sooner or later, and should not be withheld if indicated. As a routine the preparations of iodine and mercury are employed; but, as these are useless, they are unwarranted. Arsenic has sometimes seemed to influence sarcomatous and lymphadenomatous growths favorably, though only temporarily.

(c) **MEDIASTINAL HEMORRHAGE**.—This term signifies hemorrhage into the mediastinal connective tissue. It oftenest results from the rupture of aneurysms of the arch. It may also be of traumatic origin.

PART VII

DISEASES OF THE CIRCULATORY SYSTEM

I. DISEASES OF THE PERICARDIUM

PERICARDITIS

Definition.—An inflammation of the serous covering of the heart.

Varieties.—(a) Plastic, or fibrinous; (b) serofibrinous, or subacute; (c) purulent; (d) hemorrhagic; (e) adhesive. There is also a tuberculous pericarditis which has been described (*vide* Tuberculosis, page 266).

Bacteriology.—Pericarditis may be caused by a great many different varieties of bacteria, chief among which are the pyogenic cocci, the organism that causes acute articular rheumatism, and the tubercle bacillus. Among other organisms, the *Bacillus coli communis*, and probably also a variety of the *Bacillus pyocyaneus* and the gonococcus may be named. Micro-organisms are not always found in pericarditic exudates by any means.

ACUTE PLASTIC OR FIBRINOUS PERICARDITIS

Pathology.—The morbid changes are frequently localized, and less frequently are general. At the onset the membrane is smooth, swollen, and injected, and punctate ecchymotic spots may be visible; soon it presents a grayish, roughened appearance from the deposit of a thin layer of fibrin. In the severer types the fibrinous deposit increases in thickness for a time, and the natural movements of the pericardial surfaces upon one another sometimes cause the exudate to assume a honeycombed appearance. Most examples that I have seen, however, have resembled the roughened surfaces produced by separating two slices of thickly buttered bread; the surfaces are grayish-yellow in color. In the later stages the exudation becomes partly organized, and, as the result of friction produced between the opposed surfaces by the incessant action of the heart, may present a villous appearance; hence the term “hairy heart” of the ancient authors. For like reasons we may see the exudate arranged in the form of little ridges, forming a “tripe-like membrane.” Though invariably present, the amount of serous effusion, as the term would indicate, is never large in dry or plastic pericarditis. Myocarditis may frequently be found as an associated condition.

Etiology.—In each variety of pericarditis there are special contributing factors, so that it is desirable to give its etiology separately, except in the serofibrinous and acute plastic types, which have practically the same etiology. The two latter are the more common forms of the disease. Acute plastic pericarditis most frequently occurs in young and middle-aged males. It may

be *primary* or *secondary*. It often occurs in acute articular rheumatism (in more than one-half the cases), chorea, lobar pneumonia, chronic nephritis, and, rarely, in other acute infectious diseases. Of 150 cases of acute pericarditis studied by Locke, pneumonia was the cause in 63 cases; empyema in 6; tuberculosis in 7; local or general sepsis in 28; nephritis in 16; meningitis in 3; rheumatism in 2. In this form the infective agents are transmitted to the pericardium by means of the circulation. It may be caused also by direct extension of inflammation from adjacent structures (secondary pericarditis), as in simple pleurisy; more commonly the extension occurs from a pneumonia or tuberculous pleurisy, or the condition may complicate new growths and inflammatory conditions affecting the esophagus and bronchial glands. It may also be secondary to chronic disease of the aortic valve, the pericardium becoming involved by extension through the walls of the aorta. Finally, it may be the result of traumatism, and this may cause any of the other forms of pericarditis.

Clinical History.—Owing to the fact that acute plastic pericarditis is usually a secondary affection, the symptoms that enable one to recognize it are obscured by those of the primary disease. This is particularly true of that large class of cases that develop in acute articular rheumatism, in which subjective symptoms are often entirely wanting. Only in the severest types of this sort are the symptoms referable to the heart well enough marked to arrest the attention. There may be a feeling of *distress* or *constriction* with or without slight *pain* in the precordium. During the first stage or prior to the pouring out of the effusion the pain is most marked, extending sometimes into the left arm or the back, and at others to the ensiform cartilage or even to the abdomen. This pain is, rarely, increased by pressure over the precordia. *Palpitation* and *dyspnea* may be present, and the *pulse* is increased in frequency and strength, as a rule, except in the later period, when it may be weak and slightly irregular, particularly if the muscular tissue of the heart be involved. There is some *fever*, but the degree of elevation of temperature perhaps never exceeds 102° F. (38.8° C.). In this class of cases the *urinary features* depend largely upon the character of the leading etiologic factors; though in many instances the urine is scanty, high colored, and acid in reaction.

Physical Signs.—*Inspection* discloses increased vigor of the apex-beat. Friction-fremitus (due to rubbing of the altered pericardial layers upon one another) may sometimes be felt during the earlier and later courses of the disease or when the membrane is comparatively dry, and is usually most intense near the base, just to the left of the sternum. *Percussion* gives negative results. *Auscultation* usually reveals a double friction-sound, sometimes quadruple (locomotive murmur)—the most important sign for a positive diagnosis. The friction-rub is caused partly by the exudate and partly by the dry state of the membrane. Its usual seat of maximum intensity is in the fourth and fifth interspaces and the adjacent portions of the sternum—*i. e.*, where the pericardial surfaces are but slightly separated from one another. Another favorite point is the cardio-aortic junction. It is usual to hear the rub over *small* areas, though occasionally it is audible over the whole precordia, and its distinguishing feature is its superficiality, seeming closer to the ear than endocardial murmurs. Pressure with the stethoscope, which approximates the layers, increases its intensity; though, if too much force be exerted, the murmur may disappear entirely. In like manner the friction-sound is influenced by respiration, losing in distinctness on deep inspiration. The quality of the sounds, like their position, exhibits great variability. They are sometimes soft; but quite commonly they are grating or rubbing, and in the later stages I have noticed that they may have a loud creaking quality. Though with few exceptions they are double, and are primarily produced by the rhythmic movements of the heart,

they do not always occur synchronously with the heart-sounds, and usually exceed the latter in duration—facts that go to show that the quality, location, or superficial area of a given murmur does not indicate the extent of the lesion. When the exudate is soft and the heart's action weak, the characteristic murmur may be absent.

Complications.—There may be an extension of the inflammatory process to the external surface of the pericardium, either from the deeper pericardial structures or from the pleura, particularly the left. This is a complicating condition termed *external pleural pericarditis* or *mediastinopericarditis*, in which the mediastinal connective tissue is also, as a rule, involved. It is most frequently secondary to tuberculous pleurisy (*tuberculomediastinopericarditis*), and sometimes also to pleuropneumonia, and rarely to simple pleurisy. The recognition of these combined lesions rests chiefly upon the detection of a friction-murmur that is partly dependent upon the cardiac and partly upon the respiratory movements. These sounds are most distinctly heard along the left edge of the heart. Momentary arrest of breathing suppresses the pleuritic friction-sound, there remaining merely the sounds produced by the rhythmic cardiac action, and even these may be absent. On the other hand, during forced respiration nothing is audible, as a rule, except the strong pleural rub. In normal respiration the inspiratory movements decrease while expiratory movements increase the intensity of the sounds. During inspiration the *pulse* may become small and slow, owing to the partial occlusion of the aorta, brought about by the traction of fibrous bands of adhesions which pass over the vessel, being at the same time connected with the pleura. When these bands pass from the exterior of the heart muscle or pleura, they may cause, as first pointed out by Riegel, an absence of the apex-beat during expiration. Instances of this sort are not uncommon.

Diagnosis.—Although the presence of a to-and-fro friction-sound is, as a rule, indicative of plastic pericarditis, it is an error to regard it as an infallible sign, since complete calcification of the coronary arteries, as well as excessive dryness of the pericardial surfaces, may rarely produce friction-murmurs. The etiologic factors are important diagnostically.

Differential Diagnosis.—The harsh double murmurs due to chronic *valvular lesions* can be eliminated if it be recollected that they are more constant, more distant, and that each has an area of transmission beyond the limits of the precordia. The sitting posture, leaning forward, or moderate pressure with the stethoscope, all fail to produce or to increase *endocardial murmurs*, whether acute or chronic. A double aortic murmur is associated with cardiac hypertrophy, the Corrigan pulse, and systolic flushing of the capillaries.

Prognosis.—The termination is always favorable as to life. Complete resolution does not often occur, but the exudate becomes fibrous connective tissue, and agglutinates the two layers of the pericardial sac. The acute may merge into the chronic form, and dry, plastic pericarditis often constitutes the first stage of serofibrinous and purulent pericarditis.

Treatment.—Absolute quiet should be enjoined. The diet should be composed chiefly of light, easily digested solids, and allowing little drink, thus endeavoring to avoid an overfilling of the vessels. With the same object in view, if the patient's strength be good, a half-dozen leeches should be applied over the heart, followed by the use of the ice-bag; the bowels are to be kept soluble by using stewed fruits or saline laxatives. Calomel in doses ranging from $\frac{1}{4}$ to $\frac{1}{2}$ gr. (0.016–0.032) every hour or two, combined with a little opium to prevent purgation, is serviceable. At the beginning veratrum viride may also be cautiously administered, with a view to dilating the arterioles throughout the rest of the body, and thus virtually “bleeding the patient into his own

vessels." The salicylates are indicated in cases of rheumatic origin. Tonics and a change of air may be required during convalescence.

SEROFIBRINOUS PERICARDITIS

Pathology.—The anatomic changes may be grouped into three stages—the *first* being characterized by a plastic exudation (corresponding with the lesions in dry, plastic pericarditis, though more pronounced); the *second stage*, by a variable amount of effusion composed largely of serum. The exudation usually begins about the origin of the great vessels at the base of the heart, and ultimately forms a thick covering of fibrin, especially on the visceral layer. The quantity of serous effusion may be from 2 to 10 ounces (60.0–300.0), but occasionally it is as much as 3 pints (1½ liters). The admixture of a small number of red blood-corpuscles or leukocytes sometimes occurs in this form of the complaint. The *third* is the stage of absorption in the most favorable cases. Perfect resolution rarely takes place, but, instead, the liquid effusion is alone absorbed, and the lymph causes firm adhesions of the visceral and parietal membranes. If, as sometimes happens, the serum remains, the acute passes into a chronic condition. The myocardium may become involved by an extension of inflammation from the visceral layer; it is always the seat of more or less collateral edema. The grade of the myocardial inflammation will depend much upon the extent and duration of the pericarditis, though usually it is moderate in the fibrinoserous variety.

Etiology.—The disease is most frequently observed to be associated with acute rheumatism, Bright's disease, and pulmonary tuberculosis. Sears collected 100 cases of pericarditis, of which 51 were due to acute rheumatism; and, according to Baumgarten, the former disease arises as a complication of the latter in about one-third of the cases. I believe that exceptionally both serofibrinous and plastic pericarditis may occur in the course of rheumatic dyscrasia without the slightest evidence of arthritis. The disease also occurs in the course of the eruptive fevers and lobar pneumonia, and from extension of inflammation from neighboring parts. Of 66 instances of pericarditis in children, 24 were caused by rheumatism. Next in frequency were tuberculosis and pleuropneumonia (Baginsky). (See also Bacteriology, p. 576.)

Clinical History.—When, as rarely occurs, a *primary* pericarditis develops, the initial symptoms common to inflammation of other serous membranes manifest themselves, as *anorexia*, sometimes *nausea and vomiting*, *chills*, *fever*, *increased respiration* and *pulse-rate*, together with local *pain*. The pain is usually of a dull, aching character, and less frequently merely a slight soreness, or it may be absent altogether. Acute pain is experienced only when the pleura is implicated.

When pericarditis is *secondary* there are, in many cases, no subjective symptoms to indicate its presence. In other instances there may be *precordial oppression* with or without slight pain or a feeling of soreness. Hence in affections in which pericarditis is likely to arise physical examinations of the heart should be systematically conducted. Important symptoms are due to the intrapericardial pressure of the exudate.

Dyspnea comes on simultaneously with the appearance of the effusion and may lead to actual orthopnea. Pressure is exerted upon the left lung if the exudate be large—a fact that explains in part the presence of dyspnea. The cardiac muscle, especially the right ventricle, is also pressed upon by the effusion, thus impeding the cardiac diastole. Under these circumstances the veins fail to empty themselves into the heart, the arterial system is incompletely filled, and the blood-pressure falls as the result. Prior to the occurrence of the effusion the circulation is too actively carried on, the pulse being full and strong.

It is clear from the above explanation that during the second stage the pulse is small and feeble. There is a lowered systolic pressure and a decreased pulse pressure. When the exudate is small, the heart action may be apparently feeble, while the pulse remains strong—a valuable rational sign. On the other hand, an excessive amount of fluid may cause the radial pulse to disappear during inspiration (the *pulsus paradoxus*). Fever is present as a rule; the temperature is irregularly elevated, ranging from 101° to 103° F. (38.3°–39.4° C.). In favorable cases defervescence takes place by lysis. *Nervous symptoms*, as headache and mild delirium, often appear, and sometimes give place to stupor or even coma. Acute mania is rarely observed. The urine is decreased in amount, and occasionally general dropsy occurs.

Physical Signs.—*Inspection.*—The skin surface and mucous membranes are observed to be pale and more or less cyanotic. The neck veins are prominent, and sometimes exhibit undulatory movements or pulsations. The expression is anxious; the respirations are increased, labored, and at times irregular. Wynter has observed loss of abdominal respiratory movement. The decubitus is dorsal; the head and shoulders are elevated, and the patient may be forced to assume the sitting posture. In young subjects precordial prominence, with effacement or even bulging of the intercostal spaces, may result from the presence of a moderate effusion. In adults, however, a large collection is indispensable for the production of this effect. If the lung be shrunk or if there are pleuritic adhesions, expansion of the pericardium and, hence, also bulging will be prevented. The distended pericardium may depress the diaphragm. Elevation of the left nipple in consequence of marked anterior expansive bulging has been observed. In the first stage the apical beat is exaggerated, but as the exudate increases (forcing the heart backward and upward) it is displaced in an upward and outward direction, at the same time becoming weaker as well as more diffused, since with expansion of the sac comes greater mobility of the organ. When the pericardial sac becomes filled the impulse-beat disappears, the fluid now completely surrounding the heart.

Palpation confirms the results of inspection. The apical beat is diffused and feeble or lost. When detectable it is found to be displaced upward and to the left. Altering the patient's posture changes the seat of the apex-beat (Oppolzer), and if the shock has been lost, turning the patient on his left side or bending his body forward may cause its return. The cardiac impulse disappears earlier when, on account of myocarditis, the systole is greatly enfeebled. On the other hand, old adhesions and marked hypertrophy of the heart may retain the apex-beat in contact with the chest wall despite the presence of a large accumulation. A friction-rub can be felt occasionally over the base of the heart even in the stage of effusion, and, if absorption takes place, the friction fremitus becomes more marked. Fluctuation is rarely detected. In large effusions the liver is *depressed and easily palpable*.

Percussion.—The area of cardiac dulness is increased, and assumes a characteristic triangular outline with the base downward and the apex extending up to the third or even second interspace to the left of, though near, the sternum. The lateral border-lines of dulness obviously diverge from above downward, the right passing to a point corresponding with the right edge of the sternum, along which it runs to the hepatic flatness; the other to the left, finally intersecting the base line, and extending to splenic flatness, or the lower limit of pulmonary resonance. Flatness may be met in the axillary region, even obliterating Traube's semilunar space. Rotch points out that even in moderate effusions there is flatness in the fifth interspace to the right of the sternum (*cardiohepatic triangle*—Ebstein). Broadbent, however, has found

several instances in which dulness in this area was present, but at necropsy dilatation without effusion was found. The margins of the lungs surrounding the heart may be retracted and the heart carried forward or dilated; the dull area will then appear larger than is justified by the amount of fluid. Retraction or moderate compression of the lung may give rise to a modified tympanitic resonance to the left of the flat area. Occasionally the lung is attached anteriorly, and the heart is crowded backward by the effusion, while the area of flatness on percussion is relatively diminished. The triangular shape of the flat area, noted when the patient is in the sitting posture, is lost and its area diminished when he lies down, the effusion obeying the laws of gravitation. Sibson's notch, or narrowness of the dull area at the third costal cartilage in the transverse diameter, with reflection of the dulness to the left below this level thus forming an obtuse angle, obtains in medium-sized effusions. The feeble impulse can be at times felt within the dull area and not at its boundary.

Auscultation.—The characteristic friction-rub of the first stage has already been described. It may, however, also be audible over the base during the stage of effusion, and always returns, after absorption of the fluid, for a brief period. The heart sounds grow more and more distant, faint, and muffled, though the second sound, as heard over the extreme base of the organ, may remain clear. Over the area of dull tympany corresponding to the lower anterolateral portion of the left lung (which is more or less compressed) may be heard bronchovesicular breathing.

Course and Duration.—It will appear obvious that the course must vary in individual cases with the cause and severity of the infection. Observation has shown that in one class of cases the three stages are passed through in rapid succession, while in another class each stage is proportionately lengthened. The latter form has been termed "chronic" by some and "subacute" by others. The *acute* may be followed by the *chronic* variety. Usually serofibrinous effusions complicating rheumatism are absorbed with rapidity once the process has begun, seldom requiring more than two weeks. When recovery is about to occur, the temperature falls by *lysis*; the effusion is gradually absorbed, and with it the dyspnea disappears. Convalescence is further indicated by a return of the appetite, normal heat of the skin, and a more infrequent, full, and regular pulse. In cases that tend to a fatal termination either the fever continues or there is suddenly developed *hyperpyrexia*, as may happen when pericarditis occurs in the course of acute rheumatism; in such cases the dyspnea is urgent and cyanosis is often marked, with signs of failing circulation. *Nervous symptoms*, as extreme restlessness, insomnia, and active delirium, may be present. Under these circumstances death usually ensues at the end of a few days. In a fatal case of *acute articular rheumatism* that I saw, complicated by pericarditis, with hyperpyrexia, death occurred on the sixth day.

Complications.—Copious effusion may, by causing pressure upon the recurrent laryngeal nerve, produce paralysis of the vocal apparatus, or it may press upon the esophagus, causing dysphagia. Rarely *acute pleuritis* is a complication; it lengthens the course of the pericarditis and renders the outcome uncertain. When there coexists *extensive myocarditis* syncopal attacks often endanger the life of the patient. Associated endocarditis and a complicating pneumonia may be observed.

Prognosis.—In serofibrinous pericarditis recovery is the rule under favorable conditions. The outlook, however, becomes gloomy when the above-mentioned complications arise, and particularly when there is hyperpyrexia in connection with acute rheumatism. Occurring as a secondary event in serious acute diseases, as pneumonia, or in chronic diseases, as Bright's, or organic affections of the heart, the pericarditis often precipitates a fatal

termination. The strong possibility that these cases may only partially recover or assume a chronic form must be recollected.

Diagnosis.—The disease is often overlooked because unsuspected. Ordinarily the recognition of pericarditis by the characteristic triangular area of percussion-dulness and by the friction-sound is not difficult. The causative factors, and the symptoms dependent on the mechanical pressure of the exudate, are of considerable diagnostic importance. Atypical cases, or those first seen during the stage of effusion, can only be correctly diagnosed by exclusion.

Differential Diagnosis.—*Acute pleurisy* of the left side may simulate pericarditis with copious effusion, and, as before stated, these diseases may co-exist. Acute pain, however, belongs to pleurisy alone. In pericarditis the characteristic physical signs are elicited over the precordia; in pleurisy they are apt to occupy not only the anterior but also the axillary and posterior aspects of the chest; hence the percussion flatness in pleurisy extends to the left, far beyond the boundary-line of the percussion flatness in pericarditis. The pericardial friction-sound has a different situation usually from the pleuritic, and the latter is heard synchronously with the respiratory movements, while the former is intimately related to the time of the cardiac movements. The friction murmur of pleurisy ceases if the breathing be momentarily suspended. *Encapsulated pleural effusions* limited to the anterolateral portion of the chest are exceedingly difficult of elimination, and especially in the absence of pleuritic friction. In the latter complaint, however, the heart sounds are clear and the apex-beat often pushed to the right; on the other hand, in pericarditis the general disturbance is usually greater, while a friction-rub may be detectable over the base. The heart sounds are distant and muffled. The diagnosis is often aided by the bearing of certain facts in the previous history upon the known etiology of these affections. We encounter formidable difficulties in attempting to exclude *cardiac dilatation*, though the following brief table will render assistance:

PERICARDITIS WITH EFFUSION	CARDIAC DILATATION
<i>Clinical History</i>	
Recent history of gout, acute rheumatism, acute infectious or septic disease, scurvy, chronic nephritis, or tuberculosis.	Usual history of chronic valvular disease of the heart.
Fever and slight pain often associated.	No fever or pain, as a rule.
Nervous symptoms are often present.	Less marked.
<i>Physical Signs</i>	
<i>Inspection</i> often reveals bulging (more marked in the young). Apex-beat pushed up, is feeble, and later absent.	Apex-beat usually visible, wavy, and diffused.
Heart's impulse usually absent or occupies center of dull area. Friction fremitus may be present over the base.	Though feeble, the impulse is palpable.
<i>Percussion</i> shows a triangular flat area, and the boundary-line above changes on altering the posture. There is dull tympany in the axillary region. Ebsstein's angle obtuse.	Dull area varies with chambers dilated; it is coextensive with a wavy impulse, does not extend so high (except in mitral stenosis), and does not vary with change of position. No dull tympany.
<i>Auscultation</i> shows the first sound distant and muffled; a double friction-rub is often present over the base.	First sound clear, short, and sharp. No friction-murmur present, but an endocardial murmur may appear.
Roentgen ray shows triangular, movable shadow.	Upper level of shadow (quadrangular) fixed.
Resistance gymnastics negative in their effects.	Resistance gymnastics decrease dull area (Schott).
Digitalis has slight influence.	Digitalis diminishes the field of dulness.

Treatment.—The management of the first (or dry) stage is identical with that detailed in discussing the plastic variety. During the stage of effusion the patient should be kept at absolute rest in the recumbent posture, and mental excitants should be prohibited with a view to minimizing the labor of the heart. The *diet* is to consist mainly of easily digested albuminous articles; fluids are not to be given in large amounts, since this tends to increase the arterial tension and delays absorption.

Local Measures.—Flannel should be kept over the precordia, so as to avoid exposure and undue chilling. The ice-bag or Leiter's coils (to be used in the first stage) should be cautiously employed during the second stage, until the temperature has defervesced considerably, thus indicating a subsidence of inflammation in the pericardium.¹ Subsequently, if absorption does not proceed, blisters may be applied over the precordia; but should the patient's general condition be bad, an absorbifacient containing iodine, lanolin, and ichthyol may be substituted with advantage.

The *therapeutic measures* must be chosen with sole reference to the primary disease, which the physician must continue to treat while he attempts by other means to relieve certain symptoms and promote absorption. For example, if the pericarditis be due to rheumatism, the use of the salicylates must be persevered in, and opium may be added to quiet restlessness and procure relief from pain. In my own experience absorption has been best promoted by the use of the double iodide of potassium and iron, or of iron and manganese. These agents are seldom contraindicated unless they are badly borne by the stomach. Diuretics and saline purgatives are not without value, but do good only in the later stages. Depressing measures of whatever sort are not to be resorted to unless the circulation be good. If the pulse be small, weak, and rapid, with marked cyanosis, stimulants are indicated and are to be given in moderate quantity. Strychnin and the salts of ammonium are useful. Digitalis and strophanthus are not to be thought of when myocarditis is associated; at other times they often improve the peripheral circulation and increase the urinary secretion. When the breathing becomes greatly embarrassed and the circulation fails, as shown by the feeble, broken, rapid pulse and cyanosis, cardiocentesis is indicated, and has, in recent years, given good results if not too long delayed. A preliminary puncture with a hypodermic needle should be made. In cases where the apex cannot be localized, the sixth space at about the mammillary line is the point of greatest advantage of paracentesis. "If it be definitely determined that the dilated heart extends beyond the mammillary line, one would then seek a point a little outside of the supposed position of the apex" (Thayer). In a case of extreme dilatation of the heart and marked excitement of the patient, Curschmann punctures through the eighth interspace from the rear. The operation must be performed with the strictest asepsis, and the amount of liquid withdrawn at any one time should not exceed 6 ounces. Of 60 cases of paracentesis for pericarditis of different varieties, collected by Roberts, 24 terminated in recovery.

PURULENT PERICARDITIS

(*Empyema of the Pericardium*)

Pathology and Etiology.—The condition may, rarely, follow the sero-fibrinous form. Septic and tuberculous processes involving the pericardium are apt to cause purulent effusion from the start, and many of the cases that arise in the course of the acute infectious diseases belong to this category.

¹ If the pericarditis be secondary to an acute febrile disease, this fact must modify the method here recommended accordingly.

The pneumococcus has been found in the pus (Shattuck and Porter). The membrane is much thickened and presents a gray, granular surface, and the myocardium underlying the visceral layer is softened, fragile, and pale looking (fatty).

Clinical History.—The local subjective symptoms and physical signs are the same in kind as in the former variety, but the amount of exudation is frequently less. At the onset *rigors* often occur, and may be repeated at varying intervals. The *temperature-curve* is of the suppurative type; the *pulse* is small, rapid, and irregular; and *physical prostration* is pronounced. Purulent pericarditis runs a comparatively rapid and an almost uniformly unfavorable course.

Diagnosis.—The chief clinical features are often referable to the primary or causal disease; hence in every instance in which purulent pericarditis is apt to arise a physical exploration of the chest is imperative. The purulent character of the effusion cannot readily be ascertained, as a rule; but the history of an affection having etiologic importance, the observance of rigors, a leukocytosis showing relative increase in the polynuclear forms, and the presence of the fever-curve peculiar to suppuration, would all point strongly to purulent effusion, and should lead to aspiration with the hypodermic needle—a harmless procedure if carefully performed, and one that almost constantly gives reliable results.

Treatment.—It is within the physician's province to treat the primary disease assiduously, but not pericardial empyema. Incision (after preliminary resection of a rib—Brentano) and drainage of the sac are advisable and feasible measures.

HEMORRHAGIC PERICARDITIS

In purulent pericarditis the effusion may be hemorrhagic, and particularly when it is of tuberculous origin. In non-purulent tuberculous pericarditis also the exudation is apt to be hemorrhagic. In the non-purulent instances that are due to chronic Bright's disease or that occur in the aged the effusion is sometimes blood-stained; and future observation may show that this variety is of more frequent occurrence than has hitherto been supposed. In ordinary serous pericarditis there is apt to be present more blood than in serous pleuritis. M. T. Ferrier has found 5 examples in 9 collections. Sears found a pure growth of pneumococci in the exudate from a case of hemorrhagic pericarditis. This etiologic variety scarcely calls for separate clinical consideration.

ADHESIVE PERICARDITIS

(*Chronic Pericarditis*)

Pathology and Etiology.—Chronic pericarditis follows the acute forms, and, as in the case of the latter, it may be partial or general. The effusion may rarely remain as a permanent condition, but not infrequently a clear history of the preceding acute attack is wanting. In most instances the opposed surfaces of the membrane are either universally or over a limited area firmly adherent. The amount of new connective tissue present or the degree of thickening of the layers varies greatly, and is dependent upon the type of the primary acute attack. If the latter is of mild grade—*e. g.*, the serofibrinous rheumatic form—not much thickening is encountered in the resulting chronic form.

Chronic tuberculous pericarditis is not uncommon, and is usually secondary. The disease may be chronic from the time of onset. The layers become enormously thickened, with obliteration of the sac.

In the dense exudate that remains after complete absorption of a pericardial effusion calcareous depositions occur, forming a bony casing, which either

partially or totally encircles the organ. The external surface of the pericardium may become united with adjacent tissues (spinal column, anterior thoracic wall, aorta, sinus pleuræ). The myocardium is the seat of atrophic and degenerative changes.

Etiology.—The principal etiologic factors are tuberculosis and rheumatism. Pilt analyzed 400 cases of acute pericarditis, of which 70 per cent. were due to rheumatism, about 50 or 60 per cent. died, and from 30 to 40 per cent. left the hospital with an adherent pericardium.

Symptoms.—Autopsies frequently discover an unsuspected adhesive pericarditis. Hypertrophic dilatation of the chambers usually develops sooner or later, and is due to adhesions that interfere with the free action of the organ as well as with its systole. When present the subjective symptoms point to a giving way of the right ventricle, as shown by the presence of *venous stasis* and *dropsy*. The *pulse* is rapid, of low tension, and irregular, and, though not diagnostic, the *pulsus paradoxus* is noted.

Pericarditis Callosa (Galvagni¹).—A form of chronic fibrous pericarditis which comes on insidiously during childhood and is exceedingly difficult of diagnosis (*vide infra*). Pericarditis callosa is characterized principally by facial cyanosis, slight edema, full and tortuous jugular veins without pulsation. The typical physical signs of pericarditis are wanting also. On the other hand, a congestive cirrhosis of the liver may supervene and lead to ascites.

Physical Signs.—*Inspection.*—Depression or pitting of the intercostal space, in place of the apex-beat, may be noticed. Synchronous with the systole there is also a retraction of the chest wall in the apical area, and less frequently over the whole precordia, the latter being an unerring sign of universal adhesions. The degree of systolic recession is slightly influenced by the respiration, inspiration increasing it, except adhesions exist between the pericardium and the adjoining pleura. It is best appreciated on palpation. When the apex-beat is not palpable, the systolic pitting over its site may be due to atmospheric pressure. During the diastole the heart forcibly rebounds, causing the so-called diastolic shock, which is of great diagnostic importance when associated with marked systolic retraction. Though not always visible, it can be readily felt on *palpation*. Friedreich's sign (the sudden collapse of the jugulars during diastole) may frequently be observed. Prior to the onset of dilatation the apex-beat may be forcible and visible over an increased area, indicating hypertrophy; but after the myocardium is weakened (from interference with its nutrition) and dilatation comes on, the impulse-beat is faint or wanting, and in marked systolic retraction may be vibratory. The fixed position of the apex-beat when the patient is turned upon his left side is a strong confirmatory sign.

Percussion.—The area of cardiac dulness is increased, especially upward and to the left, owing to the associated hypertrophy and pleuropericardial adhesions, and, since the latter do not allow the lungs to overlap the heart during inspiration, the upper and left lines of dulness remain fixed (C. J. B. Williams). The most trustworthy symptom is the unchanging shape of the area of precordial dulness during inspiration and expiration (Davis).

Auscultation.—In many cases no murmurs are detectable. Loud murmurs, quite independent of any value as regards cardiac lesions, however, may be audible; these may be due to the vortiginous movements in the endocardial blood-current occasioned by the jogging cardiac action. The murmur of tricuspid regurgitation, from a breakdown of the right ventricle without apparent exciting cause, is most significant.

¹ *Practitioner*, London, August, 1912.

Differential Diagnosis.—The condition is apt to be confounded with *chronic myocarditis* and *simple hypertrophic dilatation*.

As before stated, chronic pericarditis may be associated with effusion, and it is important to distinguish such instances from the adhesive form if we would institute a proper treatment. In chronic pericarditis with moderate effusion the seat of the apex-beat is higher and less undulatory, and when the amount of effusion is large the impulse is absent and there is bulging. Adhesive pericarditis with hypertrophy causes bulging in young subjects, but the apical beat is retained. There is no forward elevation of the chest during inspiration (Wenckebach). In pericarditis with effusion the upper and left limits of dulness are not stationary, and there is an absence of systolic retraction and diastolic concussion.

Course and Prognosis.—The hypertrophy that comes on early in consequence of the obstruction offered to cardiac action is compensatory, and this harmonious balance may be maintained for a long period of time with apparent comfort. After myocardial degeneration, followed by atrophy or dilatation, has occurred, the condition becomes quite serious, and death usually ensues amid signs of extreme cardiac dilatation.

The **treatment** must be ordered chiefly with reference to the nutrition of the heart muscle, following the principles noted in dealing with the management of valvular affections of the heart. Precordial thoracotomy is advocated by Bauer and others.¹ If chronic effusion be present, early operative measures are to be warmly advocated.

HYDROPERICARDIUM

(*Dropsy of the Pericardium*)

Definition.—A condition in which the pericardium contains a serous transudation, but shows no signs of inflammation.

Etiology.—(a) Hydropericardium is usually associated with general cardiac or renal dropsy, of which it forms a component part. Under these circumstances it develops late, and frequently follows hydrothorax, on account of which condition it is liable to be overlooked. It may also occur suddenly in chronic nephritis, and particularly in the scarlatinal variety. (b) It may arise from local mechanical causes, as the pressure of mediastinal tumors, aneurysm, or thrombosis of the cardiac veins.

Symptoms.—No subjective symptoms are present, save perhaps dyspnea, and the diagnosis rests upon the history and the physical signs. None of the latter, however, are distinctive. They point to the presence of fluid in the pericardial sac, and the area of percussion dulness assumes the same form and exhibits even greater change, with alteration of the patient's posture, than in pericarditis with effusion. No friction-murmurs are heard on auscultation and no bulging of the pericardium is observed. Again, there is neither a history of infectious disease nor inflammation of adjacent organs, as in pericarditis. It is rare indeed to see an excessive amount of serum in the pericardium at the *postmortem*. The symptoms and signs of hydrothorax generally precede and accompany hydropericardium, and the latter condition tends to intensify the effect of the former. In rare instances the transudate has a milky appearance (*chylopericardium*).

The **treatment** suitable for cases of general dropsy, as a rule, affords relief. In large serous accumulations aspiration should be practised.

¹ *Semaine médicale*, September 7, 1910.

HEMOPERICARDIUM

By the term "hemopericardium" is meant hemorrhage into the pericardial pouch—a rare event. Among the causes are—(a) perforation by aneurysms of the aorta and the coronary arteries into the sac; (b) rupture of the heart due to injuries or cardiac aneurysms and fibrous formations from myocarditis; (c) direct injuries, especially stab and bullet wounds. The *symptoms* and *course* depend greatly upon the nature of the exciting cause. The most frequent factor, rupture of an aneurysm, proves quickly fatal from overcrowding of the heart. In rupture of the heart muscle there is sometimes a slow outpouring of blood, with a correspondingly slow course, varying from a few hours to a couple of days in duration. The physical signs of pericardial effusion come on with dyspnea and failing circulation, which lead to cardiac exhaustion and death. The blood-stained effusions occurring in certain forms of pericarditis (*vide supra*) are not to be regarded as instances of hemopericardium. Unconsciousness appears early, to be quickly relieved when the pressure is removed.

PNEUMOPERICARDIUM

(*Air in the Pericardium*)

In this complaint, besides air or gas, there is usually present pus, and less frequently blood; hence an appropriate term in most instances would be *pyopneumopericardium*. The *causes* are the following: (a) wounds; (b) a fistulous connection between the adjacent air-containing organs and the pericardium as the result of disease processes, such as pulmonary tuberculosis or empyema; (c) rarely decomposition of liquid pericardial effusions, or the development of gas-producing bacteria. The *symptoms* are equivocal. In the main they do not differ from those of pericarditis with effusion, excepting that dyspnea is more intense than in the latter affection. The physical signs, however, are different. In pneumopericardium there is tympanitic percussion-resonance over the precordia, though the fluid, when present, gives rise to a boundary-line of dullness. The change of the patient's posture decidedly alters the area of the tympanitic note. On auscultation may be heard loud, rasping friction-sounds having a metallic quality, intermingled with churning, splashing noises, or the so-called "water-wheel sounds." *Pneumothorax* when encysted in close proximity to the heart, displacing the latter organ, must be eliminated. The latter complaint gives cardiac dullness in an abnormal position and a metallic auscultatory sound synchronous with the respiratory movements—two diagnostic points of pneumothorax that are absent in pneumopericardium. The *prognosis* is grave, death coming on most commonly in a day or two. The admission of air alone might result in a spontaneous cure, as occurs rarely in pneumothorax. The *treatment* is the same as has been recommended for purulent pericarditis.

II. DISEASES OF THE HEART

ENDOCARDITIS

Definition.—Inflammation of the lining membrane of the heart. The process is usually confined to the valves, though the cardiac layer may also be affected.

Varieties.—(a) Simple acute endocarditis; (b) ulcerative endocarditis; (c) chronic endocarditis. The pathologic processes involved in the first two, the acute forms, are identical in nature, though they differ in severity. I have met with two instances that apparently occupied a middle ground.

SIMPLE ACUTE ENDOCARDITIS

(*Endocarditis Verrucosa*)

Pathology.—The disease is characterized by the formation of small vegetations on the segments, varying in size from excrescences that are scarcely visible to those the size of a pea. They are found chiefly on surfaces that are opposed to the blood-current, near the margin of the valve, and “forming a row of bead-like outgrowths.” Their seat corresponds to the point of maximum contact (Sibson), but the mitral valve is much more commonly affected than the aortic. With the segments the chordæ tendineæ are sometimes affected, and very rarely the latter are alone involved. The left side of the heart is much more frequently the seat of acute endocarditis than the right, except during fetal life, when the right side is almost exclusively involved. To account for the greater frequency of occurrence on the left side after birth it has been suggested that freshly oxygenated blood affords the most favorable condition for the multiplication of the micro-organisms principally concerned in the inflammatory process. Corroborating this view is the fact that during fetal life the blood in the right chamber is the more completely oxygenated. It has also been pointed out that before birth the right side, and after birth the left side, is the more active, and that the active side is apt to suffer on account of higher pressure. Obviously, the vegetations form an obstruction to the current of the circulation as it flows through the valvular opening. In the early stage the membrane in the vicinity of these excrescences shows a bright red color, which has usually disappeared in fatal cases before they come to autopsy. The *histologic changes* consist in a proliferation of the subendothelial tissue (small-celled infiltration), which forms the principal component part of the vegetation. On this basal mass of granulation tissue there is deposited fibrin from the blood, the latter being separable from the former in acute forms of the complaint. Micro-organisms have repeatedly been found in the fibrinous depositions, but the specific causal irritant has not as yet been discovered. Köster first advocated the view that endocarditis may begin as an embolic process, and Rosenow has shown that cocci may lodge in the capillaries of the valves, “the avascular structure of which serves to protect the cocci until they grow into clumps, around which fibrin is precipitated.” Intact valves have no capillaries, so Rosenow says that his experiments can best be understood in those cases in which old injury to the valves has led to their vascularization. In favorable cases either the vegetation is ultimately absorbed or there remains a small indurated mass. When the vegetations are of considerable size emboli may become detached by the force of the blood current, and be carried to the vessels of the extremities and to the various viscera, particularly the brain, spleen, and kidneys, giving rise to embolic infarcts. The latter event is frequently observed in cases in which acute endocarditis is engrafted upon chronic valvulitis.

Simple acute endocarditis may end in the more serious or ulcerative variety (*vide infra*). More commonly, however, does the simple form terminate in chronic valvulitis with deformity.

Etiology.—The most frequent cause of acute endocarditis is *acute articular rheumatism*, which induces the disease in not less than 40 per cent. of the cases. In young rheumatic subjects the liability to the complaint is particularly pro-

nounced. The severity or mildness of the rheumatic attack does not, however, influence the appearance of the cardiac complication. Cases of acute endocarditis of rheumatic origin are met with in which the arthritic phenomena are secondary. It may complicate *tonsillitis* when the latter is due to or associated with rheumatism. In *specific fevers* it is also encountered, and is common in scarlet fever, but rare in typhoid fever, diphtheria, measles, erysipelas, variola, and varicella. It is not uncommon as a complication in *pneumonia*. Osler, as the result of 100 autopsies in cases of pneumonia, found it present in 5 instances. *Tuberculosis* is not infrequently the basal disease. Of 11,000 records of autopsies in cases of tuberculosis, 151 instances of endocarditis were found (G. W. Norris). It has frequently developed in the more serious forms of *chorea*, and intercurrent acute endocarditis may result from chronic diseases attended with emaciation and general weakness or suppuration, such as ulcerative carcinoma, gleet, gout, chronic Bright's disease, and diabetes. Lastly, acute endocarditis may occur as a secondary event in pre-existing sclerotic endocarditis, when it is termed *acute recurrent endocarditis*. In chronic endocarditis the liability to the acute form is greatly increased by the puerperal state, and, to a lesser extent, by pregnancy.

Bacteriology.—All cases of acute endocarditis are micro-organismal in character. The disease, however, is the result of various micro-organisms or their toxins, whose action is assisted by the friction between the blood-current and the surfaces of the valves. Fränkel and Sängner affirm that the *Staphylococcus pyogenes aureus* is the chief specific organism. The *Diplococcus pneumoniae*, the *Streptococcus pyogenes*, the *Streptococcus viridans*, and, less commonly, the *Bacillus coli communis*, the gonococcus, the *Bacillus diphtheriae*, the bacillus of Eberth, that of Pfeiffer, and the *Micrococcus endocarditis capsulatus* and *rugatus* are found. Oille, Graham, and Detweiler believe that a low-grade streptococcic endocarditis, leading especially to mitral stenosis in females, is more common than so-called rheumatic endocarditis.

Clinical History.—It is only occasionally that definite **subjective symptoms**, as precordial *pain* (sometimes extending down the left arm), *dyspnea*, and *cardiac palpitation*, are complained of by the patient. If fever has been present, as is common, the temperature usually rises rather abruptly. In the vast majority of instances the condition is discovered accidentally. This being true, its frequent occurrence in acute articular rheumatism, and its occurrence in other diseases mentioned under Etiology, should be kept in remembrance. The symptoms of *embolism* are rarely observed. F. Billings reports a case with multiple emboli.

The **physical signs** by which acute endocarditis is recognizable are dependent upon the valvular insufficiencies caused by the morbid lesions previously described. In some cases, including those in which the valves are not affected, distinct physical signs are absent.

On *inspection* the area of visible impulse may be seen to be increased, to the left in most cases. The impulse is sometimes forcible and often irregular during the initial period, but later it becomes less distinct and more feeble. *Palpation* confirms the result of inspection. I have found the impulse to vary at each visit, with a general tendency to lessen in intensity in the later period of the disease. A very weak impulse is indicative of associated myocarditis or of the poisonous effect of a severe type of primary infection. In recurrent endocarditis the apical impulse is often heaving on account of pre-existing compensatory hypertrophy, and its area is exceedingly variable. A systolic thrill is sometimes felt.

On *percussion* the area of cardiac dulness is found to be either normal or, more commonly, enlarged in the transverse diameter, especially to the left;

this results from the increased diastolic tension in the left ventricle. While the right ventricle meets with greater resistance, it rarely dilates, owing to its power of accommodation during the course of acute endocarditis. In recurrent acute endocarditis the area of dulness corresponds to the increased area of the apical beat.

Auscultation.—Acute endocarditis is usually attended with a soft blowing, systolic murmur, which, since the mitral segments are the favored seat of the disease, is heard much more frequently at the apex than at the base. The point of maximum intensity of this murmur is often movable, but its area of transmission is limited. In rheumatic endocarditis this murmur is preceded by a prolongation of the first sound. It is associated with accentuation of the second pulmonic sound. The murmur is sometimes heralded by a dull first sound and delayed radial pulse, with apparent intensification of the second, suggesting ventricular dilatation as the cause of the murmur. The characteristic presystolic murmur, indicating mitral stenosis, may be, in exceptional cases, associated. In acute endocarditis affecting the mitral valves aortic murmurs may coexist, but their true nature is more than doubtful. There is also a short, low-toned, and double systolic murmur over the tricuspid orifice in a small proportion of the cases; this is due most probably to a relative incompetency. When acute endocarditis arises in connection with chronic valvular disease, the auscultatory signs of the latter are but little changed, and hence an assured diagnosis is not possible.

Complications.—There may be developed by direct extension secondary myocarditis (*vide* p. 643) and pericarditis.

The **diagnosis** is based principally on the physical signs, though these are by no means trustworthy. The points gained by careful inspection and palpation are of especial diagnostic importance, as is also the previous history of the patient. Leube¹ points out that if the dulness is slightly increased to the left and there is fever—in fact, if there is infectious disease present—a diagnosis must be made of acute insufficiency of the ostium mitralis occurring in the course of acute endocarditis. Rosenau states that blood-cultures should be made for the identification and study of the infecting organism as well as for prognostic reasons. There is usually a slight polynuclear leukocytosis.

Differential Diagnosis.—The soft bellows murmur is often present in *acute febrile diseases* in which the autopsy fails to reveal the lesions of acute endocarditis. The functional murmurs that arise in the specific fevers, however, are principally heard over the aortic and pulmonary areas, while those occurring in endocarditis are commonly heard over the mitral area. The murmurs present must be called *accidental* (functional) if the area of cardiac dulness is normal, the second pulmonary sound not accentuated, and if the murmur be heard only at the pulmonary cartilage, or at this point and at the apex, and, at any rate, more distinctly at the pulmonary cartilage (Leube²). The distinction between simple acute endocarditis and *pericarditis* should be categorical in view of the manifold differences between their signs. But the fact that these two affections may be associated, more especially when they are of rheumatic origin, must be steadily borne in mind, and also that when combined the pericardial friction-sound and the later effusion obscure the signs belonging to the endocarditis. I have found, however, that, fortunately, endocarditis precedes pericarditis in the majority of the cases. The elimination of *old endocarditis* or *chronic valvular disease*—a matter of importance—may be accomplished by attention to the character of the murmur in acute

¹ *Deutsch. Arch. für klin. Med.*, November 5, 1896.

² *Loc. cit.*

endocarditis, as well as to its limited area of diffusion, and by the absence of the signs of hypertrophy and of marked accentuation of the second pulmonary sound.

A *relative insufficiency* distinguishes itself by a pure systolic murmur, loud and not invariably uniform, by a weak cardiac impulse, a slight accentuation of the second pulmonary sound, and a comparatively small and often irregular pulse. It is met with in excessive dilatation of the left ventricle, in anemia, "and particularly in certain changes of the valvular muscles due to myocarditis" (Leube).

Prognosis.—The immediate dangers are few, and depend largely upon the primary disease. In many instances, however, acute endocarditis initiates permanent lesions of the valves.

Treatment.—**Prophylaxis.**—The prevention of acute endocarditis in rheumatism has been dealt with in discussing the latter disease. No known direct measures can prevent the development of this condition in the course of the specific fevers, though absolute rest in bed and protection of the body against "cold" may diminish somewhat the tendency to it.

The Attack.—The sick-room should be free from drafts, though well ventilated, and flannel is to be applied to the chest. The diet may be liberal, but should be composed chiefly of milk and other light nutritious substances. Stimulants are required in most instances, and in abundance should the heart be failing. Digitalis is to be employed cautiously if at all. When the myocardium is involved, its use is not without danger; under these circumstances the drug increases the sufferings of the patient by throwing the inflamed and weakened cardiac muscle into firm contractions. I am convinced that in endocarditis due to acute articular rheumatism it is wise to continue the exhibition of the salicylates, though in moderate doses, provided that the heart is guarded by the use of stimulants. During convalescence from an acute endocarditis the patient should be kept at rest, so as to minimize the strain upon the affected valves and heart muscle; even after he has apparently recovered, and particularly should the murmur still be present, perfect quiet is to be enjoined for a period of several weeks.

ULCERATIVE ENDOCARDITIS

(*Malignant or Infectious Endocarditis*)

Malignant endocarditis is variously characterized, though usually either by perforative ulceration, by suppuration of the valves, or by both, giving rise to the physical signs of acute endocarditis. These develop amid the symptoms of a severe primary infectious or septic disease. There is at hand enough clinical evidence to warrant the assumption that ulcerative endocarditis also occurs, though rarely, as a primary affection.

Pathology.—(a) *Valvular Endocarditis.*—In its early development the valves are the seat of vegetations (such as are met with in simple acute endocarditis) which later undergo necrosis. The latter process tends to spread, destroying more or less of the endocardium. In the interior of the vegetations suppuration not infrequently takes place, and the abscesses thus formed rupture and produce various lesions according to their size and situation. After rupture the blood-current may enter the abscess cavity, and, if there be no complete perforation, the endocardium will be pouched out, and an aneurysmal dilatation of the valve will result. Ulcerative lesions are most frequently observed. They may be mere erosions of the endocardium, but, as a rule, are penetrating and often result in complete perforation. The vegetations take on a grayish- or yellowish-green appearance. Histologically, they

are composed of granulation tissue, veiled by granular and fibrillated fibrin, containing numerous micro-organisms. At the base there is usually developed more or less reactionary inflammation. Osler, in an analysis of 209 cases examined by him with a view to ascertaining approximately the relative frequency with which the different parts of the heart were affected, obtained this result: Aortic and mitral valves together, 41; aortic valves alone, 53; mitral valves alone, 77; tricuspid in 19, pulmonary valves in 15, and the heart wall in 33 instances. In 9 instances the right heart alone was involved.

(b) *Malignant mural endocarditis* gives the same set of changes as the valvular form; indeed, the two may be combined throughout. It is a comparatively rare condition, as is shown by the foregoing figures of Osler. The ulcerative process may invade the chordæ tendinæ and the valves, and may perforate the septum or even the ventricular wall itself. The vegetations are detached in small or large masses, and are conveyed by the blood to various organs, especially to the spleen and kidneys, less frequently the intestines, meninges of the brain, and the skin. Their site is determined largely by their size, and they may be so large as to plug vessels of the caliber of the external iliac. When found in the lungs they may originate in endocarditis affecting the right heart. These emboli, containing as they do the agents of inflammation, form suppurative infarcts that may be either white or red in color. The detached vegetations are sometimes so laden with irritants as to cause rapid softening of the coats of the vessel at the point where they become arrested, with consequent aneurysmal dilatation directly opposite their seat. The number of infarcts varies greatly in different cases; thus there may be only one or two, as in a case in my own knowledge in which the spleen alone contained two small infarcts, or there may be more than a thousand minute abscesses widely scattered throughout the body.

Etiology.—It is to be kept in remembrance that the condition is, with few exceptions, most probably a secondary one. This explains why the lesions peculiar to simple acute endocarditis usually precede and accompany those of the ulcerative form.

Bacteriology.—The specific irritant is usually the *Streptococcus pyogenes* (Fränkel and Sängner); hence the diseases in which ulcerative endocarditis occurs as a complication merely furnish the opportunity for the invasion of the streptococcus. The *Bacillus diphtheriæ*, however, as well as the staphylococcus, the pneumococcus, the *Bacillus coli*, the *Bacillus anthracis*, the gonococcus, and other organisms, have been found in some cases in the absence of the streptococcus.

In purely septic diseases the cardiac element serves to facilitate the generation and rapid diffusion of the poison; and, since the latter is prone to attack the valve segments, the morbid lesions within the heart not rarely constitute the chief pathologic factor in septicopyemia.

Predisposing Affections.—The malignant form occurs, in connection with acute articular rheumatism, in about 10 per cent. of the cases in which acute endocarditis appears. In lobar pneumonia the ulcerative type is common, occurring almost as frequently as the simple variety, and was found by Osler in 11 out of 23 cases. The septic processes that arise from the puerperal state or from gonorrheal infection may also be complicated with ulcerative endocarditis. Among many other diseases that furnish occasional instances of this serious complication are measles, scarlet fever, typhoid fever, erysipelas, small-pox, chorea, tuberculosis, and chronic nephritis.

Clinical History.—That form of ulcerative endocarditis which is a more or less prominent factor in septic diseases has been considered in connection with septicemia. Malignant endocarditis being usually an intercurrent

event, its clinical features must not be confounded with those of the primary affection. I shall describe first the common *typhoid form*.

Local symptoms are often entirely wanting, or, when present, consist merely in slight precordial pain and oppression, and are not sufficiently well pronounced to arrest attention. Subjective symptoms are, however, connected with other organs than the heart, and are due to the irritating effects of emboli that occupy the various organs of the body. *Gastro-intestinal disturbance*, as shown by the occurrence of vomiting and diarrhea, is common. *Pain* ascribable to local peritonitis over the spleen, and sometimes also over the liver, is observed. *Hematuria* and *dimness of vision* are also frequent concomitants, and are due to renal and retinal hemorrhages. The *urine* may be scanty and albuminous. The more *general features*, that are the result of the local embolic processes or small abscesses, and, in part, of the valvular lesions, are for the most part typhoid in character. The *onset* is usually signalized by a severe rigor that may be repeated at intervals varying from one to several days, and there is often an irregularly continued fever-curve, often touching a high mark (105° or 106° F.— 40.5° – 41.1° C.). I saw a case in which the febrile movement pursued the continued type for seven weeks. The *pulse* is rapid and irregular, though frequently becoming slow within a brief period. The patient rapidly *emaciates*, and from the onset is profoundly prostrated; *nervous symptoms*, as headache, mild delirium, followed by somnolence, and sometimes even coma, appear. Profuse sweating sets in and persists, and as a result the *skin* may be covered by sudamina. An ecchymotic eruption due to cutaneous *emboli* is also common, often associated with a papular or a diffuse roseolar rash. At times arthritis may occur. Micro-organisms may be discovered in the blood (90 per cent.—Gordinier). There is a hyperleukocytosis with polynuclear predominating present.

Physical Signs.—These may be negative as regards the heart. In the majority of instances, however, a *systolic murmur* is present, which, when associated with other clinical indications of this affection, is valuable for diagnosis, and especially so if developed while the patient is under treatment for the primary attack. The second sound is sometimes accentuated even when no organic lesions have previously existed. The physical signs of pneumonia and pleuritis (particularly the latter) may not infrequently be noted. Cases occur in which infarcts of the right lung give rise to signs of localized consolidation; the spleen becomes swollen, easily palpable, and is quite tender as a rule; the liver is likewise moderately enlarged and slightly sensitive.

Cerebral Variety.—In a small though decisive percentage of the cases all the clinical features of acute suppurative meningitis are presented, and sometimes to the almost total exclusion of symptoms pointing to the primary disease or to the more typical typhoid form of ulcerative endocarditis. For a description of the symptoms that characterize the cerebral form the reader is referred to the discussion of Purulent Meningitis.

Recurrent Malignant Endocarditis.—By this term is meant an acute ulcerative endocarditis coming on in the course of chronic valvular disease. As has been pointed out, simple acute recurrent endocarditis is common, though difficult of recognition. The latter condition, as well as the lesions in chronic valvular disease, predisposes to secondary infection by the streptococcus and other organisms. The onset is usually abrupt and marked by a chill. The patient has fever, which may be quite high (104° F.— 40° C., or over), and may present either an irregularly intermittent or a truly intermittent curve. The latter is often associated with recurring chills. In either of the above *groups* the course is likely to be acute. In some cases the pre-existing murmur becomes louder and more decidedly blowing; the character of the superadded

murmur is changeable; in many other instances, however, there is no appreciable alteration. The condition may arise suddenly, amid the signs of failing compensation, as in a fatal case reported by Dr. H. P. Loomis, in which the patient was semiconscious, cyanotic, and suffering from intense dyspnea and general dropsy. It was impossible to diagnosticate the cardiac lesions by the murmur present. Occasionally these severe intercurrent febrile attacks end in recovery. There is a third group of cases that run a subacute or even chronic course, with more moderate elevations of temperature, or, as rarely happens, none at all. Mullin, of Hamilton, has reported a case that lasted more than a year. Here the other clinical phenomena, especially those referable to the heart, are often scanty and indefinite.

In a series of 14 cases of chronic infectious endocarditis reported by F. Billings¹ 5 were implanted on normal valves, while in 2 previous heart lesions were in doubt.

Diagnosis.—It is of paramount importance to consider the previous history and all the circumstances under which individual cases occur. These points, together with the early symptoms, more particularly the severe rigor, early high temperature and profound prostration, the sweatings, the various embolic phenomena, and the presence of cardiac symptoms, are often adequate for a certain diagnosis. With a clear history and the presence of the more characteristic general symptoms (in particular, the *signs of embolism*), a correct diagnosis is possible, even though cardiac murmurs be absent. Instances in which no data can be found to explain the occurrence of the disease are especially puzzling, and will remain unrecognized if the heart manifests no special symptoms and embolic phenomena are absent. Here the existence of a chronic valvular affection would afford strong probability of the presence of recurrent malignant endocarditis, especially if an intercurrent fever be present. A blood-culture should be undertaken in all cases. A negative result, however, means little.

Differential Diagnosis.—The subjoined Table will, I feel, be found valuable as an aid in eliminating enteric fever from the typhoid form of malignant endocarditis:

ULCERATIVE ENDOCARDITIS	TYPHOID FEVER
Previous or associated disease, as acute rheumatism or pneumonia.	Previous health good. History of an epidemic.
Very rarely a primary affection. No prodromes observable.	Always idiopathic, with a prodromal stage.
Ushered in suddenly by a severe rigor, which may recur.	Invasion marked by slight recurring chilly sensations. (Severe chill rare.)
The fever rises rapidly.	More gradually, in step-like fashion.
Profound prostration as early as third day.	Profound prostration not earlier than seventh day.
The fever is markedly irregular from time of onset, as a rule.	Less so, especially in the first week.
Embolic symptoms (hemiplegia, etc.) may appear.	Extremely rare.
Cardiac symptoms, especially loud systolic murmur, often present.	Sometimes a soft systolic murmur.
The blood usually shows signs of septic leukocytosis.	The blood shows a leukopenia.
Blood-culture may show a micro-organism other than the typhoid bacillus.	Blood-culture may show the typhoid bacillus.
Widal reaction and characteristic eruption absent.	Both symptoms usually present and diagnostic. ²

¹ *Arch. Int. Med.*, November, 1909.

² The septic form may simulate malaria in its general course. The points of dissimilarity may be found in the discussion of Septicemia.

When no etiologic factors are discoverable, and embolic and cardiac phenomena are absent, we must rely upon the Gruber-Widal reaction, and other laboratory tests, to distinguish typhoid fever from ulcerative endocarditis.

Prognosis.—Most cases that run an acute course terminate in death, and when supposed instances of malignant endocarditis recover they are usually to be regarded as being of benign character. Subacute or chronic varieties, however, such as are most frequently met with in connection with organic heart disease, sometimes end in recovery.

Treatment.—This is largely supportive. The feeding is to be pushed vigorously, and concentrated forms of liquid food should be given at regular, brief intervals. *Rest* and stimulants in liberal quantities are also demanded. Antistreptococcic serum has proved efficacious in certain cases in which the streptococcus was the causative agent. Broadbent thinks the vaccine treatment affords a better chance of success than the antistreptococcic serum. Moritz treated a case with antistaphylococcic serum, with a favorable issue. Autogenous vaccines have been used, but, on the whole, the results have not been very promising.

CHRONIC ENDOCARDITIS

(Chronic Interstitial Endocarditis)

Two clinical varieties are met with—one following the acute form, the other beginning as a chronic inflammation.

Pathology.—The lesions may be limited to the valvular endocardium (their most common seat), or the mural endocardium may also be involved. In not a few instances the lesions are confined to the edges or bases of the segments, and when seen in the early stages there may frequently be observed merely a slight thickening of the free border of the leaflets; in most cases small prominences appear near their free margins. The endocardium looks opaque and its normal elasticity is lost quite early. When the auriculo-ventricular valves are affected the primary seat of inflammation is the auricular face, but lesions of the semilunar valves begin on the ventricular side and implicate the Aurantian body. Extension of the morbid process to other and all parts of the valvular curtain is common, and it is in cases of this sort that the greatest degree of shrinking and crumpling occurs. The most characteristic lesions consist of inflammation and exudation, which produce cohesion of the segments, roughen the surfaces, and lead to the deposit of fibrin upon them. The *histologic alterations* consist for the most part in a proliferation of the endothelium and a round-cell infiltration of the subendothelial connective tissue. Organization of these products of inflammation into fibrous connective tissue, with resulting induration and contraction, is the subsequent pathologic event. In old cases calcification of the diseased structure is frequent. The fibrous deposits in acute endocarditis may become calcareous “at the same time that the sclerotic processes are taking place in the valve” (Stengel). The shrinking shortens the curtains or curls their free edges, and produces insufficiency in either case, since on dropping into the plane of the valvular orifice they fail to close it perfectly. Valves thus deformed may also obstruct the blood-stream. Cohesion of the invaded segments leading to constriction or stenosis may take place.

Involvement of the semilunar (aortic) segments in the ways previously described opposes an obstruction to the outflowing blood-current on the one hand, and, owing to the inability of the segments to effect perfect closure of the aortic orifice, allows on the other hand a diastolic reflux of blood into the left ventricle. The aortic ring to which the semilunar segments are normally attached becomes sclerosed, and finally the seat of atheromatous changes,

either fatty or calcareous. Again, chronic inflammation of the intima of the aorta produces a similarly thickened condition of this layer in spots, followed by atheroma. These changes are most prone to take place in the course of the ascending arch of the aorta or just above the aortic segments. The diseased processes before described may extend to the coronary arteries. Hence sclerotic and atheromatous alterations in the blood-vessels are found frequently in association.

Much less commonly similar lesions are noted at the orifice of the pulmonary artery. A similar involvement of the auriculoventricular valves also causes regurgitant and obstructive deformities at the mitral orifice, and in advanced cases the chordæ tendineæ, and even the papillary muscles, are almost invariably invaded by direct extension from the valves. As these structures undergo marked thickening with subsequent contraction, they become shortened and rigid, causing an actual narrowing of the cardiac orifice. In mitral stenosis during the early stages a more or less complete ring of vegetations encircles the mitral orifice on its auricular aspect. The margins of the orifice also become hardened and roughened, with extension to the valvular curtains and the chordæ tendineæ. Under such circumstances the thickened valve could not, during the ventricular diastole, be forced back against the ventricular wall, but would occupy a nearly central position. Owing to cohesion of the free edges of the valvular structures and to contraction of the chordæ tendineæ drawing the leaflets toward the apex of the heart, the transition from this condition to the formation of a hollow cone (*funnel mitral*) is by natural, easy stages. Extensive union of the segments along their free margins may reduce the aperture to a mere button-hole slit (*button-hole mitral*) as viewed from the auricular aspect. The last two forms of lesions are far less commonly met with at the aortic orifice, though they occur rarely in moderate degree; on the other hand, curling of the valvular edges is far more commonly seen at the aortic than at the mitral orifice, if we except the cases that occur in children. The curtains of the thick, rigid valves may also permanently occupy the plane of the orifice, presenting a small ring-like opening (*annular mitral*).

Fatty degeneration leading to the formation of necrotic (atheromatous) ulcers is common; and calcareous deposits are frequently seen in old cases, either in localized areas or coextensive with the diseased tissue, converting the entire valve into a calcified mass, with loss of the valvular outlines.

Under such conditions of the valves the deposit of fibrin would be greatly favored, and the presence of an ulcerative surface on the valves affords a ready and satisfactory explanation of the occurrence of embolism in these cases. Emboli may also become detached from cardiac thrombi or from thrombi formed in the peripheral veins. For anatomic reasons the favored seats of embolic processes are, as in acute endocarditis, the spleen, brain, and kidneys, and irritants that cause acute endocarditis find here a tissue soil whose capacity for resistance to invasion is greatly lowered. *Chronic mural endocarditis*, which exhibits lesions in the form of grayish-white patches, and chronic myocarditis are, as a rule, due to the extension of the inflammation from the valves, though the ventricular endocardium may be invaded independently of the valvular affection. In one instance of mitral stenosis I observed an enormous calcareous mass partly in the subvalvular tissue and partly in the wall of the ventricle, the segments remaining altogether intact. In advanced stages of most cases of chronic endocarditis myocardial degeneration occurs. It takes the form of fibroid change or fatty degeneration, or both. Aortic valve involvement, especially when complicated with atheromatous change in the coronary arteries, is most prone to these forms of myocardial disease. Chronic

endocarditis may be said to persist until death, although Musser has reported 2 cases in which the murmur of this lesion disappeared during life.

Sequelæ of Valvular Lesions.—The various valvular defects constantly produce dilatation of the heart cavities, which is followed by anatomic hypertrophy up to a certain point, which in turn is succeeded by myocardial weakness with consequent lowering of the blood-pressure in the arterial system and increased pressure in the veins. The variations in arterial and venous pressure causes the blood-current in the capillaries to become slowed, the blood loses more of its oxygen to the tissues, and as the result of this abnormal condition of the circulation cyanosis and, finally, edema ensue. The effect of valvular deficiencies upon the several cardiac chambers will be most advantageously studied when the individual lesions of the segments are considered.

Etiology.—There can be no doubt that most cases of organic heart disease occurring in children and young adults are caused by primary *acute rheumatic endocarditis* and *tonsillitis*, and, although the latter affection cannot in truth be said to terminate invariably in chronic endocarditis, it probably does in many instances. This result, in my opinion, is more frequent in children suffering from acute endocarditis than in adults. On the other hand, not a few cases of chronic endocarditis originate in a very mild grade of acute valvular inflammation. Indeed, acute endocarditis may be the sole expression of rheumatic disease. Not less than one-half of all cases of organic valvular disease are caused by rheumatism, and more than one-half occur between *twenty and thirty* years of age. Acute endocarditis complicating scarlatina, measles, chorea, pneumonia, may also be followed by the chronic variety, although probably not so commonly as in the case of acute endocarditis of rheumatic origin.

The *second variety*, in which slow interstitial changes occur from the beginning, is dependent upon—(a) biologic irritants (*e. g.* syphilis, malaria, and chronic rheumatism); (b) chemical irritants (alcohol, lead), and (c) mechanical influences. Doubtless the influence of *repeated straining efforts* may have some influence in this class of cases. Heavy muscular labor increases constantly the tension in the arterial system, and this acts injuriously upon the valve segments, setting up a gradual sclerotic change. In like manner, *arterial sclerosis* and *Bright's disease* may cause chronic interstitial endocarditis by maintaining a persistent increase in the vascular tension, though the fact that these affections may in turn result from the action of some of the leading causes of organic heart disease must also be recollected. *Trauma* has produced in valves previously healthy a sudden, incontestable proof of valvular paresis or laceration that has persisted in a few well-attested cases. This accident is more frequent in cases in which the valves have been already diseased (*e. g.*, ulcerative processes).

The **predisposing causes** of organic valvular disease may be discussed briefly. Any malformation of a valve is certain to throw an undue strain upon certain portions, and hence is likely to be followed by interstitial change. Osler, in 17 cases of bicuspid aortic valve, has reported the segments to be uniformly sclerosed. The cases of supposed hereditary transmission are doubtless, however, for the most part, due to the causes mentioned above, and particularly to rheumatism. *Age* exerts a predisposing influence, its effects, however, varying with the valve implicated. During fetal life this is on the right side of the heart in a vast majority of cases; during childhood, adolescence, and early adult life, when the infectious diseases and rheumatism are frequent, it is the mitral valve in most instances; and finally, during middle and especially during advanced life the aortic segments are especially involved. I have, however, found aortic disease to be more common in young adults than most

writers are ready to admit, and that it is favored especially by an occupation involving muscular strain (*e. g.* blacksmiths, draymen, soldiers during campaigns). Sex *per se* has little if any effect, though, owing to the greater frequency of certain well-known causes of valvular disease (chorea and rheumatism) in girls and young women, females may be more frequent sufferers than males.

AORTIC INCOMPETENCY

(*Aortic Insufficiency; Aortic Regurgitation*)

Definition.—The failure of the aortic valves to prevent a return flow of blood into the ventricle, owing, as a rule, to a diseased condition of the aortic leaflets (sclerosis) that is followed by crumpling and attended with contraction, shortening, or curling of the edges, and finally calcification.

Pathology.—Apart from the commoner lesions described above, the aortic orifice may be enlarged (relative insufficiency), and here the normal cusps fail to effect complete closure when they become tense. The cusps of the diseased aortic valves sometimes adhere to the intima of the aorta, and laceration of the semilunar segments, which are the seat of disease processes (particularly ulceration), is sometimes found *postmortem*, and may be the chief factor in determining the development of the condition. This accident may, though rarely, occur as a result of a severe straining effort in the case of valves previously healthy. Occasionally, also, the principal factor in the production of this valvular lesion is a congenital malformation of the segments whereby they are rendered very prone to chronic endocarditis in consequence of the undue strain to which they are subjected. At times the lesions that give rise to stenosis may coexist with simple aortic incompetency. Aortitis is very frequently coexistent.

Mechanical Influence of the Lesion.—The reflux current passes from the aorta backward through the imperfectly closed semilunar valve into the left ventricle during the diastole of the heart or while the left ventricle is being filled by the normal blood-flow from the auricle. It is clear that overdistention of the left ventricle must result at once from two simultaneous influx currents of blood, with a tendency to an increasing dilatation, especially since the lesion itself is steadily progressive. To expel the increased amount of blood from the left ventricle demands increased cardiac power, and the over-exertion causes a compensatory *hypertrophy*. Dilatation and hypertrophy of the left ventricle develop *pari passu* until this chamber reaches enormous dimensions, forming the *cor bovinum*, which weighs 1000 grams or more (30 to 50 ounces). Under these circumstances the arterial system is overfilled at each ventricular systole. In the very early stage the reflux of blood from the aorta into the ventricle tends to lessen the volume of the circulating medium in the arterial tree, but this depleting influence is successfully counterbalanced by the augmented column of blood thrown from the ventricle during cardiac systole. Hence the requirements for bodily nutrition are, for a longer or shorter time, satisfied. The abnormally large amount of blood that is thrown into the arteries with undue force subjects them to increased tension, and as a result arteriosclerosis, leading sometimes to atheroma, is commonly developed, and presents its ulterior dangers (aneurysm, apoplexy). The coronary arteries are similarly involved, their caliber being reduced, and particularly at the point of origin. Soon or late the blood-supply to the heart muscle may become inadequate, and nutritional disturbances now manifest themselves in fatty and fibroid degeneration of the cardiac muscles; these pathologic changes

are attended with *secondary dilatation*, which soon predominates over the hypertrophy. The imperfect blood-supply to the ventricular tissue may be accounted for, in great measure, by the narrowed lumen of the coronary vessels, and also in part by the inelasticity of the walls of the latter and by the inefficiency of the aortic recoil. In consequence of the increased tension to which they are constantly subjected the *mitral leaflets* may become the seat of sclerotic endocarditis, and this may lead to mitral insufficiency (usually of mild grade); or there may be a displacement of the mitral segments in the direction of the auricle, producing a considerable degree of incompetency. There is also in the majority of cases a marked degree of fatty degeneration, with more or less flattening, of the papillary muscles. Again, *secondary dilatation* commonly produces relative insufficiency at the mitral orifice. When incompetency has been established here, impeded pulmonary and general venous circulation, together with the secondary lesions in the left auricle, pulmonary vessels, and right ventricle that are characteristic of mitral incompetency, are the necessary result. The blood-current through the mitral ring may be retarded owing to the simultaneous influx into the left ventricle from the aorta, thus causing pulmonary congestion without either change in the segment or overdistention of the orifice.

Etiology.—(1) "Syphilis is now generally regarded as an essential factor in the causation of aortic incompetency, more particularly in cases which develop before the forty-fifth year of life. The chronic aortic endocarditis is commonly associated with mesaortitis, as before stated, affecting the root of the aorta in such cases. It is worthy of note that this etiologic variety of aortic incompetency is often met with unassociated with wide-spread arteriosclerotic changes. In this connection it should be stated that a pure mitral lesion is seldom produced by lues, but a combined aortic and mitral lesion is commonly caused by syphilis.

"There is a consensus of opinion to the effect that the most important etiologic factor in the production of aortic incompetency is luetic infection. This view is amply supported by statistical observations. Thus Longcope,¹ in a series of 37 autopsies showing mesaortitis, found 13 instances of chronic aortic endocarditis (35.1 per cent.). Again, of 21 cases of aortic insufficiency, 11 either gave a definite history of syphilis or syphilitic lesions were discovered at autopsy. Citron obtained a positive Wassermann reaction in 10 out of 16 cases of this cardiac lesion, or in 62.6 per cent. Fiessenger² obtained a history of syphilis in 28 out of 37 cases of aortic insufficiency.

"Collins and Sachs³ found a positive Wassermann reaction in 10 out of 13 instances of aortic valvular disease. Babcock⁴ records 16 cases of aortic regurgitation, of which 11 were submitted to a Wassermann test with a positive reaction in all of the cases.

"My own collective investigations into the question of the frequent association of aortic insufficiency and syphilis embrace a total of 219 cases inclusive of the figures cited above. Of these, 133, or 60.7 per cent., were clearly due to lues. In a considerable number of the cases of aortic incompetency no reference to the Wassermann test was noted. Obviously, then, the above figures underestimate the true rôle of syphilis in the production of this condition."⁵

(2) Sclerosis of the valves secondary to arteriosclerosis is another frequent cause for the condition. Here the etiologic agents are the same as

¹ *Jour. Amer. Med. Assoc.*, January 8, 1910, p. 118.

⁴ *The Lancet-Clinic*, August 15, 1912.

⁵ Quoted from article by Anders, *Amer. Jour. Med. Sci.*, 1915, cl, 835.

those that produce sclerosis of the vessels, and include gout, lead, alcohol, wear and tear of life, chronic infectious processes, and so on.

(3) An acute endocarditis, in a few cases, may attack the aortic valves during the course of the septicemia. The secondary and late effects of this invasion may be shown by the production of chronic aortic valvular disease.

(4) At times rupture of one of the leaflets of the valve may occur during some sudden overstraining. It is likely, however, that such valves are previously weakened by some other process.

Among the more effective predisposing factors are *age*, *sex*, and *race*. The disease occurs much more often in males than in females on account of the fact that a greater percentage of the former are engaged in occupations that predispose to the disease, and the greater incidence of syphilis in males. As to age, a preponderating proportion of the cases arise during advanced middle life. In the negro race the condition is twice as frequent as mitral disease.

Symptoms.—So long as the hypertrophy of the left ventricle successfully overcomes the otherwise injurious consequences of the valvular defect the harmonious balance of forces may be maintained, and then there is an almost entire absence of symptoms. I have observed, moreover, that compensation does not fail so early in young subjects as in those more advanced in years, and also when aortic incompetency is a sequel of atheroma combined with hypertrophy and dilatation of the left ventricle. With the development of marked hypertrophy severe muscular exertion and strong mental excitement will, by exciting overaction of the powerful heart, bring on a train of symptoms, as *throbbing headache*, *vertigo*, and *tinnitus aurium*. *Per contra*, the clinical manifestations of arterial *anemia*, particularly of the brain, and also those of general *arteriosclerosis*, frequently coexist. The patient's countenance exhibits *pallor*, and he complains of *headache*, *flashes of light* before the eyes, and *dizziness*. Dilatation of the peripheral vessels often leads to hot flushes and drenching sweats. Cases exhibiting the latter symptoms may be mistaken for *phthisis*. *Dizziness* is often distressing, and is more marked upon rising quickly from the recumbent to the erect posture. *Dyspnea* may come on early, but this rarely happens except upon inordinate exertion or great mental excitement—conditions that cause strong cardiac action and prohibit the discharge of blood from the left auricle into the left ventricle, thus causing *pulmonary congestion*. To some extent the cause of the dyspnea may be acidosis. Oppression in the precordial region and cardiac palpitation are commonly present, as is a *dull aching pain*, but it radiates not infrequently to the shoulders, and thence down the arms, particularly the left. Genuine *angina pectoris* may be a concomitant. I have seen instances of aortic regurgitation in which severe pain simulating rheumatism was located in the left shoulder-joint.

Following immediately upon **failure of compensation** the cardiopulmonary circulation is retarded, and there is increased *dyspnea*, the latter symptom being greatly intensified by undue exertion and at night. There may be *cough*, and not rarely *hemoptysis*, though less frequently than in simple mitral disease. Later on *general venous congestion* of a moderate grade follows pulmonary congestion, and the dyspnea now becomes severe. It is nocturnal, and often compels the patient to assume a semi-erect posture in bed. In the later stages the symptoms, particularly those of venous stasis as shown by cyanosis and malleolar dropsy, are due to ensuing relative mitral incompetency. Marked enlargement of the liver due to passive congestion may now ensue and give rise to the suspicion of a new growth. *Edema* of the feet rarely goes on to general anasarca. In aortic incompetency a higher grade of *symptomatic anemia* is reached than in any other cardiac lesion—a recent blood-count showing

2,800,000 red corpuscles to the cubic millimeter. Hence slight edema of the feet may be due solely or in part to anemia. The intercurrent of acute endocarditis, as evidenced by prostration and irregular fever, is observed not infrequently as a terminal condition. The symptoms of cerebral, splenic, and renal *embolism* may arise. Probably *sudden death* ensues as the result of involvement of the coronary arteries, with greater frequency in this than in all other forms of valvular disease combined; and yet this accident is by no means frequent. Instances of aortic incompetency, in which *nervous phenomena*, as peevishness, irritability, delusions, or melancholia, manifest themselves, are too common to be looked upon as mere coincidences. Many patients are led to commit suicide because of their cardiac lesion, when other and erroneous explanations are given to account for their acts.

Physical Signs.—*Inspection* brings to light an enlarged apex-beat; this is displaced downward and outward, being visible in the sixth and seventh spaces, and most marked between the midclavicular and anterior axillary lines. The precordial zone may be arched, particularly in young subjects, and the apex-beat is usually markedly heaving in character. The carotids throb forcibly, as do the temporals, brachials, and radials, though less violently. These abnormal pulsations are due chiefly to the strong action of the hypertrophied ventricle, though frequent factors of lesser influence are associated—an arteriosclerosis and a regurgitant blood-stream from the aorta into the left ventricle. The impulse becomes widely diffused and wavy with the progressive enfeeblement of the left ventricle, and venous pulsation due to tricuspid insufficiency may be associated with arteriopulsation later in the affection. Epigastric throbbing may be noticed, and on gently rubbing a spot upon the forehead an alternate paling and blushing appear (*Quincke's capillary pulse*); this may also be noted in the finger-nails. It is not peculiar to aortic insufficiency, however, and may be observed in cases of vasomotor insufficiency and in anemia. Very rarely the pulse-wave is propagated from the capillaries to the veins of the neck, hand, and back of the foot, giving rise to a visible venous pulsation. L. Webster Fox informs me also that the retinal vessels are often seen to pulsate in this disease.

On *palpation* a forcible heaving impulse is usually felt. When, however, dilatation predominates over hypertrophy, the impulse is weak and undulating. A diastolic thrill is sometimes felt over the base of the heart, and a presystolic thrill is also discoverable, though rarely. The arteries are lengthened and the pulse is characteristic; it is quick, leaping, and full, but, upon striking the finger, recedes abruptly, and is known as the *Corrigan* or *water-hammer pulse*. This sudden collapse of the pulse is most decided when the arm is held in a vertical position. It may lose its distinctive character after compensation is lost. Broadbent has noted a considerable increase in the interval between the apex-beat and the pulse-wave in severe aortic regurgitation. The systolic pressure, as a result of the cardiac hypertrophy, usually reaches figures between 180 and 200. The diastolic pressure is unusually low, and if taken by the auscultatory method when the fifth phase, the disappearance of sound, supposedly represents the diastolic pressure, such a sound may persist even down to 0. As it is obviously impossible not to have a diastolic pressure, the fourth phase should be read as the diastolic pressure. In such cases it will be found to be between 40 and 60. There is marked excess in the arterial pressure in the recumbent position in the lower extremity over that of the upper (Hill).

Percussion.—Cardiac dullness is coextensive with the impulse, extending in some cases downward to the eighth rib, and to the left from 1 to 2 inches without the midclavicular line. Later, enlargement of the left auricle may cause dullness upward and to the left of the sternum. Enlargement of the right

ventricle causes an increase of dulness to the right. When the dilatation exceeds the hypertrophy the area of dulness will be much extended transversely and slightly upward, the apex now being more rounded.¹

On *auscultation* a diastolic murmur is audible with its seat of greatest pronunciation at, or a little below and to the left of, the aortic cartilage and is transmitted down along the left edge of the sternum; this is produced in the left ventricle. From the xiphoid it may be transmitted to the left as far as the spinal column as a mere diastolic whisper. It may be heard, at times, in the vessels of the neck. A. Borgherini affirms that the special direction taken by the regurgitant current determines largely the variable position of the murmur and the variable size of the heart. The *rhythm* of the murmur can be most readily determined by auscultating over the base, for while the pulmonic second sound is usually audible at the apex (the murmur appearing to follow it), it is not so when, as sometimes happens, the murmur is quite loud. The first sound is often dull, indefinite, and widely diffused, owing to hypertrophy of the left ventricle. In *quality* this murmur is usually soft, blowing (long-drawn), and frequently musical; sometimes, however, it is somewhat rough and loud. *Associated Murmurs*.—In most instances a systolic murmur, brief and harsh in character and transmitted into the vessels of the neck, is also discovered over the aortic region (*double aortic*). The presence of the murmur with the first sound is not diagnostic of actual aortic stenosis. It is more often due to a mere roughening of the semilunar segments or of the intima of the aorta. In advanced cases a soft systolic murmur is commonly heard at the apex; it is readily distinguished from the diastolic murmur by its rhythm, and is occasioned usually by a relative mitral incompetency. Still another murmur, of rare occurrence, is rolling in character, generally presystolic in time, and may be heard at the apex over a limited surface area. This may be accounted for by the presence of excessive dilatation of the left ventricle, in consequence of which the mitral leaflets must remain free in the blood-stream during the diastole, and here they set up vortiginous movements that cause the presystolic (Flint) murmur. Duroziez discovered a double murmur in the femoral, but this may be noted occasionally in the absence of aortic regurgitation. Traube has described another arterial phenomenon—a systolic sound in the leg (“pistol-shot”), probably due to sudden systolic distention of vessels that were previously empty.

The **diagnosis** demands the presence of a diastolic murmur, the signs of left ventricular hypertrophy, the peculiar arterial pulsations, and the characteristic water-hammer or Corrigan pulse. The secondary manifestations are usually confirmatory. The diastolic murmur may be absent, in which case a certain diagnosis must not be made. It may be rarely heard with the unaided ear, and not with the stethoscope. In rare cases a diastolic murmur has its origin in the veins adjacent to the heart (*e. g.*, in the anemias). For the *differential diagnosis*, see Aneurysms of the Arch.

AORTIC STENOSIS

Definition.—A narrowing or stricture of the aortic orifice, due to thickening or adhesion of the valve segments, and causing an obstruction to the flow of blood into the aorta.

¹ A dilated aorta with thickened walls—a condition sometimes associated with aortic regurgitation—may give rise to dulness over and to the right of the manubrium sterni.

Simple aortic stenosis may be met with, though it is a great rarity. Its development is soon followed by more or less valvular incompetency. It may be secondary to aortic insufficiency; but this is rare, the latter lesion being unfavorable to the development of the former.

Special Etiology.—Rarely rheumatic endocarditis, and still less commonly other forms of acute endocarditis, cause union of the semilunar segments, with resulting stenosis. The most common causative factor is a *slow sclerosis of the aortic valve*, accompanied by calcareous deposits. The more or less immobile, rigid valves narrow the aortic orifice and oppose a barrier to the outflowing blood-current from the left ventricle. The aortic ring may be the seat of changes similar to those just described, resulting in a moderate grade of stenosis with intact leaflets. The lesions are most frequently to be regarded as a part of a general arterial sclerosis, most marked in the region of the thoracic aorta; sometimes, as Peter contends, they are distinctly secondary to sclerotic changes at the root of the aorta. The coronary arteries may be the seat of sclerotic changes. The condition is also rarely congenital. *Males* who have reached *advanced years* are especially prone to aortic stenosis, atheromatous processes belonging to that sex and period of life. Gallavardin¹ has described a rare non-congenital and non-rheumatic form of aortic stenosis occurring in young subjects; it is characterized by extreme latency.

Mechanical Influence of Lesion.—To propel the normal volume of blood through the constricted aortic orifice requires increased strength on the part of the left ventricle, and, as a consequence, the latter hypertrophies. This hypertrophy develops slowly, is uncombined with extensive dilatation unless incompetency be associated, and keeps pace with the progress of the valvular lesions. The undue ventricular tension sometimes induces more or less sclerotic change in the mitral valves. Hypertrophy of the left ventricle eventually gives way to extreme dilatation, resulting in relative mitral incompetency, with its sequelæ, namely, pulmonary, followed by general venous, stasis.

The **symptoms** date from the commencement of failure of compensation often many years after the onset of the disease. Their appearance will be found to follow some unusual muscular effort or the operation of some depressing influence, as the too free use of tobacco or alcohol. They are due to disturbances of circulation arising from a gradual secondary dilatation of the left ventricle, which is now unable to propel the normal quantity of blood into the arterial tree. Hence *anemia*, especially of the brain and peripheral parts of the body, becomes pronounced, and is evidenced by such symptoms as *syncope*, *dizziness*, *headache*, and *pallor*. Since aortic incompetency usually manifests itself secondarily, the clinical features of both affections are sooner or later variously commingled. In cases in which mitral lesions develop they are overcome by compensatory enlargement of the right ventricle: the latter chamber may at a later period become dilated, in which event tricuspid regurgitation and the symptoms of general venous engorgement appear. *Slight edema* of the feet is common as a terminal symptom; marked dropsy, however, is uncommon. From the fibrous deposits on the segments, as well as from any small clots behind the valves, *emboli* are apt to become dislodged by the forcible blood-stream and be conveyed to the brain, spleen, kidneys, or other organs.

Physical Signs.—*Inspection.*—The apex-beat is gradually displaced downward and to the left, owing to left ventricular hypertrophy. It is, as a rule, slow, forceful, and heaving, but less frequently may be lacking in strength. It may be enfeebled, diminished in area, or absent, owing to associated emphysema. Absence of the apex-beat may be occasioned by diminished contraction

¹ *Lyon méd.*, January 31, 1909.

of the myocardium, or during vigorous contraction of the heart, the ventricle emptying itself from the beginning, so that there is "no closing period and with it no apex-beat" (Leube).

Palpation discloses the forcible and heaving impulse-beat unless obscured or even absent owing to emphysema. A marked systolic thrill, with the seat of greatest intensity in the aortic region, is quite generally present. I have rarely felt this thrill in the apex region. The pulse-wave is small, regular, not compressible, and of normal or slightly lessened frequency (*sluggish*). The estimated blood-pressure is about normal.

Percussion.—Although hypertrophy of the left ventricle is present, the area of cardiac dullness is largely dependent upon the degree of emphysema associated. In the absence of this condition the dullness is increased to the left and downward, especially so when insufficiency coexists.

Auscultation.—A systolic murmur, harsh in quality, most audible at the aortic cartilage (the second right), and transmitted into the carotids, is present in typical aortic stenosis. When non-compensation is advanced the murmur is neither so rough nor so loud, and quite late it may be missing altogether. The second sound is faint or inaudible on account of the diminished blood tension in the aorta and the character of the valvular lesion. As aortic incompetency is commonly associated, a regurgitant or diastolic murmur is also heard, forming a *double* or *see-saw* murmur, the stenotic bruit more or less completely masking the regurgitant. A soft, blowing apical murmur (with the systole) is not infrequent after relative insufficiency of the mitral valves has appeared.

The **diagnosis** demands the concurrence of the following signs: a systolic thrill, most marked at the base; a tense, small, somewhat slow pulse; indications of left ventricle hypertrophy (unless emphysema be present); a rough, loud, systolic murmur at the aortic cartilage, propagated into the vessels of the neck, and a feeble second aortic sound.

Differential Diagnosis.—A calcareous plate lying on the intima of the aorta and a markedly roughened condition of the aortic segments are conditions frequently mistaken for aortic stenosis, since they give rise to a murmur possessing many of the characteristics of the one above described. These murmurs, however, are seldom musical, while the murmur of aortic stenosis is often so; moreover, the second sound is decidedly accentuated, while in aortic stenosis it is faint. In *chronic Bright's disease* with arterial sclerosis and left ventricular hypertrophy a murmur of maximum intensity may be developed at the base; but here the urinary symptoms, together with intensification of the second sound, are sufficient for a discrimination. In *aortic regurgitation* a systolic murmur frequently coexists, but it cannot be reckoned as indicating actual stenosis unless it has a musical quality and a systolic thrill can be felt on palpation. In combined aortic regurgitation the characteristic condition of the pulse of stenosis may be missing. The basic murmurs of *chlorosis* and other forms of anemia are soft, distant, not transmitted, and not harsh; the intense thrill and ventricular hypertrophy are absent. The venous hum may also be heard in the veins of the neck. *Pulmonary stenosis* occurs in young subjects, and while it gives rise to a harsh systolic murmur, is best heard to the left of the sternum, is propagated upward and to the left, and the second pulmonic sound is weak.

MITRAL INCOMPETENCY

(Mitral Regurgitation; Mitral Insufficiency)

Definition.—Imperfect closure of the mitral valve due to rupture (rare) or contraction of the mitral leaflets. It is also caused by dilatation of the left ventricle and by a diseased condition of the chordæ.

Pathology.—This is the most frequent form of organic disease of the heart. Thomas G. Ashton, from clinical observation of 1012 cases of heart affection, comprising all the different varieties, found that 54.4 per cent. were instances of mitral regurgitation. The predominating lesions may be brought under four heads: (a) Acute endocarditis, leading to contraction and deformity, particularly curling, of the margins of the valve; (b) primary sclerotic form; (c) relative insufficiency from excessive dilatation of the left ventricle (the segments being healthy); also from insufficiency of the valvular muscles; and (d) adhesion of a segment with the walls of the ventricle, and also contraction and weakening of the chordæ tendineæ.

Mechanical Influence of the Lesion.—The mitral leaflets normally close, and prevent the reflux of the blood from the left ventricle into the left auricle during systole. Hence incomplete closure of the mitral segments allows a portion of the blood to return into the left auricle during the systole. This regurgitant wave meets and offers an obstacle to the normal blood-current coming simultaneously from the pulmonary veins into the left auricle. It is clear that vortiginous movements must result under these circumstances and give rise to a murmur. The double blood-current, entering the left auricle during the systole of the left ventricle, causes overfilling (hence dilatation) of the left auricle, and in a gradual manner induces compensatory hypertrophy of its walls since its labor has been increased. During the next diastole the abnormally large contents of the auricle stream under increased pressure into the left ventricle, producing overdistention (dilatation of that chamber). This increased volume of blood in the ventricle is not all expelled into the aorta, but a portion of it returns into the left auricle. Thus the left ventricle, in consequence of its increased labor, becomes hypertrophied as well as dilated. Under these circumstances the volume of blood that is poured into the aorta remains about normal, and hence the arterial tension for a longer or shorter period is also normal. Soon the cardiopulmonary circulation becomes impeded.¹ The blood that returns into the left auricle must, by reason of pressure, offer increased obstruction to the outflow of blood from the pulmonary veins, and the pressure in the latter must, in turn, be similarly increased. The current of the blood through the pulmonary capillaries and branches of the pulmonary artery is thus retarded owing to the gradual backward accumulation. The walls of the lung vessels are the seat of a sclerotic process, and present an abnormal obstacle to the passage of the systolic wave from the right ventricle to the distal end of the cardiopulmonary arc. As a consequence of the lung congestion and vascular changes the right ventricle becomes dilated and hypertrophied. The abnormally increased tension in the pulmonary vessels is shown by the accentuated pulmonic second sound. Thus the right heart compensates the lesion in the left, though to supply an adequate amount of blood to the peripheral arteries the left ventricle must maintain its proper degree of

¹ While this theory of back-pressure from obstruction has been universally held until recent times, Mackenzie and many other cardiologists now hold that it is impossible to cause pressure symptoms simply as a result of a valvular obstruction, *per se*. Mackenzie says that any case of progressive valvular disease will show, if carefully followed, that back-pressure does not occur until insufficiency of the myocardium takes place.

hypertrophy. As soon as this harmonious balance is disturbed, either as the result of increase in the degree of incompetency or of failure of muscular power, the progress of the blood from the right auricle to the right ventricle is hindered. Increased pressure in the right auricle produces dilatation of its chamber, with subsequent general venous congestion as a natural backward effect (*vide* Tricuspid Regurgitation). It is now seen that when the right heart fails a lessened amount of blood reaches the left ventricle, and hence an abnormally small amount finds its way into the aorta; this fact explains the presence of the low arterial tension late in the disease. Hypertrophy of the left ventricle in this disease has also been attributed in part to the augmented tension in the general capillary vessels that is occasioned by the venous stasis.

Special Etiology.—(a) *Rheumatic endocarditis* is the most frequent cause, though mitral regurgitation also results less frequently from acute endocarditis due to other causes. (b) It may be a part of a *general arteriosclerotic process*, caused, not rarely, by syphilis and alcohol. (c) *A diseased condition of the columnæ tendineæ*, if it contracts them or weakens their structures so that the free edges of the segments pass beyond the plane of the orifice, produces insufficiency. (d) It rarely arises in the course of *aortic valvular disease* (a secondary mitral affection), and is then excited mainly by undue tension of the blood in the left ventricle. Here the lesion is of a mild grade, as a rule. (e) It is frequently occasioned by *enlargement of the left auriculoventricular ring* (relative incompetency), resulting from excessive dilatation of the left ventricle, as in aortic incompetency, aortic stenosis, long-continued fevers (toxic myocarditis), and the graver anemias. (f) *Ulcerative endocarditis*, either by perforating or producing rupture of the valve-curtains or by destroying the chordæ tendineæ, may bring about mitral incompetency. Among *predisposing factors* age and sex are worthy of special mention, the incompetency occurring with greatest relative frequency in young adults (from twenty to thirty years of age, according to Ashton's figures) and somewhat more commonly in males.

Symptoms.—*During Compensation.*—In healthy persons the compensatory forces keep pace with the valvular lesions for an indefinite and usually lengthy period, during which time there may be an entire absence of symptoms. When present they are dependent upon disturbances of the cardiopulmonary circulation that are occasioned by trivial causes, such as excitement, going up stairs, or other forms of active physical exertion. Under these circumstances the force of the regurgitant current is increased (by the hypertrophied left ventricle), thus producing more or less *pulmonary congestion* that may proceed to edema of the lungs or hemoptysis. The condition is usually a temporary one, and is attended by *dyspnea*, *palpitation of the heart*, a *short, hacking cough*, and *expectoration of a frothy serum* that may be blood-stained. The relation existing between the severity of the dyspnea and the degree of active physical exertion is positive and vital. Shortness of breath may be the sole feature during a long period. The rational symptoms rarely warrant a suspicion of the existence of mitral disease until compensation has failed, but the patient's appearance often indicates heart disease. The *face* is pale and the features peaked, the eyes, lips, and ears are dusky, and the minute vessels of the cheeks are prominent. Clubbing of the finger-nails is observed most frequently in the young.

After Failure of Compensation.—Failure of compensation implies failure of the right ventricle to cope efficiently with the augmented tension in the pulmonary circulation, with accompanying congestion of the lungs, followed by engorgement of the systemic veins. The latter process begins at the right heart and proceeds toward the periphery, involving the viscera, mucous membranes, and extremities until it is universal. The *pulmonic symptoms* above

detailed are now more marked, particularly the dyspnea (which may be constant), cough (with expectoration of alveolar epithelium containing brown pigment granules), and cardiac palpitation with arrhythmia. *Pain* is rare unless stenosis coexists. *General venous engorgement* manifests itself by an enlargement of the liver and of the spleen, in the features of gastro-intestinal catarrh, in hemorrhoids, in marked cyanosis of the surface, and in the passage of a scanty albuminous urine containing tube-casts and blood-corpuscles. Dropsy follows, beginning in the feet and progressing upward, until finally the trunk and the serous sacs are involved. The blood-pressure is frequently higher during the stage of decompensation than when there is complete compensation on account of the accumulation of CO₂ in the blood which stimulates the vasomotor center and because of the increased amount of fluid in the vascular tree (hydremic plethora). By stimulation the heart may be reinforced, and all of the unfavorable symptoms disappear. I have at present under observation a case in which not less than half a dozen instances of broken compensation have occurred at intervals of six to eight months.¹ In all cases, however, there comes a time when compensation cannot be restored, and the end is soon reached.

Physical Signs.—*Inspection.*—The precordia is prominent, particularly in children, and the area of the apex-beat is enlarged, later becoming diffuse and wavy. It is carried to the left and downward, sometimes to the sixth interspace, corresponding with the degree of hypertrophy of the left ventricle. A pulsating epigastrium is in frequent association, particularly after dilatation of the right ventricle appears. With the failure of the right heart also come wavy pulsations in the cervical veins.

Palpation sometimes discovers a thrill at the seat of the apex-beat synchronous with the first sound. The impulse is forceful and heaving. Auricular fibrillation may set in, particularly toward the end of the disorder. When it does, the apex-beat is extremely irregular. The pulse bears a definite relation to the apical impulse; it is commonly regular and full during the compensatory period (though at times the tension is slightly lowered), but becomes small, easily compressible, and exceedingly irregular during the period of broken compensation in those cases in which auricular fibrillation is present during the stage of decompensation. One meets with cases in which absolute irregularity appears during the period of compensation.

Percussion.—The dull area is increased to the left, extending frequently to the anterior axillary line; and also to the right, frequently from $\frac{1}{2}$ to 1 inch (1.2–2.5 cm.) without the right sternal margin. Dilatation of both ventricles exerts a widening influence; hence cardiac dullness is increased more laterally than vertically. The upper arc of cardiac dullness commences usually at the third intercostal space.

Auscultation reveals a systolic murmur, with greatest intensity at the apex (see Fig. 49). It is rarely loudest in the fourth or third space in the vertical nipple line. Balthazar Foster first called attention to the fact that the murmur of mitral regurgitation may be loudest at the base of the heart, and at times audible only in that situation—an occurrence that has since been confirmed. It is sometimes audible in the recumbent posture and inaudible in the erect. From the apex it is transmitted to the left as far as the angle of the scapula, with progressively diminishing clearness. It has a blowing quality, and frequently ends in a musical tone. Loudness implies strength of contraction (Broadbent). It is fair to assume that on account of the defect in the closing of the mitral valve there is often a decreased tone formation with

¹ Neglect of hygienic precautions and intercurrent complaints of various sorts often determine the occurrence of failure of compensation.

systole. Over the third left costal cartilage, and frequently at the apex, there is heard the accentuated pulmonic second sound due to the increased tension in the pulmonary vessels engendered by the hypertrophy of the right ventricle. *Combined murmurs* may be heard, and not infrequently a rough, rolling, or rumbling presystolic murmur is detected. A frequent late occurrence is secondary dilatation of the right ventricle, causing relative tricuspid insufficiency with its characteristic soft, low-pitched, systolic murmur, heard best at the ensiform cartilage. A spurious diastolic murmur may be noted, though rarely, when the sounds are timed with the pulse. This is due to a weak systole that fails to cause a radial pulse.

Diagnosis.—In the presence of the following group of features the diagnosis is set at rest: A marked broadening of the area of cardiac dullness; a

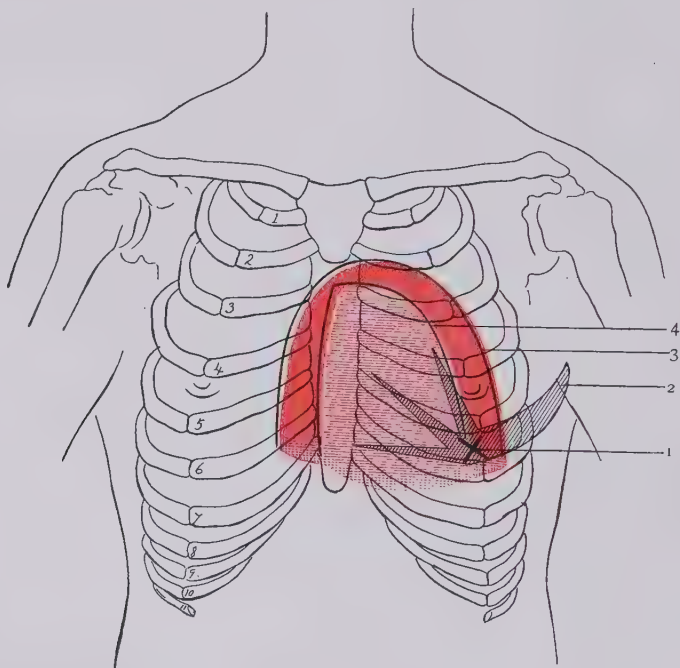

Fig. 49.—1, Seat of greatest intensity; 2, direction of chief transmission; 3, boundary-line of relative dullness; 4, boundary-line of absolute dullness (modified from Sahli).

systolic, *apical* murmur that is conveyed to the left axilla and may be heard even at the back; and a decided accentuation of the pulmonary second sound. Obviously, the latter sound becomes feeble after dilatation of the right ventricle has occurred. A systolic thrill is of the highest diagnostic importance, but is unfortunately absent in perhaps a majority of the cases. Free regurgitation through the mitral orifice may be safely inferred when the following signs are concurrent: (a) An absence of the sound of mitral-valve tension, a murmur replacing the first sound; (b) accentuation of the pulmonic second sound; (c) an enlarged area of the left cavity; (d) an enlarged area of the right cavity (Sansom).

Differential Diagnosis.—There are two organic lesions of the heart that are sometimes mistaken for mitral incompetency, since both are accompanied by a systolic murmur—the one *aortic stenosis*, and the other *tricuspid regurgita-*

tion. How to distinguish mitral from tricuspid incompetency is a question that will receive due attention when the latter disease is considered. *Aortic stenosis* generates a systolic murmur, but it is loudest over the base, and is transmitted through the great vessels of the neck; while the mitral systolic is most intense over the apex and is transmitted far to the left. In mitral incompetency the pulmonary second sound is accentuated; in aortic stenosis it is not. In mitral insufficiency both ventricles are enlarged, as shown by percussion and other signs; in aortic stenosis the hypertrophy affects chiefly the left ventricle. In mitral incompetency a thrill, most marked over the apex-beat, may be felt; in aortic stenosis a thrill, rough and having its chief seat at the base, is present. Additional points of distinction are furnished by the contrasting factors of the pulse, the age of the patient, and other etiologic influences. *Cardiopulmonary murmurs* may simulate the murmur of mitral insufficiency, but can be readily differentiated, as they disappear when the patient holds the breath.

Functional systolic murmurs are often confounded with mitral insufficiency. The considerations on which the greatest dependence is to be placed in the differentiation are given in the subjoined parallel tables:

MITRAL INCOMPETENCY	FUNCTIONAL AND HARMLESS MURMURS
<i>History</i>	
Previous history of rheumatism or other disease causally related.	History of one or other form of anemia, of debility, or of Graves' disease, in many cases.
Frequently there is definite knowledge of rheumatism and organic heart disease, in combination in the same individual.	No such association.
<i>Physical Signs</i>	
<i>Inspection</i> .—Dusky lips, ears, etc.; later wavy pulsation in veins of neck.	Pallor of skin and mucous surfaces common.
<i>Palpation</i> .—Finger-tips placed over apex-beat forcibly lifted. Pulse-tension somewhat lowered and not prolonged. Impulse displaced.	Finger not lifted by the impulse, which often cannot be felt. Impulse not displaced.
<i>Percussion</i> .—Evidence of dilatation of both ventricles.	No change in percussion outline of the heart.
<i>Auscultation</i> .—A systolic apex-murmur (often musical), with characteristic area of transmission. This murmur is often heard posteriorly; pulmonary sound accentuated.	Soft systolic murmur at apex (variable in intensity, rarely transmitted to axilla), usually preceded by or associated with a basic systolic murmur and a venous hum in the veins of the neck. Tachycardia common.

To differentiate *relative* from *organic mitral incompetency* is difficult. It rests upon two points: (a) the character of the murmur, which is softer and shows greater changes in intensity (*e. g.*, being either less pronounced or disappearing if the heart is "whipped up" by digitalis) than that due to valvular lesions; and (b) the antecedent history of the patient. Thus, relative insufficiency of the mitral segments probably exists in patients in the middle period of life, in whom the previous history either furnishes such etiologic factors as chronic gout, syphilis (the latter, however, may also cause chronic valvulitis), or evidences of myocarditis, fatty heart, or anemic conditions; or in persons who exhibit arteriosclerosis or organic disease of the aortic valve and an apex-systolic murmur. Again, if present in chronic *renal* disease, with concurrent symptoms of high arterial tension and of left ventricular hypertrophy—accentuation of the second aortic sound, a mitral systolic murmur—it is to be ascribed to relative insufficiency. On the other hand, if the signs of mitral

regurgitation occur in a younger subject or in one who has been afflicted with acute rheumatism, it is highly probable that the mitral-valve segments are the seat of chronic endocarditis of rheumatic origin. *Compression of the edge of the left lung* by the ventricular systole may produce a spurious murmur. A rare sequel of mitral incompetency is mitral stenosis, owing to the contraction of the mitral orifice.

MITRAL STENOSIS

Definition.—Constriction of the left auriculoventricular orifice due to either thickening or cohesion of the segments. In most cases adhesions of the free borders of the valve or of the chordæ tendineæ obtain. Mitral stenosis is generally followed by insufficiency, and it is also frequently associated with adhesive pericarditis.

Special Pathology and Etiology.—It is to be recollected that the constriction may be almost inappreciable, and yet an uneven, roughened surface be presented, producing a murmur. A high degree of constriction, however, "which is more frequent than is generally supposed" (Elliott), may be encountered. Thus, in the *funnel-shaped* form of mitral stenosis the aperture may be so small as scarcely to admit the passage of a goose-quill. When moderate in degree the tip of the index-finger is admissible; in the *button-hole* form the slit may be so narrow as not to allow an object larger than a shirt-button to pass through it. This form is comparatively rare in children, while the *funnel* variety is common, and is occasionally a congenital condition (possibly hereditary). In adults, however, the funnel-shaped constriction is rare, while the button-hole valve is common; in 62 *postmortem* examinations only 3 showed funnel-form contraction (Hayden and Fagge). Mitral stenosis is, generally, dependent upon a mild or limited endocarditis of rheumatic origin. It is more common in *young adults* and in *children* after the fifth year than in older persons, and a greater incidence is shown in *females*, for the reason that the affections that are causally related to endocarditis are more frequent in females (rheumatism, chorea, tonsillitis). The endocarditis of measles and scarlatina may also lead to narrowing of the mitral orifice, and I quite agree with Osler in the belief that whooping-cough, owing to the great strain that it imposes upon the heart-valves, may be accountable for certain cases. In adults *arteriosclerosis* and *chronic nephritis* may act as causes. The hemorrhagic cases may at times be the immediate effect of an accident.¹ In not a few cases the etiology is obscure, particularly in adult women. Ball-thrombi have been found in the auricle.

Mechanical Influence of the Lesion.—The task of the left auricle is greater than normal, and as a consequence its walls hypertrophy. They may be found to be $\frac{1}{4}$ or even $\frac{1}{2}$ inch (0.6 or 1.2 cm.) in thickness, the normal thickness being only $\frac{3}{20}$ inch (3.7 mm.). Dilatation of the auricle comes on early, since this chamber cannot take on much hypertrophy owing to lack of muscular structure, and in the later stages its walls become extremely thin. For a varying period of time the increased power due to hypertrophy of the left auricle and the increased resistance to the circulation that is the result of the mitral lesion are exactly balanced. At a comparatively early period, however, the auricle can no longer maintain this equilibrium; and then, owing to retardation of the current from the pulmonary veins to the auricle,

¹ See also "Trauma and Heart Disease," by J. C. Wilson, *Jour. Amer. Med. Assoc.*, February 10, 1912, p. 405.

the vascular tension in the lungs and right ventricle is increased. The right ventricle, in seeking to overcome the obstruction, becomes greatly hypertrophied and dilated, and late in the disease tricuspid incompetency supervenes. The hypertrophy of the latter chamber counterbalances the lesion during the period of compensation. For a brief time the left ventricle exhibits no abnormal proportions. Later and at autopsies its cavity is found smaller and its walls thinner than the normal, these conditions being due to its abnormally light labor. The apex of the heart is formed almost exclusively by the enlarged right ventricle. If the left ventricle be hypertrophied, it is owing to coexistence of mitral incompetency.

Symptoms.—The subjective symptoms are scanty. During the period of compensation they may be absent except on going up stairs or on attempting some unusual muscular effort, when *dyspnea* appears. Fragments of fibrinous coagula dislodged from between the muscoli pectinati of the auricle or swept from the valves may give rise to the phenomena of *cerebral embolism* (aphasia and hemiplegia). The same conditions may arise, and in the same way, from recurring endocarditis, to which such patients are specially liable. The patient in well-marked cases presents an *anemic* appearance; a *stitch-like pain* in the apex region is frequently present, and active exertion, by overtaxing the left auricle, induces *cardiac palpitation* and *dyspnea*. Hemoptysis and pulmonary signs are quite common, so common, in fact, that State tuberculosis sanatoria will not admit patients with mitral stenosis unless the tubercle bacilli have been found in the sputum.

After failure of compensation the symptoms referable to the pulmonary system are almost identical with those manifested in mitral incompetency. Owing to the pulmonary engorgement the *dyspnea* is constant, and is increased by exertion. After severe physical exercise, *congestion*, followed by *edema* of the lungs, may supervene, attended by a copious blood-stained, serous *expectoration*. True *hemoptysis* may arise from time to time. The sputum often contains large, mostly oval, nucleated cells showing yellowish-brown pigment ("heart-failure cells"). The increased tension in the pulmonary vessels leads to sclerosis, followed by atheromatous degeneration of their walls, and may result in *pulmonary apoplexy*. Intercurrent *febrile attacks* (due to recurring endocarditis) are common, particularly in the later stages, and are attended with aggravation of the circulatory disturbances. Mitral stenosis differs from mitral incompetency in that *general anasarca* due to venous engorgement is rare, though marked enlargement of the liver and other evidences of portal congestion (including ascites) are commonly present. Mitral stenosis also differs from other cardiac valvular lesions in that it is extremely commonly associated with auricular fibrillation. Boinet, Osler, and others state that paralysis of the left recurrent laryngeal nerve (aphonia) may occur either as the result of compression or traction.

Physical Signs.—*Inspection.*—The apex-beat is diffused, but not displaced downward unless there be excessive enlargement of the right ventricle or associated hypertrophy of the left. There is usually observed pulsation in the second left intercostal space caused by the increased tension of the pulmonary artery and sometimes in the third and fourth, occasioned by the right ventricular hypertrophy; there is also a diffuse impulse along the right border of the sternum. Epigastric pulsation is common. A prominence over the fifth and sixth left costal cartilages and the lower half of the sternum is observed, particularly in children. After failure of compensation the impulse is feeble and undulating, with engorgement and pulsation of the jugular veins.

Palpation discovers a presystolic thrill in a great proportion of cases. In certain instances active physical exertion may render this appreciable, or when

in the recumbent posture on the left side the elevation of the arms may accomplish the same result. It is, however, absent in rare instances before failure of compensation occurs, and more frequently by far the latter event. The thrill usually disappears with the onset of fibrillation of the auricles, though in rare cases it may persist. The systolic shock remains. This fremitus is best felt over the third and fourth (less frequently the fifth) interspaces, just within the nipple, and during expiration. It commences after the second sound (during the diastole) as a purring fremitus, increasing steadily in volume and intensity, and terminates abruptly with the severe shock of the new impulse. The fremitus and systolic shock are pathognomonic, and may be relied upon in the absence of the murmur. The heart's impulse is most forcible over the lower portion of the sternum and along the right border, being due to the enlarged right ventricle; in a smaller proportion of cases, in the third, fourth, and fifth interspaces to the left of the sternum. The radial pulse is small and compressible. An arrhythmia of time, force, and volume is frequently present and is due to auricular fibrillation (*q. v.*).

Percussion shows an extension of heart dulness to the right, frequently 5 cm. (2 inches) beyond the sternal margin, as a result of hypertrophy of the right ventricle, and upward as high as the second rib on either side of the sternum. Increase in the cardiac dulness to the left also occurs not infrequently, and is attributable to excessive enlargement of the right ventricle, though more often of the left ventricle in consequence of associated mitral insufficiency.

Auscultation reveals a rough, presystolic murmur, which may be characterized as churning or rolling, acquiring increased intensity (*crescendo*). It occurs synchronously with the thrill. Its point of greatest pronounciation is just above and about 1 inch within the normal apex-beat. The area of transmission does not exceed a couple of inches in any direction. Griffith, however, has shown that the murmur may be widely transmitted. This murmur sometimes exhibits atypical characters: it may be brief, low-toned, and inconstant. After auricular fibrillation makes its appearance the murmur may absent itself either temporarily or permanently. Lewis says that no murmur precedes the first heart sound when the rest of diastole is free from murmurs.¹ Diastolic murmurs are, however, frequent when the auricle contraction is absent; they vary much in character according to the length of diastole, which in auricular fibrillation varies much from beat to beat. In most cases the clear, accentuated first sound is retained, even though the murmur disappears. Improvement in the muscular power of the heart as the result of judicious treatment may cause the murmur to reappear. For purposes of diagnosis nothing is so vitally important as the timing of the murmur, hence the observer must palpate the heart, and not the radial pulse, while practising auscultation. The finger as well as the ear will thus become sensible of the systolic shock which replaces the cardiac impulse, and it will be noted that the murmur terminates at the same moment. In cases in which the impulse cannot be felt, the finger should be placed over one or other carotid, since here the pulse is practically synchronous with the systole. In most cases the murmur occupies only the latter half of the diastole. In some cases it is purely diastolic, the blood being driven under high pressure in the lesser circulation, from the auricle into the relaxed ventricle, at the beginning of the long pause. Owing to the presence of right ventricle hypertrophy the second pulmonic sound is greatly accentuated, being distinctly audible at the apex, while the second aortic sound is often absent or feeble. Reduplication of the second sound is not rare.

¹ Wiggers, *Circulation in Health and Disease*, Phila., 1915, p. 321.

Secondary Murmurs.—While mitral stenosis may rarely follow mitral incompetency or aortic valve disease, in the vast majority of instances it is a primary affection. Secondary murmurs are not uncommon, however. Among these the bruit of *mitral incompetency* is relatively frequent. After compensation is ruptured the murmur of *tricuspid insufficiency* usually becomes audible at the lower end of the sternum and persists until the end. In so-called *relative mitral stenosis*, associated with primary dilatation of the left ventricle, which holds the orifice open, there occurs also a mitral regurgitant murmur. Hall suggests that relative pulmonary insufficiency may be found in possibly 3 to 5 per cent. of cases of mitral stenosis.

Diagnosis.—The distinctive features of mitral stenosis are: (1) A presystolic thrill at the apex. (2) An increase in the precordial dulness upward and to the right. (3) A murmur which (*a*) has its seat above, yet near, the normal apex-beat; (*b*) is usually localized; (*c*) is presystolic in time, terminating abruptly with the systolic shock (sharp impulse), and (*d*) is rough and vibratory in character. (4) A marked accentuation of the second pulmonic sound.

Differential Diagnosis.—When the murmur of mitral stenosis is very brief, it is difficult to eliminate a *mere roughening* without valvulitis. In the latter condition, however, there is no increase in intensity of the murmurs on exertion or when the arms are uplifted, they are not vibratory in character, and there is no right ventricular hypertrophy. From simple mitral stenosis the lesion of *mitral incompetency* is easily distinguished by its systolic rhythm, greater area of transmission, and by the soft, more blowing character of its murmur. As stated, the majority of the cases of mitral stenosis are associated with mitral incompetency; it is clinically important to recognize the combined presence of these two valvular lesions, and also which lesion predominates in the individual case. The presence of the systolic murmur is distinguishable by its synchronism with the impulse or carotid pulse, and by its area of transmission to the left as far as the axilla. If now the stethoscope be applied just above and to the right of the normal apex, a limited superficial area will be found where a typical presystolic murmur is distinctly heard. Points can also usually be found where a continuous bruit, covering a portion of the period of diastole and the systole, is audible. A rumbling apical sound resembling a presystolic murmur may be heard in pericardial adhesion. Its seat is different and it does not end in sharp systolic shock.

In *aortic regurgitation* the presence of a presystolic thrill and murmur has rarely been recorded, and Fisher, Phear, and others have noted them in simple dilatation ("relative mitral stenosis"). When a purely diastolic murmur is present in the aortic area, indicating aortic regurgitation, the diagnosis of mitral stenosis must be made with due caution.

TRICUSPID INCOMPETENCY

(*Tricuspid Regurgitation*)

Definition.—An imperfect closure of the tricuspid valve, due either to a dilatation of the right ventricle that is secondary to mitral or lung disease, or, less frequently, to an inflammatory shortening of the valves.

Pathology and Etiology.—As a primary disease tricuspid incompetency is rare. It, however, is not uncommonly due to chronic organic changes, though originating in fetal endocarditis. After birth this variety is most common during childhood, and the frequency of occurrence is in inverse ratio to the age. At any period of life, however, chronic affections of the

lungs or organic disease of the left side of the heart may, by augmenting the tension in the right ventricle, produce chronic interstitial changes in the tricuspid segments. These are usually of mild grade. In chronic bronchitis associated with emphysema, and in pulmonary tuberculosis, extensive lesions of these valves are seen rarely, owing to the fact that dilatation of the right ventricle is soon followed by relative insufficiency, and thus the strain is in great part removed from the valves themselves. And yet, according to Byron Bramwell, the tricuspid valve is implicated in 50 per cent. of all cases of acute endocarditis. He suggests that the acute form frequently results in cure because of the relatively diminished right intraventricular tension. In rare instances one of the leaflets has been ruptured by straining. The relative tricuspid insufficiency, produced in a manner analogous to relative mitral insufficiency, is an exceedingly common secondary condition in affections of the lungs and heart that cause hypertrophy and dilatation of the right ventricle (mitral incompetency and stenosis, pulmonary carcinoma, emphysema, pulmonary tuberculosis, sclerosis of the lung).

Physiologic Pathology.—In tricuspid leakage every systole of the right ventricle is accompanied by a reflux of venous blood through the imperfectly closed tricuspid orifice into the auricle, and thence into the veins. This causes venous stasis and visible pulsation, and in this manner the engorged pulmonary circulation is somewhat relieved. An unfavorable consequence, however, of the reflux current from the right ventricle is the lessened blood-supply to the already engorged pulmonary arteries. The hypertrophied and dilated right heart now undergoes further enlargement in the same manner as in the hypertrophy of the left ventricle following mitral incompetency, though to a less extent. In mitral incompetency the right ventricle compensates the mitral lesion after failure of the left auricle, but there can be no such effective compensatory mechanism after failure of the right auricle in tricuspid incompetency, since the right heart is not reinforced by a fellow as is the left. The blood-stream flowing into the right ventricle during diastole, however, is abnormally large, owing to moderately increased venous tension. When the right ventricle fails to maintain the pulmonary circulation, progressive dilatation of its chamber occurs, with a proportionate thinning of its walls, until its dimensions are enormous.

Symptoms.—The general symptoms are those of exaggerated cardiac insufficiency. In most instances the indications of the primary or causal affection must be noted, though these are often more or less screened by the more characteristic features of the disease under consideration. The symptoms of tricuspid incompetency point to passive congestion of the lungs and engorgement of the systemic veins, and have been described in connection with mitral lesions. *Cardiac dropsy* is common, though present in by no means all cases. It is a prominent feature in the cases that are secondary to mitral disease. Frederick Taylor contends that *ascites* is absent frequently because the liver acts as a diverticulum to accommodate the excess of venous blood.

Physical Signs.—*Inspection.*—Systolic venous pulsation, caused by the backward blood-wave from the right ventricle and auricle, is a pathognomonic sign. It is confined to the lower portion of the jugular veins so long as the valve that lies above the jugularis remains closed, but soon this yields, and then the veins seem to pulsate through their entire course. This is best seen when the patient is in the semirecumbent posture, and is most marked in the right side. The venous pulse is presystolic-systolic in time (Leube). The increase in the venous tension, and the slowing of circulation in the capillaries, combine to produce a cyanosis that is more noticeable when the breathing is discontinued temporarily than in ordinary respiration. Tricuspid incompetency may be

shown by pressing on the vein with the finger rather firmly, commencing just above the clavicle and passing upward, thus emptying it of blood. If, now, the right ventricle be capable of producing a return wave sufficiently powerful to overcome the valve in the external jugular, pulsation is seen in the vessel slowly and increasingly until the vein, as far as the point compressed, becomes filled. The vein fills "by jets synchronous with the heart-beat" (Sansom). If an impulse be communicated to the jugulars from the underlying carotid artery, the light pressure upon the vein below does not arrest the pulsation above, as is the case in tricuspid incompetency. A feeble presystolic venous pulse, due to the weaker contraction of the right auricle as compared with that of the right ventricle (*anadicrotic venous pulse*) may occur. The area and seat of the apex-beat vary with the nature of the primary affection; in mitral in-

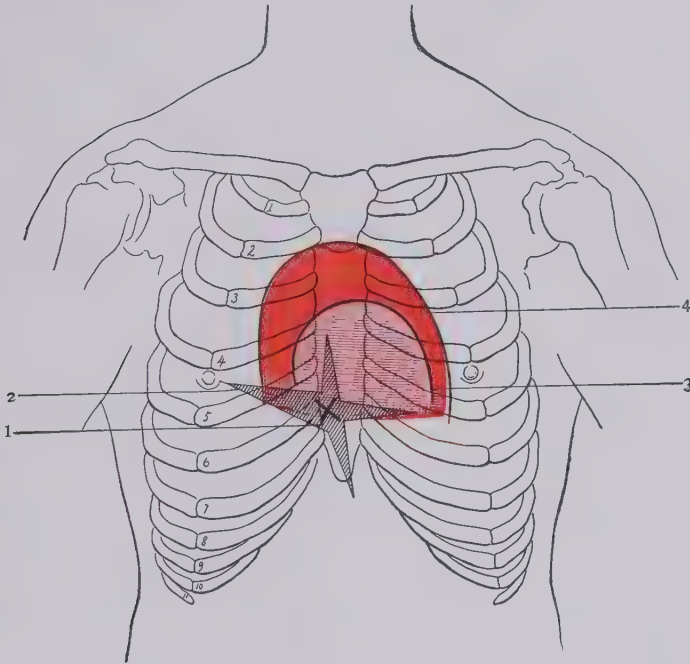

Fig. 50.—1, Seat of greatest pronunciation; 2, chief direction of conveyance; 3, boundary-line of absolute dulness; 4, boundary-line of relative dulness (modified from Sahli).

competency, for example, the beat is displaced to the left and downward, while in uncomplicated mitral stenosis no appreciable displacement occurs. To the right of the sternum an undulatory pulsation is seen, due to contraction of the right auricle and ventricle, but this is not characteristic, since it may take place in simple mitral stenosis without tricuspid regurgitation. Epigastric pulsation is almost invariably observed.

Palpation detects the heaving impulse of the right ventricle in the upper epigastric region. Rhythmic expansile pulsation of the veins of the liver is quite diagnostic and is usually detectable. To obtain this sign the patient should lie on the back with the arms raised, and the examiner should place the palm of his left hand over the right midaxillary region, and that of the right hand over the upper abdominal region. He will thus be enabled to feel an expansile pulsation of the liver synchronous with the ventricular systole.

This is to be carefully distinguished from mere systolic depression of the organ due to the impulse of an enlarged right ventricle, transmitted through the diaphragm and left lobe of the liver to the epigastrium.

Popoff and others have noted an inequality in the radial pulses in tricuspid regurgitation. This is probably due to the pressure of an enlarged auricle. The radial pulse is small and often rapid. The blood-pressure in the arterial tree is low.

Percussion.—The extent and form of precordial dulness are variable according to the nature of the causative disease, but a dulness extending far beyond the right edge of the sternum is especially characteristic.

Auscultation.—A systolic murmur having its seat of greatest intensity at the base of the ensiform cartilage (Fig. 50) is almost constantly audible. The area in which it is best heard varies according to the intensity of the murmur. Lowering the patient's head, while in the recumbent posture, causes murmurs to become evident which were not previously heard (Stern's sign). It is clearly conveyed to the left 1 inch beyond the left sternal margin, and to the right and upward for an equal distance beyond the limit of cardiac dulness. It is soft in character, short, and often faint. If the heart be weak, it may be absent. Additional murmurs, due to primary lesions, are often heard, and usually at other orifices. The second pulmonic sound is not much accentuated.

Diagnosis.—I believe that the most valuable symptom for diagnosis is the venous pulse, whether observed clearly in the neck or determined positively by bimanual palpation of the liver. Neumann holds that a slight venous pulse, visible only on retracting the head, excludes tricuspid insufficiency. The murmur is generally audible. Relative-incompetence distinguishes itself from that due to valvulitis by greater extension of dulness to the right, and by disappearance of the positive venous pulse and murmur, with restoration of compensation. The **differential diagnosis** between mitral and tricuspid regurgitation is easy when either exists alone, if it be remembered that the seat of greatest pronunciation, the area of transmission, and the acoustic character of the respective murmurs are widely different. But it is extremely difficult to discern a faint tricuspid murmur when it develops secondarily to the murmur of mitral incompetency. If a careful observation of the murmur fails to establish the diagnosis of tricuspid insufficiency, absolute reliance should, in my opinion, be placed upon the venous pulse when present. On the other hand, with characteristic symptoms of tricuspid insufficiency, the diagnosis of simultaneous mitral insufficiency is assured if the systolic murmur is heard dorsally.

TRICUSPID STENOSIS

This is a rare condition, occurring as a congenital and an acquired disease with about equal frequency. As a primary, independent disease tricuspid stenosis is very rare, being usually seen in association with organic disease of the left side of the heart. The lesions of mitral and tricuspid stenosis are observed to be combined most frequently, while those of tricuspid stenosis and aortic insufficiency coexist less frequently. The morbid changes are practically identical with those of mitral stenosis, the right auricle becoming dilated, and this being followed by general venous stasis. The right ventricle, however, is usually hypertrophied, owing to the obstruction in the pulmonary circulation that results from the combined valvular deficiencies.

Special Etiology.—The fact that mitral and tricuspid stenosis frequently

have a common cause, acting concurrently, can scarcely be doubted. Judson Daland and E. L. McDaniel, who have collected 186 cases of associated mitral and tricuspid stenosis, believe that most of them occur in hearts overdistended as the result of attempts at compensation, after acute endocarditis and simple mitral disease. *Rheumatic antecedents* are furnished by the history in from 30 to 40 per cent. of the cases of tricuspid stenosis. As in mitral stenosis, *sex* is a potent factor, the statistics of Bedford, Fenwick, Herrick, and of Leudet (which embrace a total of 160 cases) showing a ratio of 5 to 1 in favor of the female sex.

Symptoms.—These are those of the combined affections—venous stasis, marked polycythemia, and dropsy, particularly hydrothorax.

Physical Signs.—*Inspection* may reveal a feeble venous pulse in the jugulars, due to right auricular systole, hence presystolic in time. *Palpation* may detect a presystolic thrill over the body of the right ventricle. *Percussion* may reveal the enlarged right auricle. *Auscultation* gives usually a presystolic rolling murmur, which is best heard over the lower sternum and along its right border. The above physical signs are to be relied upon in *uncombined* cases, which are exceedingly rare. On the contrary, it is difficult in the extreme to differentiate the signs of tricuspid stenosis from those of the lesions with which it is almost uniformly associated—viz., mitral stenosis and aortic insufficiency.

PULMONARY INCOMPETENCY

(*Pulmonary Regurgitation*)

This is an exceedingly rare complaint that results from acute (malignant) or chronic endocarditis after birth; it is also rarely due to a congenital malformation. In the latter form union of two of the segments is often observed; in the former, the usual sclerotic processes, with the occasional adhesion of one or more segments with the pulmonary artery wall, may be noted. The effect of the lesion is to cause hypertrophy and dilatation of the right ventricle. Cases have been reported by Allyn, Gibson, and others. The pulmonary symptoms, with cyanosis, are marked. The *physical signs* furnish no diagnostic characteristics. There is developed a diastolic murmur which is most audible in the second left interspace, and is transmitted to the lower sternal region, simulating the murmur of aortic regurgitation. The water-hammer pulse and marked hypertrophic dilatation of the left ventricle are present in the latter complaint, however, and are absent in pulmonary regurgitation. In pulmonary insufficiency, on the other hand, hypertrophy and dilatation of the right ventricle ensue. Preble reports a case of *relative insufficiency* of the pulmonary cusps (the so-called Graham Steele murmur); at the autopsy aortic and mitral insufficiency were also found.

PULMONARY STENOSIS

A quite frequent form of *congenital malformation* of the heart is the narrowing of the pulmonary orifice. In the rarest cases it is of *postnatal* date, and may result in induration, contraction, and fusion of the segments. In one of Osler's cases the orifice "was only 2 mm. in diameter, with vegetations of acute endocarditis on the segments." I saw one case in which the pulmonary

artery near the valve was contracted to one-half its normal caliber. *Myocarditis* with resulting contraction of the conus arteriosus may cause pulmonary stenosis, and some of the cases that originate during adolescence and later in life are due to *atheromatous* change, while others possibly are the result of *chronic endocarditis*, direct violence, and *ulcerative endocarditis*. The lesion is compensated by a hypertrophy of the right ventricle, following which dilatation and tricuspid incompetency may appear.

Symptoms.—*Cyanosis* and *distention of the systemic veins* and, later, *dropsy* are observed.

Physical Signs.—A *systolic thrill* may be felt at times over the base. There is considerable enlargement of the right ventricle, as elicited by *percussion* and *palpation*, and a *systolic murmur* is audible, its greatest distinctness being, as a rule, in the third left space near the sternum. It is *harsh*, superficial, and transmitted a short distance upward and to the left. Occasionally this murmur is heard best at the aortic valve, but it is never conveyed to the vessels of the neck, and hence is easily distinguished from the aortic systolic murmur. Its harsh character and loudness would serve to obviate confusion with *functional* or *anemic murmurs* that are sometimes heard here. The pulmonic second sound is weak, and, not rarely, there is a diastolic murmur of the same character, indicating *pulmonary regurgitation*. Broadbent asserts that a *temporary* systolic murmur due to severe exertion may be observed, and I have noted a systolic murmur in the pulmonary area in young adults of remarkably vigorous build and unusual endurance. A careful review of the literature indicates that stenosis of the pulmonary artery predisposes to lung tuberculosis. The conditions are not favorable to healthy nutritive processes, especially of the lungs (Anders¹).

COMBINED FORMS OF CARDIAC DISEASES

It may be asserted safely that in more than one-half of all cases combined lesions or murmurs are exhibited before the fatal termination. As already stated, stenosis of an orifice when due to valvular disease is associated with incompetency of the corresponding valve. Thus aortic stenosis is constantly combined with or followed by aortic incompetency, and in like manner mitral stenosis by mitral incompetency. The association may also have reference to lesions at two or more different valves. In the table of F. J. Smith the relative frequency of the chief murmurs found in combination is as follows:

Aortic diastolic and systolic and mitral systolic,	16.55 per cent.
Aortic stenosis and mitral stenosis,	6.12 "
Aortic diastolic and mitral systolic (common in children),	5.21 "
Aortic diastolic and systolic and mitral presystolic and systolic,	3.77 "

When two lesions coexist as the same valve, the one may compensate, in part at least, for the other, as, for example, in the case of aortic stenosis in association with aortic regurgitation. Here the stenotic deficiency lessens the reflux current from the aorta into the left ventricle during the diastole; hence the latter receives a correspondingly diminished amount of blood. During the contraction of the ventricle the distending force in the aorta is diminished, both on account of the narrowing at the aortic orifice and the relatively lessened contents of the hypertrophied ventricle. Similarly, in dominating mitral incompetency an associated mitral stenosis by lowering the strength of the

¹ *Amer. Jour. Med. Sci.*, January, 1902.

regurgitant current renders the conditions more favorable. Relative insufficiency at the mitral valve, following aortic insufficiency, may prove salutary by preventing overdistention of the left ventricle, and also the overfilling of the arterial tree and the possible rupture of a blood-vessel. On the other hand, when mitral incompetency is secondary to aortic stenosis, the latter defect may hasten the unfavorable tendencies in the former.

Relative tricuspid insufficiency, secondary to mitral disease, usually results in the development of a serious impediment to the systemic venous circulation, and if it occur in the course of diseases of the aortic cusps, an early fatal termination is reached. In advanced mitral disease a slight leakage at the tricuspid valve may be the means of obviating disastrous consequences to the right ventricle in case of undue strain.

Physical Signs.—These are confusing, but a systematic analysis often leads to the correct inference. That one of the valvular lesions predominates over all others is a fact of paramount importance for the solution of these cases. The chief lesions can usually be determined by noting the *seat*, the area of transmission, and the character of the most pronounced murmur. More important still is the *correct timing* of any murmurs that may be audible. When a murmur occupies both the aortic and mitral areas the student will note two points of maximum intensity, and that each grows weaker as the stethoscope is moved toward the midprecordial region. The secondary alterations in the heart frequently coincide with the predominating murmur, and observers should recollect that mitral murmurs are often secondary to aortic, and that tricuspid murmurs point to accompanying mitral disease. In children, however, rheumatic endocarditis often affects both valves on the left side of the heart. Unquestionably, a single observation of these cases, however carefully made, is often profitless.

Complications of Valvular Disease.—Most of these have already been spoken of at sufficient length, but to restate them collectively in this connection may prove useful to the student and physician. They are: (1) Acute endocarditis (including the ulcerative form); (2) acute pericarditis; (3) pleurisy; (4) pneumonia; (5) nephritis, followed by uremia; (6) local or general arterial sclerosis; (7) chronic gastric or intestinal catarrh with intercurrent acute attacks; (8) embolic processes; (9) angina pectoris; (10) edema of the lungs; (11) hysteria, neurasthenia, epilepsy, and insanity; (12) rupture of the skin of the extremities in consequence of excessive edema, with erysipelatous inflammation; (13) febrile paroxysms, accompanied not rarely by synovitis, occur at varying intervals of time, and are due to various causes, as rheumatism, simple, acute, and ulcerative endocarditis, and pericarditis.

Course and Duration.—When valvular disease consists in rupture of a segment the course is brief and usually proves quickly fatal. Apart from these exceptional instances the duration is measured by months, or more often by years or even decades. Statements applicable to all cases cannot be made, however, owing to the wide differences in different cases. Among the circumstances affecting the duration I would mention in particular the patient's mode of life, the hygienic conditions under which he lives, his occupation, mental condition, and the severity of the morbid processes. Every experienced physician has doubtless met with a small class of cases that have terminated fatally in from six months to a year, having developed in that period all of the serious phenomena and complications of the more chronic forms of organic heart disease. In the preponderating proportion of cases, however, the course is exceedingly slow, and often cases have existed many years before they have finally been recognized. In numerous instances the patient follows his usual vocation, which may even be laborious, for years, and without discomfort.

In other cases the symptoms, as dyspnea on exertion, are so slight as not to excite suspicion. Facts such as these render it obvious that while the period of compensation is long, its exact limits are indeterminable.

The *progress after failure of compensation* is more definitely known, since frequent opportunities for observation are afforded. At this time the cases also exhibit wide differences in duration; in my own experience they have varied from two or three months to as many years (rarely even longer), depending much on the patient's mode of living. The course may be shortened by severe external injury, intercurrent acute illness (especially febrile disease), vicious habits, straining efforts, and the like.

Prognosis.—The detection of a cardiac murmur should not alone lead to a gloomy prognosis. Says Osler: "With the apex beat in the normal situation and regular in rhythm, the auscultatory phenomena may be practically disregarded." Mackenzie rightly holds that the condition of the heart muscle is the most important criterion upon which to base the prognosis. Individual cases require separate and careful consideration. It is well not to advance positive assertions until all the circumstances that may influence the prognosis of any given instance have been well weighed. Observation of a case for some weeks and months enables the physician to speak with greater confidence and knowledge concerning the probable outcome. A high blood-pressure is an unfavorable sign, especially in cases in which chronic interstitial nephritis is associated (Satterthwaite). Prior to the occurrence of disturbances of compensation the prognosis is measurably favorable. After this pivotal event the prognosis as to life becomes wholly unfavorable in direct proportion to the extent of the degenerative changes of the myocardium. Disturbances of compensation that are attended with marked arrhythmia, urgent dyspnea, and general dropsy may admit of complete relief. Later, restoration of the balance of forces becomes only partial, and finally the above-mentioned symptoms become more pronounced; Cheyne-Stokes' breathing may then develop, and after a prolonged and distressing struggle for breath the patient succumbs. Death may also occur suddenly from ventricular fibrillation. Among ominous and yet common *complications* and intercurrent affections may be cited again extensive edema of the lungs, pneumonia, marked arteriosclerosis, embolic processes, ulcerative endocarditis, acute endocarditis, obstinate gastritis, and nephritis. On the contrary, *favorable indications* are sound general health, good external conditions (absence of poverty, hunger, etc.), strong and regular action of the heart, evidences of heart muscle which is functionally unimpaired, absence of arteriosclerosis, of excessive hypertrophy, of syphilis (unless recognized early), and of rheumatic antecedents, as well as any vices of life. *Age* influences the prognosis to some extent. In children under ten years the lesions are usually somewhat more rapidly progressive than in adults, and the compensatory hypertrophy is developed with corresponding rapidity; hence the period of failing compensation is reached earlier. This may be said to be a broad general rule, and I have found that it is one to which there are many exceptions. Among other reasons for the more gloomy prospect when heart disease occurs in young children are the following: the mitral valve is generally implicated, the liability to rheumatic interurrences is great, and there is a greater tendency to overtax the reserve cardiac power by violent forms of exercise. After the twelfth year the prognosis becomes more favorable. *Sex* is also a modifying prognostic factor, women bearing valvular lesions better than men, apart from the influence of childbearing, though even this is an influence the significance of which has been greatly magnified by many writers. To explain the more favorable outlook in women we have two main facts—viz., a less laborious as well as a more quiet life, and a diminished liability to arterio-

sclerosis and involvement of the coronary vessels. The particular valve involved has some influence on the prognosis.

Aortic regurgitation gives a fairly good prognosis in those cases that begin in early adult life, and in which the second sound in the neck is not abolished, granting that the patient regulates wisely his manner of living. A long, loud murmur indicates a strong heart with slight leakage. When the lesion is due to acute endocarditis, the prospect of life is better than when it originates in degenerative changes. A chief danger arises from associated arteriosclerosis—a frequent occurrence, particularly in advanced life—and from implication of the coronary arteries. Much depends upon the condition of the latter vessels. When their lumen is narrowed, starvation of the heart muscle quickly ensues, followed by myositic degeneration. Blocking of one of the branches of the coronary artery is the most frequent cause of sudden death in this affection. After failure of compensation, the prognosis is less satisfactory by far in aortic regurgitation than in mitral regurgitation, since restoration of compensation is not as readily accomplished in the former as in the latter variety. Taylor¹ claims that the gravity of the lesion, which is always serious, is lessened by the occurrence of ensuing mitral incompetence. Aortic regurgitation stands first among valvular affections in the order of gravity (Broadbent). In *aortic stenosis* favorable predictions are warrantable when the disease is uncomplicated. When the left ventricle gives way the condition is serious. Osler states that the rheumatic form of early life is more serious than the late sclerotic variety. The size of the radial artery is proportionate to the size of the blood-stream, hence indicative of the degree of stenosis.

Mitral regurgitation, when a primary lesion, is propitious, except in the very young, and not infrequently the progress of the morbid process is apparently arrested. In a considerable proportion of cases the disease does not materially shorten the life of the sufferer. In a larger percentage, however, there is special liability to a renewal of the causative affections (*e. g.*, rheumatism) and to pulmonary conditions of serious import, producing exacerbations and permanent aggravations of the disease. The gravity of these intercurrent complaints is also increased by the existence of the cardiac lesion. If a good first sound is audible as well as the murmur, it is of good prognostic significance. Failure of compensation at once renders the prognosis decidedly unfavorable. In *mitral stenosis* compensation of the right heart fails somewhat earlier than in mitral insufficiency, and hence the accidents and conditions referable to the lung (diffuse pulmonary apoplexy, edema) are not so long delayed as in the latter disease. The greater tendency to fibrillation of the auricle that occurs in mitral stenosis as contrasted with other valvular lesions also causes the heart muscle to become functionally inefficient sooner than it would did not this complication occur. In my experience mitral stenosis is better borne by women than by men, and better during adolescence and early adult life than during more advanced years. The congenital forms are comparatively benign. Mitral stenosis causes sudden death more frequently than any other form of organic disease of the heart except aortic regurgitation. *Tricuspid incompetency*, whether secondary to disease of the lung or of the left side of the heart, is grave; it is extremely serious when it arises in the course of aortic incompetency. It is usually indicative of dilatation following hypertrophy of the right ventricle. Compensatory hypertrophy, however, can be re-established repeatedly.

Treatment.—This falls naturally into three subdivisions: (1) Prophylaxis; (2) management during the stage of compensation; (3) treatment of the stage of non-compensation.

¹ *The Lancet*, London, July 15, 1916, p. 96.

(1) **Prophylaxis.**—The statistics of Sibson show that complete rest and protection of the surface during an attack of acute articular rheumatism lessen the average percentage of cases in which acute endocarditis develops. When the latter complication occurs in acute rheumatism the patient should keep to his bed for some time after all rheumatic symptoms have disappeared (two to six weeks) or until the improvement in the cardiac condition has ceased absolutely. This precautionary measure will often lessen the extent of the ensuing chronic endocarditis, and also increase the proportion of perfect recoveries. When the physician is cognizant of hereditary predisposition to organic heart disease, or has to deal with the alcoholic habit, he can frequently, by timely advice and hygienic suggestions, direct his patient to adopt measures that will obviate the occurrence of valvular disease. Systematic treatment of syphilis would greatly lessen the incidence of valve disease. All persons predisposed by heredity or otherwise should be told of the probable effect of muscular strain (*e. g.*, competitive sports), alcohol, and other exciting factors; too often, however, when he first sees his patient the physician is confronted by an incurable malady.

(2) **Management During the Stage of Compensation.**—Three main objects are to be accomplished: (*a*) The avoidance of every agency that tends to aggravate or maintain the lesion or lesions. Under this head the detection and removal of all causal factors is imperative. Thus, if the patient's vocation entails undue muscular effort, it must be abandoned; violent exercise, as running up flights of stairs, heavy lifting, or straining at stool, is dangerous and must be prohibited. If alcohol has been a factor, it must be discontinued; if syphilis, it must be treated specifically. A gouty taint must be overcome as far as possible by special measures. Fatigue and exposure must be avoided, particularly if the patient be young. Emotional excitement and mental overexertion injuriously affect the cardiac lesion; therefore tranquillity of mind should be insisted upon, though moderate and systematic mental exercise has no risks for the patient. In the case of children at school careful supervision of their studies as well as of their recreative exercises is essential. Fright and sudden emotion must be avoided if possible. The use of tea, coffee, and tobacco should be rigidly prohibited. In mitral disease bronchitis is to be especially guarded against.

(*b*) The diet of the patient demands careful regulation. Only a moderate amount of food, composed for the most part of readily digested albuminous articles (milk, eggs, light forms of meats), green vegetables and stewed fruits, is to be taken, since overloading the stomach will disturb the action of the heart; particularly is this true at night. The carbohydrates may be allowed, but only in limited quantities, since they are apt to decompose and form gases that distend the stomach and intestines. The coarser and more indigestible food-stuffs should also be avoided. The amount of liquids taken should not exceed the actual requirements of the patient, inasmuch as overfilling of the blood-vessel system increases the work of the already overburdened cardiac forces. Alcoholic beverages should not be used, as a rule; but if the patient has been moderate in the use of alcohol, and particularly if he be advanced in years, light wines may be allowed in small quantities to aid digestion.

(*c*) *Carefully regulated exercise* is beneficial, but it must be gentle and should be taken out-of-doors. A good general muscular development is an aid of no mean value to the conservative powers of the heart. Oertel, with a view to assisting the compensatory forces of the heart, has recommended graduated physical exercise; he advises that patients be instructed first to ascend low elevations, and with increased endurance, mountains of a considerable height, the object being to bring about full compensation. This method, however, has been

found to be inapplicable to a large percentage of cases. Cardiac distress, palpitation, and dyspnea are complained of by this large group of patients if other than the gentlest forms of exercise be undertaken. With respect to exercise, then, the sensations and experiences of each patient must be consulted before the physician can advise judiciously. Woolens should be worn next to the skin during both the warm and cold seasons. The skin should be kept clean by daily sponge-baths, followed by friction of the surface. Thus the nutrition will be improved and the liability to intercurrent attacks of bronchitis lessened. The bowels should be moved each day, and usually the use of stewed fruits suffices to accomplish this end; if not, salines, must be brought into requisition. In winter a warm climate may prove advantageous, though long journeys are often ill borne, owing to the fatigue induced thereby. If the patient be anemic or his nutrition is notably impaired, a suitable change of air,¹ or the use of hematinics, arsenic, small doses of mercury, and cod-liver oil, is to be recommended. Digitalis should not be employed when compensation can be preserved in other ways. We should train the heart up to the amount of work required of it (Brunton).

(3) **Treatment of the Stage of Non-compensation.**—The principal object to be kept in view in this stage is the reinvigoration of the exhausted cardiac muscle, and thus to relieve the impeded circulation. *Sudden death* may, though rarely, occur from the blocking of a branch of the coronary artery or from acute dilatation. Failure of compensation, however, *begins gradually* as a rule, the condition often existing without marked or characteristic symptoms; but its early recognition is important from the standpoint of therapy. Increased dyspnea on exertion, and nocturnal seizures of shortness of breath and irregular action of the heart (*arrhythmia*) are among the earliest clinical features. The latter symptom may have been present before, particularly during active exercise in mitral disease, but is now more marked, and may be constant. The patient's nutrition often suffers, and he is pale and rather feeble. Absolute quiet, liberal feeding with suitable food, and iron may in a little while restore the impaired cardiac tone. If this treatment fails, a small dose of digitalis should be exhibited (5 minims—0.3—of the tincture three times daily). *Decided indications* of lost compensation are marked dyspnea and arrhythmia; the canter rhythm; and cyanosis, with or without the presence of dropsy. (a) *Absolute rest in bed.* This diminishes greatly the work of the heart, and thus enables it to regain largely its former vigor. Rest joined with massage, careful yet liberal feeding and attention to the bowels will often restore disturbed compensation in from one to two weeks. In a considerable number of cases treated at the Medico-Chirurgical Hospital this method succeeded admirably.

(b) *Cardiac stimulants and tonics.* Of these the most important is digitalis. By stimulating the pneumogastric, by causing the systole to be more complete and the period of diastole to be lengthened (prolonged conduction time, partial heart-block), thus increasing the blood-supply to the heart muscle, digitalis becomes an invaluable aid to the nutrition of the cardiac muscles. As a result of the use of this drug the tissue calls upon the cardiac forces from the outlying portions of the body are satisfied and the reserve energies of the heart muscles are maintained.

In *mitral disease* the influence of digitalis is most beneficial, the pulse becoming slower, of better tension and more regular, while the urine increases in amount. In mitral incompetency its good effects are ascribable in part to the powerful contractions of the left ventricle, whereby the blood-stream from the

¹ Observation and experience have confirmed my belief that sea-air during the warm season and high altitudes at all times are injurious in their effects in valvular disease of the heart.

ventricle to the aorta is greatly increased. On the contrary, the patient's condition is occasionally aggravated by the drug, because "the leak is increased as much as the normal flow" (Hare). Digitalis exercises its most beneficial influence by rendering the systole of the right ventricle more energetic, the blood-pressure being raised in the pulmonary circuit and left auricle; this fills the left ventricle better during diastole and "resists reflux through the mitral orifice in the systole" (Broadbent). In mitral stenosis digitalis, by lengthening the period of diastole, allows time for the blood to pass from the auricle through the narrowed orifice into the ventricle. It is in auricular fibrillation that accompanies mitral stenosis that digitalis acts almost as a specific. Toxic effects may sometimes result from digitalis, the first indication being nausea and vomiting, signals that show that the drug should be temporarily stopped. If persisted in, heart-block occurs with marked slowing of the pulse as the most evident clinical manifestation. Under these circumstances the drug should be discontinued.

In *aortic regurgitation* digitalis exercises a beneficial effect in cases dependent on chronic valvulitis: the theoretic view, however, that by prolonging the diastole digitalis causes overfilling of the left ventricle rests on too slender a foundation to be regarded as a valid objection to its use. It may, however, produce excessive hypertrophy, in which case it should be withheld. High tension in cases of failing heart is benefited by digitalis, which lowers the pressure as a result of increased elimination and more efficient circulation (Norris). Digitalis is also powerless and probably harmful in proportion to the extent of fatty and fibroid degeneration of the myocardium. When secondary dilatation comes on in aortic stenosis, digitalis is needed to increase left ventricular power. The dose is to be calculated according to the degree of cardiac exhaustion. When tricuspid incompetency is secondary to mitral disease, striking results are obtained from the use of digitalis (*supra*); but when it exists alone—*e. g.*, following emphysema or cirrhosis of the lung—digitalis often fails. The cardiac contractions, if they have previously been irregular, may become regular, but the precordial distress will often be increased, while the circulatory disturbance, as evidenced by the objective signs, will remain unrelieved. It is important to give sufficiently large doses of digitalis—15 minims (1.0 c.c.) of a potent preparation of the tincture should be given four times a day for four or five days or until nausea occurs. The infusion, if freshly made from a good leaf, is also valuable in doses of ʒss (15.0) q. d. The tincture and the infusion are alike in their properties of increasing cardiac tone, promoting diuresis, raising blood-pressure, and so on, but are cumulative and slow in action. For prompt effect digipuratum solution (gr. iss—0.1) may be given intramuscularly. Caffein and sodium salicylate in conjunction may be combined with the digitalis to promote diuresis. Quantitative estimations of the urine should be made during the use of the drug, and if the effect be good, the daily amount will often be greatly increased; if bad, there will be a diminution rather than an increase in the amount. There are not a few patients in whom the symptoms of commencing failure of compensation recur as soon as the drug is discontinued. To such digitalis may be administered continuously or until toxic symptoms are manifested. With this exception, it should be a cardinal rule to discontinue the digitalis when the symptoms of disturbed circulation have vanished. When it fails of its effect or is not well borne, and when as often happens, the arrhythmia is not favorably influenced by it, the physician is compelled to resort to other stimulants. These are numerous, and, while their effects are not comparable to those of digitalis in every respect, some of them seem to meet certain indications that are not met by this drug. Among the more important are nitroglycerin, strophanthus, strychnin, cocain, spartein,

and caffein. Nitroglycerin in small doses is at the same time a stimulant and an arterial relaxant, and hence is more often useful in aortic than in mitral valvular disease. In larger doses, when left ventricular hypertrophy is excessive, as may occur when general arteriosclerosis is associated with aortic regurgitation and also (though rarely) aortic stenosis, it is highly useful, widening the blood-paths and causing less powerful contractions of the heart. Strophanthus should not be employed in instances in which digitalis must be interrupted on account of toxic manifestations, since the action of these two remedies is very similar. It may be used if digitalis is not well borne. The tincture is usually employed, the dose (varying with the indications of each case) being from 4 to 10 minims (0.2-0.6) every three or four hours, and in controlling the irregularity or intermittency of cardiac action it is sometimes better in its influence than digitalis. Many cases of marked arrhythmia will not yield to either when but one is given; and in such I have occasionally obtained good results from digitalis and strophanthus in combination. It should be stated that, rarely, strophanthus, like digitalis, does harm rather than good, being sometimes badly borne by the stomach. Under these circumstances I have employed the following combination:

R. Strychninæ sulphatis, gr. $\frac{1}{3}$ (0.02);
 Sparteinæ sulphatis, gr. iij (0.20);
 Caffeinæ citratæ, gr. xxx (2.00);
 Sacch. latis, gr. xxx (1.30).

M. et ft. cap. No. xij.

Sig. One every three or four hours.

The above prescription is not only a good heart stimulant, but also a good diuretic. Caffein citrate is superior as a diuretic. Spartein is a potent diuretic and heart stimulant in doses of gr. $\frac{1}{6}$ to $\frac{1}{2}$ (0.01-0.032) every four to six hours, and is especially serviceable when dropsy as a symptom and nephritis as a complication exist. Strychnin, given hypodermically in full dose, gr. $\frac{1}{30}$ to $\frac{1}{15}$ (0.002-0.004), is an efficient stimulant. Newburg¹ and others have shown that strychnin is valueless as a heart stimulant *per se*, but it acts reflexly, increasing the stimulability of the vasomotor system and improving generally the patient's condition. It should be employed in this manner in sudden failure of heart power. Given in doses of average size its effects in chronic valvular disease are not striking. Atropin may be advantageously combined with it. Sugar by the mouth, 1 to 6 ounces, is recommended by Dr. Goulston in failing heart. It has also been given per rectum. In both forms of administration it supposedly supplies ready nutrition to the myocardium.

When the indications are urgent and the above agents are not available, diffusible stimulants, as ether or ammonium, may be used until more suitable remedies can take effect. A single dose of strophanthin (gr. $\frac{1}{60}$ to $\frac{1}{20}$) may be used intravenously when there is urgent need for cardiac stimulation, or digipuratum as well. Cocain simulates strychnin in its action. The dose is gr. $\frac{1}{4}$ (0.016) every four hours, and the drug may be given with digitalis in pill form. There are two rapid ways of relieving the right heart:

(a) *Venesection*.—When the right heart is overdistended, as shown by its very feeble efforts at contraction, and the whole venous system is intensely engorged, as shown by marked cyanosis and orthopnea, bleeding directly from a vein is not only warrantable, but often imperatively demanded in order to save life. From 16 to 30 ounces (480.0-900.0) may be removed safely, and the heart's action will almost immediately be observed to grow stronger and

¹ *Amer. Jour. Med. Sci.*, 1915, cxlix, 696.

more regular, and the pulse fuller and of better tension. As before intimated, the form of dilatation of the right ventricle that follows emphysema is disinclined to yield to digitalis. In such instances, following the suggestion of Osler, I have obtained brilliant results from free bleedings.

(b) *Depletion by purgation* affords less pronounced relief to the heart, though it is of the greatest value in cases in which a moderate grade of cyanosis and dropsy exist. As in the case of venesection, a feeble, irregular pulse is not a contraindication to the use of purgatives, since the latter remove directly a considerable portion of the heart's burden. The purgative to be used will vary with different cases. I select at the outset Rochelle or Epsom salts, employing them after the method of Matthew Hay—*i. e.* from 1 to 2 ounces (30.0–60.0) of Rochelle or 1 to 1½ ounces (30.0–45.0) of Epsom salts, in concentrated solution, to be given from a half to one hour before breakfast. Watery evacuations (three to six in number daily) usually follow the administration of the saline; but, unfortunately, one meets with many patients in whom it produces symptoms of marked catarrhal irritation. Next to salines, the most satisfactory results have been obtained from the use of elaterium; I often combine this with podophyllin and belladonna. I have never seen good results from the use of mercurials when the object has been to procure venous depletion, but they are of service in dropsy, and particularly in ascites.

Later, systemic tonics are often demanded by the *anemia* and other constitutional indications, and here iron and quinin should be joined with strychnin. Unquestionably, the value of iron in full doses as an aid in the completion of the work of restoring broken compensation has been and is still scarcely appreciated by the profession at large. When iron disagrees, arsenic may be given instead. In the treatment of syphilitic disease of the aortic segments, salvarsan may be employed; but it should be given in very minute initial doses and increased with great caution. In many cases of failure of compensation the restoration of the balance of the cardiosystemic circulation can be greatly assisted by depleting the overfilled venous system.

Schott of Nauheim has introduced a special treatment by baths and resistance movements that is applicable to most forms of valvular disease, simple dilatation, and nervous affections of the organ. The beneficial effects are principally attributable to the salt and the carbon dioxid, which act as cutaneous stimulants. Greene regards the warmth and moisture as the important features. Twenty-one baths are given in one month, dropping one every fifth, fourth, third, and second days. The water contains sodium chlorid, calcium chlorid, and carbon dioxid, and the temperature ranges from 82° to 95° F. (27.7°–35° C.). The first bath lasts seven or eight minutes; the time is then gradually lengthened, the temperature lowered, and the carbon dioxid increased. After the bath the patient is rubbed and allowed to rest for an hour.

Artificial Nauheim baths are successfully employed in certain American hospitals at the present time. They are prepared as follows: 5 pounds of sodium chlorid and 8 ounces of calcium chlorid are dissolved in one-half bath (30 gals.—114 liters), the temperature of the water being 95° F. (35° C.). In a few days the bath is charged with carbon dioxid by adding sodium bicarbonate (1 lb.—453.6) and HCl (½ lb.—226.8), the latter just before the bath is taken. The effects are to lower the pulse-rate, to decrease the size of the heart, to stimulate the nerves, and, indirectly, the cardiac nutrition. There is also a tendency toward improvement of the nutritive processes and an increase of the urine.

Gentle resistance exercises (consisting of all the more reasonable movements that a person naturally makes, and resisted by an attendant) form an important element of the treatment, since they tend to stimulate the muscles and nerves and propel the blood from the congested veins. The Nauheim

treatment is not suitable in aortic regurgitation, aneurysm, advanced arteriosclerosis, marked dropsy, or fatty degeneration of the heart, although the movements alone are beneficial in these conditions and may be employed without the baths.

Individual symptoms frequently demand special treatment.

(1) *Dyspnea and Orthopnea*.—When these phenomena are caused by engorgement of the pulmonary vessels, the cardiac stimulants above detailed usually afford relief. Frequently the patient cannot lie down, in which case a suitable bed-rest often gives immediate comfort and support. For the severe attacks of nocturnal dyspnea (amounting sometimes to orthopnea), particularly when accompanied by cardiac palpitation, the subjoined formula has proved itself of great benefit:

R. Sodii bromidi, 3j (4.0);
Tinct. opii deod., f3j (4.0);
Aquæ menth. pip., q. s. ad f3j (30.0).—M.
Sig. Two teaspoonfuls in water when necessary.

In the late stages of heart disease morphin, given hypodermically, is to be preferred in combating this symptom, and is entirely free from the usual objections to the habitual use of the remedy. Its influence for good is inestimable. Dyspnea may also be produced by associated bronchitis, edema, emphysema, and hydrothorax—conditions that must be treated according to the customary rules. Frequent physical explorations of the chest should not be omitted. Hydrothorax demands aspiration, and this repeatedly in some instances.

In valvular disease (particularly aortic), owing probably to coronary arteriosclerosis, paroxysms of severe dyspnea (*cardiac asthma*) are apt to arise. These are best overcome by nitroglycerin in ascending dosage in combination with sodium bromid at bed-time, to be repeated as needful. His lauds the Karell "milk cure," which is a strict diet of 800 to 1000 c.c. of milk per day, in four doses at four-hour intervals, for a period of five or six days. "During the next two days an egg is added to this treatment, given about 10 o'clock in the morning, and a slice of dry toast, or zweiback, at 6 p. m. Then up to the twelfth day the food is gradually increased, first to 2 eggs a day, then more bread, then a little chopped meat, then rice or some cereal, and by the end of two weeks the patient is about back to his ordinary diet."¹ The Karell treatment should be carried out only in bed patients. One factor causing dyspnea in valvular disease is acidosis due to insufficient tissue combustion, hence Hoxie and others have advised the inhalation of oxygen.

(2) *Cough* is common after failure of compensation, and is due to bronchitis resulting from stasis in the pulmonary vessels. In mitral disease it may come on before the rupture occurs. Beyond the treatment directed to the causal condition (the cardiac failure) nothing is needed to relieve the cough. These subjects, however, are prone to suffer from catarrhal bronchitis due to cold, and this impairs the compensatory mechanism. J. Weiss extols heroin in cases not relieved by the ordinary remedies.

(3) *Hemorrhage* may take place, and generally from the lungs, though it may also proceed from the nose, stomach, bowels, or uterus. In a recent case of double aortic disease and relative mitral insufficiency hemorrhages occurred from the bowel with apparent relief to the patient. The hemoptysis, which is an accompaniment of mitral lesions, is rarely excessive, and is probably always beneficial. I would advise against active treatment unless the hemorrhage is actually copious in amount.

¹ *Jour. Amer. Med. Assoc.*, September 23, 1916, p. 952.

(4) *Palpitation* may be due to different causes, the recognition of which in each case is important. At times undue hypertrophy maintains a constant throbbing and distress in the precordial region, the condition being distinguished by the strength of the impulse and by the full, tense pulse at the wrist. Palpitation is best met by the use of the tincture of aconite, mj to iv (0.065–0.26) every four hours. With the aconite I frequently associate the bromid with excellent effect. An ice-bag to the precordia is worthy of recommendation. Unless the patient's discomfort is significant, however, this symptom does not call for active treatment. The administration of a saline purge not infrequently serves to quiet the heart. The patient may suffer from pure nervous palpitation, in which case the diet and the condition of the stomach must be carefully looked to, while for the throbbing the bromids of ammonium and sodium, together with preparations of valerian, are the most reliable.

(5) *Anginose Pains*.—These are seen in aortic incompetency accompanied by sclerotic vessels, and also in mitral stenosis. The former lesion is often due to syphilis (*vide* Etiology, p. 599), in which case the pains and other symptoms are best relieved by intensive antisyphilitic treatment. When dependent upon rigid blood-vessel walls nitroglycerin should be tried; if the attacks be severe, amyl nitrite by inhalation deserves a trial, this failing, morphin and atropin may be employed hypodermically. Local measures alone may be sufficient when the pain is only moderately intense, and the ice-bag may be tried. The sedative effect of a blister (4 by 6 in.—10–15 cm.) has more often proved effectual in my experience, though its use should be limited to patients whose general strength is not materially impaired.

(6) *Pain* referred to the stomach, and less frequently to the abdomen also, occasionally assumes prominence and is relieved with great difficulty. It is dependent, in part at least, upon obstinate subacute gastritis, and I have quite recently seen an instance of the sort verified by autopsy. Among many drugs tested in this case, opium alone gave relief. Should this fail, however, carminatives in combination with some antiseptic agent, as salol or guaiacol carbonate, should be used.

(7) *Gastric Symptoms*.—Soon after compensation is broken the appearance of mild symptoms of catarrh of the stomach may be said to be the rule, and these yield to simple measures in addition to the cardiac stimulants and laxatives already indicated. But there are not a few instances in which such symptoms as gastric distress and uneasiness, constant nausea with frequent vomiting, particularly after food, occur, and assume a distressing phase. In such cases digipuratum deserves a trial. These patients sometimes do well on the capsules before adduced composed of strychnin, spartein, and caffein. When the above remedies cannot be borne I employ hypodermically digitalin and strychnin or caffein citrate, the latter being made soluble by the addition of sodium benzoate in solution. Cases of this class reach an early fatal termination, as a rule. The symptoms may be partly due to uremic intoxication.

(8) *Nervous Symptoms*.—Insomnia and restlessness are almost constantly present at some period in the course of heart disease, and notably in the more advanced stages. The restiveness is rendered more distressing on account of hideous dreams and cardiac palpitation on awaking. For these phenomena stimulation often answers a better purpose than sedation. Hoffman's anodyne (3j —4.0, well diluted), spirits of chloroform (℥xv —1.0), or ether (3ss —2.0), taken in whisky (3j —30.0), are serviceable. The elixir of ammonium valerianate is also of value. Recently trional (gr. xv.) in combination with sodium bromid (gr. xx) has given satisfaction. Paraldehyd, veronal, and medinal are among the remedies of choice in the treatment of this symptom, but I have had no experience with their employment. In the later stages there is no objec-

tion to the use of morphin hypodermically. Headache due to uremia may frequently be a troublesome symptom in connection with sleeplessness, and in such cases morphin is the remedy *par excellence*; it is to be supplemented by free purgation and cardiac stimulants. Should the right heart be found flagging, venesection may be practised.

(9) *Dropsy*.—As above pointed out, rest with attention to the diet and the judicious use of hydragogue cathartics will often restore broken compensation. In the severe grades of failure of the balancing forces, complete rest, purgatives, and a cautious employment of morphin hypodermically, often suffice to remove the dropsy. If this method of treatment proves unsuccessful, then the therapeutic indications, so far as the dropsy is concerned, are for the use of cardiac stimulants, diuretics, and purgatives. Diaphoretics, particularly the hot-air and vapor baths, are not to be thought of, since they tend to depress the already weakened heart. When digitalis fails to remove the dropsy, Fraenkel uses strophanthin intravenously, giving as the initial dose 0.5 mg. and repeating only when the favorable effect is no longer apparent. Where a more powerful diuretic action is desired than is afforded by digitalis alone, the diuretics of the purin group are combined, such as caffein, theobromin, theophyllin, or theocin, which act by dilating the renal vessels and by direct action on the epithelium. Of this group the most convenient form of all is the water-soluble acet-theocin-sodium in doses of about 3 grains three times a day (Hirschfelder). Members of this group, however, may diminish renal secretion when the kidney cells are much damaged, and a preliminary phthalein test, to determine the exact extent to which the renal epithelium is injured, should be made. For example, if the phthalein excretion is less than 30 per cent, in two hours, we should rely upon digitalis and other remedies that tend to improve the circulation rather than stimulate the kidneys. Nitroglycerin may also be prescribed, especially in cases presenting evidences of advanced arteriosclerosis. Theobromin sodium salicylate has acted well in recent cases as a diuretic. An unirritating yet highly effective diuretic mixture in these cases is the following:

R. Potassii acetatis, 3j (4.0);
 Inf. digitalis, ʒij (60.0).—M.
 Sig. ʒss (15.0) every three hours.

Purgatives are of the utmost value. Frequently, after a few copious watery evacuations as the result of the action of hydragogue cathartics, a free discharge of urine can be established, when before the latter event it has been impossible. Salines and elaterium, with podophyllin and belladonna, are agents that have been already recommended as purgatives (to deplete the venous system), and these should be first employed in the order named. Compound jalap powder may also be combined with the elaterium. A course of calomel, followed by salines until free catharsis is set up, is valuable from time to time. Mercury is especially applicable when the liver is much enlarged and ascites is present or there is a history of syphilitic infection and a positive Wassermann reaction. It may be combined as follows:

R. Pulv. digitalis fol.,
 Pulv. scillæ, āā gr. xij (0.77);
 Mass. hydrargyri, gr. xxiv (1.55);
 Ext. belladonnæ, gr. ss (0.032).
 M. et ft. pil. No. xii.
 Sig. One every three or four hours.

When efforts at relieving the dropsy by means of medicines fail, then the most dependent parts of the body, or those most swollen, should be scarified under strict aseptic precautions. Fine silver trocars with rubber tubes attached (Southey's tubes) may be inserted and the liquid allowed to drain off in a gradual manner.

Means to Prevent Recurrence of Broken Compensation.—When the compensation has been successfully re-established, the after-treatment must be prosecuted with vigor for at least a year. The cause of the rupture of compensation is most probably fibroid and fatty degeneration of the cardiac muscle, and hence the mere restoration of the compensatory power of the heart does not imply a complete cure of the impaired muscular structure of that organ. Much can be done, however, to overcome the tendency to degeneration by the persistent use of hematinics and other tonics, as cod-liver oil and mercuric chlorid, the latter in small doses. I have obtained excellent results from the use of the following prescription in these cases:

R. Liq. arsenici chlor.,	℥xlviij (3.2);
Tinct. ferri chlor.,	℥ss (15.0);
Hydrarg. chloridi cor.,	gr. ss (0.03);
Elixir digestivi comp., q. s. ad	℥iij (90.0).—M.
Sig. ʒj (4.0) after each meal, well diluted.	

This preparation may be taken indefinitely with occasional brief interruptions. The patient should lead a very quiet life, and follow rigidly all hygienic rules that tend to prevent the production of valvular disease. In cases of aortic insufficiency vigorous antisiphilitic treatment is indicated. Frequently very small doses of digitalis may be indicated as a mild cardiac stimulant. Appropriate *diet*, it should be emphasized, is not inferior to appropriate medication in its salutary effect. Should the faintest evidence of failure of the right ventricle manifest itself, the patient must be put to bed and the foregoing treatment carried out. I am inclined to the view that the plan herein advocated not only renders the course of recurring attacks of failing compensation milder, but that, in a considerable proportion of the cases, the much-dreaded recurrence is thus prevented.

CARDIAC THROMBOSIS

Pathology.—True cardiac thrombi are seen most frequently on the right side of the heart, in the auricular appendices, and, less commonly, in the right ventricle near the apex. They are of firm consistence, and are tightly adherent to the endocardium, considerable force being required to dislodge them. The color, while generally grayish-brown or red, varies with the age of the thrombus, being more colorless as it becomes older. Cardiac thrombi may be pedunculated or sessile, and their contour is, as a rule, more or less rounded. Recklinghausen and others have observed globular masses, the so-called "ball-thrombi," in the auricles, without the slightest endocardial attachment. They vary greatly in size, from a mustard seed to a hen's egg, and sometimes exhibit calcareous degeneration. Cardiac thrombi may occur singly or in groups of considerable numbers. From the cavity in which they have their primary seat they may project into other chambers of the heart, or from the left ventricle into the aorta for a considerable distance. It is evident that fragments detached by the blood-stream from these cardiac blood-concretions will tend to lodge in various viscera and in the peripheral tissues, and set up embolic

processes. The microscope shows degenerated round cells and detritus, but no pus-cells. Secondary degenerative changes, and later softening, may take place in the central portions of a thrombus, and these areas may contain a reddish-brown liquid.

Etiology.—The causes of cardiac thrombosis are to be found chiefly in some previously diseased or injured condition of the endocardium, though sometimes alterations of the blood constitute a factor of considerable importance. The condition may occur in the course of both acute and chronic diseases, in which the intracardiac conditions favor the formation of a blood-clot. Hence it is seen in connection with organic diseases of the heart in which the valvular and often the mural endocardium are roughened, and the obstructive and regurgitant lesions at the various valves cause retardation in the blood-current. Chronic obstruction in the lungs may contribute to the result by slowing the circulation in the heart. Cardiac thrombosis has been observed in many of the acute affections, and almost invariably there is a loss of endocardium, due to inflammatory action (endocarditis) at some point in the cavities of the heart. This becomes the seat of the fibrinous deposit which is subsequently imperfectly organized. Among the most important of these acute primary diseases are *rheumatism*, *diphtheria*, *lobar pneumonia*, and *pyemic* and *puerperal conditions*. It may be questioned whether, given a healthy endocardium, as contended by some writers, the slowing of the circulation alone suffices to cause true cardiac thrombi.

Symptoms.—These will depend very much upon the rapidity with which the thrombus is formed, as well as upon its seat and dimensions. Thrombi invariably lack definiteness, and, as their effects are largely mechanical, signs of obstruction to the cardiac circulation and failure of the cardiac muscle are developed. The *pulse* becomes weak, rapid, and irregular; *dyspnea*, *vertigo*, and attacks of *syncope* are frequent; and later *cyanosis* may appear. It is probable that at times the liquefied products of a clot may be absorbed, producing blood-poisoning. When the thrombus is formed rapidly the symptoms are suddenly developed and the course is rapid. Rarely a valvular orifice, an efferent vessel, or the coronary artery may become blocked and instant death follow. Since the right heart is the most frequent seat of these thrombi, pulmonary embolism with its usual symptoms is a common event. When portions of a clot are broken off and swept into the systemic circulation, the clinical phenomena of cerebral, splenic, or renal *embolism* are exhibited. A localized gangrene of the foot has been described.

The **physical signs** consist of a feeble impulse with marked arrhythmia; the area of dulness is somewhat increased to the right, and often upward; and the heart sounds are greatly enfeebled and quite irregular, with marked change in any murmurs that may previously have been audible. A presystolic murmur may be engendered.

Differential Diagnosis.—It is important to distinguish true cardiac thrombi, such as are above described, from the less dense and usually darker clots that are formed either immediately before or after death. The latter may seldom show an attempt at a very low grade of organization, and may present a somewhat decolorized appearance, but they do not adhere firmly to the endocardium. Moreover, *antemortem* and *postmortem* clots, as the latter may be appropriately termed, have a different causation from true thrombi. For instance, they are apt to form in diseases in which the fibrin-factors of the blood are greatly increased, as in pneumonia. Perhaps a more potent causal element is the progressive weakening of the heart muscle, resulting in partial expulsion of the contents of the right ventricle; the blood that remains in the chamber is merely whipped up, and the deposition of its fibrin

must thus be greatly favored. Such heart-clots may be generated if the endocardium be healthy, and cannot be separated positively from true cardiac thrombi by clinical observation.

The **prognosis** is uniformly bad and sudden death may be expected.

Treatment.—Beyond measures calculated to meet the symptomatic indications nothing can be suggested.

HYPERTROPHY OF THE HEART

(*Hypertrophia Cordis*)

Definition.—Hypertrophy is an increase in the muscular structure of the heart, evidenced usually by an increased thickness of its walls. It is almost invariably associated with dilatation of the chambers.

Pathology.—When the two processes—hypertrophy and dilatation—coexist, they cause great enlargement of the organ. To this condition the term *eccentric hypertrophy* has been given. Hypertrophy without dilatation receives the name *simple hypertrophy*, and hypertrophy with diminution in the size of the cavities was formerly described as *concentric hypertrophy*, but this term should now be regarded as obsolete, inasmuch as the condition is due to postmortem contraction of the ventricles.

The increase in size may affect the whole heart, one chamber on either side, one whole side, or but a single cavity (*general* and *partial hypertrophy*). The process may also be limited to a minute division of the heart (*circumscribed hypertrophy*). Owing to its important physiologic function the left ventricle is more frequently enlarged than the right, while the right auricle is more frequently involved than the left. The *weight* of the normal heart in a man of average size is approximately 9 ounces (255.0); in a woman it is 8 ounces (256.0). In bilateral hypertrophy, however, the weight of the heart may be greatly increased; hearts weighing from 15 to 25 ounces (425.0–710.0) are seen in moderate grades of hypertrophy, and those from 40 to 50 ounces (1134.0–1420.0) in extreme cases (*cor bovinum*). Measurements showing the thickness of the walls also indicate the degree of hypertrophy¹ and the exact seat of the enlargement when not general. The normal diameter of the left ventricular wall is from 8 to 12 mm. ($\frac{1}{3}$ – $\frac{1}{2}$ in.); that of the right ventricle, from 5 to 7 mm. ($\frac{1}{5}$ – $\frac{1}{4}$ in.); that of the left auricle, about 3 ($\frac{1}{8}$ in.), and of the right 2 mm. ($\frac{1}{16}$ in.). In cardiac hypertrophy the normal thickness of the various cavity walls is usually doubled, not infrequently trebled, and, rarely, even quadrupled. In cases in which there is a concomitant dilatation the walls may appear thinned, while the measurement will show them to be in reality thickened.

The *shape* of the heart is also altered according to the seat and extent of the hypertrophy. If both ventricles are enlarged, the apex is widened and appears flattened; if only the left ventricle is involved, the apex is lengthened and is more or less pear shaped; and if the right ventricle alone is hypertrophied (as in mitral stenosis), it may form the largest part of the apex, which will be less conical than in health.

The papillary muscles and columnæ carneæ are greatly thickened, and, particularly in the eccentric form of hypertrophy, they are often decidedly flattened. In this form the septum frequently shows increased thickness—

¹ Measurements should not be attempted until the *rigor mortis* has been overcome by soaking the organ in water.

a condition that I have never observed in simple hypertrophy. The muscular trabeculae generally assume greater prominence on the right than on the left side. The muscular structure is usually of a deeper red color and also firmer than normally. The hypertrophied left ventricle can, as a rule, be lacerated readily, while the right, as first pointed out by Rokitsansky, may be tough and leathery. As the heart continues to enlarge it sinks lower in the chest cavity, owing to an increase in weight as well as in size. In hypertrophy of the heart there is a multiplication of muscular fibers, to which alone the enlargement of its walls is attributable.

Etiology.—Hypertrophy of the left ventricle (sometimes termed *general hypertrophy*) results from obstructions to the arterial circulation of whatever sort. These may be classified, according to their seat, into—(1) **Lesions of the Heart.**—(a) Aortic incompetency and aortic stenosis; (b) mitral insufficiency; (c) the fibroid form of myocarditis; (d) pericardial adhesions, particularly in the young. In such cases the adherent pericardium exerts a counter-traction force during the systole, and thus the work is increased beyond the capacity of the normal heart, with consequent hypertrophy.

(2) **Abnormal Conditions of the Blood-vessels.**—(a) Narrowing of the aorta—*e. g.*, congenital stenosis, external pressure, and the development of an aneurysm; (b) general arteriosclerosis, by increasing the peripheral resistance and hence the amount of work required of the heart; (c) increased arterial pressure, due to contraction of the peripheral vessels in consequence of the local action of certain chemical and biologic irritants (lead, Bright's disease, gout, syphilis). Hassenfeld has shown that hypertrophy of the left ventricle occurs only when the visceral arteries exhibit an extreme degree of sclerosis, or when the thoracic aorta is sclerotic. In cases of pure contracted kidney all the chambers of the heart are hypertrophied; but when extreme arteriosclerosis is present also the left ventricle is disproportionately enlarged. In all of these cases, whether the blood-pressure is raised in larger or smaller vessels, increased cardiac action is essential to meet the demands of the system circulation.

Attention should be called to the causes of the so-called “**primary idiopathic hypertrophy**.” The main causal conditions are: (1) Prolonged physical exertion, as in certain occupations (blacksmiths, locksmiths, draymen, and athletes). Excessive bicycling causes hypertrophy, particularly if arteriosclerosis exists. (2) Constant overdistention of blood-vessels, as in the case of excessive beer drinkers (*beer-heart*). Here the direct action of the alcohol upon the heart muscle must also be taken into account. (3) Functional disturbances (neuroses), constant overaction of the heart (exophthalmic goiter), and even paroxysmal tachycardia, tea, coffee, tobacco, and alcohol may give rise to primary and general hypertrophy. Idiopathic hypertrophy of the heart is undoubtedly due to increased activity, which is dependent on a variety of irritating influences acting upon the heart muscle (De Domenico). *Primary congenital hypertrophy of the heart* is attributable either to circulatory disturbance or, as Virchow holds, to a diffuse myomatous neoplasia of congenital origin.

Hypertrophy of the right ventricle develops secondarily to any condition that offers obstruction to the pulmonary circulation or to the blood-current through the right ventricle. Among them may be mentioned—(1) Mitral incompetency and stenosis; (2) emphysema, chronic bronchitis, collapse of a portion of the lung, contraction of a lung from pleural adhesions, and cirrhosis of the lung; (3) right-sided valvular lesions, particularly obstruction at the pulmonary orifice; (4) it is doubtful whether, on account of the normal situation of the right ventricle, pericardial adhesions induce hypertrophy of this chamber.

Hypertrophy of the Auricles.—Hypertrophy with dominant dilatation of the left auricle occurs in mitral disease, and especially in mitral stenosis. The right auricle hypertrophies, though not invariably, when the blood-pressure in the pulmonary vessels is pronounced from any cause. Stenosis of the tricuspid orifice is occasionally the sole cause of thickening of the right auricular wall, which also becomes hypertrophied in tricuspid incompetency.

Symptoms.—There is usually an entire absence of subjective symptoms when compensation is efficient. When present, their intensity varies with the degree of the hypertrophy, which is then pronounced, as a rule, and often already attended by incipient dilatation. They may be *local* entirely, though frequently *general* as well. Of the former, *precordial discomfort* and *uneasiness* from the violence of the impulse occur. They are most annoying when the patient is in the recumbent posture on the left side and when the hypertrophy is dependent upon nervous causes. *Pain* and *palpitation* are seldom complained of except by neurasthenics and patients suffering from enlargement due to tobacco or excessive muscular exertion. Decided aggravations of the local manifestations may follow undue mental emotion or excitement, physical exhaustion, active bodily exercise, and gourmandizing.

The *general symptoms*, when present, may fluctuate or even intermit. Those most frequently observed are fulness in the head, often amounting to actual *headache*, *tinnitus aurium*, *carotid pulsations*, *flushing of the face*, *flashing of light before the eyes*, and often *prominent eyeballs*. These symptoms are attributable to the increased vigor of the cerebral circulation.

Remote Effects.—General or total hypertrophy promotes high tension throughout the arterial tree. Endarteritis and arteriosclerosis are, as a consequence, frequent simultaneous developments in advanced cases, especially when the cause of the enlargement has been increased tension in the peripheral vessels, as in Bright's disease. With a circulation too forcibly carried on, as in hypertrophy, the sclerotic vessels are overstrained, and are apt to rupture. The break often occurs in the brain (*apoplexy*) or in the lung (*pulmonary apoplexy*), and hemorrhage from the lung (*hemoptysis*), due to left ventricular hypertrophy, is more common, I believe, than is supposed. The blood-pressure is high, although the records vary with the dominating cause. Some of the symptoms are due to the cause or causes of the hypertrophy.

Physical Signs in Left-sided Hypertrophy.—*Inspection.*—In females and in children with soft, yielding ribs there is visible arching. The intercostal spaces are much broadened and the apex-beat covers an increased area, the extension being downward and to the left. The whole body of the patient, and even the bed on which he may be lying, may share visibly in the cardiac impulse.

Palpation.—In pronounced grades the impulse may be felt as low down as the seventh interspace and as far to the left as the axilla. In simple hypertrophy it is carried downward to the sixth intercostal space and outward to a point near the anterior axillary line. The impulse is slow, forcible, and heaving, the "thrust" lifting the fingers of the examiner. In eccentric hypertrophy (hypertrophy with dilatation), though heaving and forcible, it is somewhat more abrupt, as in cardiac dilatation. Over the aortic orifice a short diastolic impulse may also be felt occasionally (double impulse). Pressing the fingers into the second and third right spaces will detect an impulse if the aorta be dilated. The pulse in pure hypertrophy is full, strong, regular, and of normal rate; it is also prolonged, owing to increased tension. In eccentric hypertrophy it is more abrupt, soft, full, and somewhat accelerated.

Percussion.—This defines only approximately the degree of enlargement, as the hypertrophy may take a backward direction or there may be more than the usual overlapping of the heart by the lung. Traced upward, dulness

may terminate in the second interspace, while to the left it may extend 1 or 2 inches (2.5–5 cm.) beyond the midclavicular line. When hypertrophy is of moderate extent the left limit of dulness corresponds with the results of palpation and inspection; but when it is of immoderate extent the extension of dulness does not keep pace with the systolic impulse, which is diffused to points without the limits of contact of the heart with the thoracic wall. If concomitant hypertrophy of the right ventricle be present, dulness will also extend to the right (*vide infra*).

Auscultation.—The sounds vary with the grade of the morbid process and the variety. In simple hypertrophy of marked type a prolongation of the first sound is always appreciable, and usually it is duller than the normal. The second sound (aortic) is intensified, clear, and often ringing. The degree of accentuation depends partly upon the vigor of the left ventricle, though chiefly upon the condition of the blood-vessels. Reduplication of the second sound, due to high tension, is common (*e. g.*, in Bright's disease). The first sound may also be duplicated. In dilated hypertrophy the first sound is clearer and more abrupt, while the second is less marked or even faint. Modification of these sounds occurs when hypertrophy is due to chronic valvular disease.

Hypertrophy of the Right Ventricle.—One or more of the causal factors that produce augmented tension in the pulmonary vessels are present, and, if properly appreciated, will throw light upon the condition. There may be an absence of all symptoms if the hypertrophy exactly balances the result of the obstructive forces, and this state may be maintained for a long period of time. Undue exertion, however, soon leads to *temporary dyspnea* in many cases. When secondary to emphysema or cirrhosis of the lung the symptoms occasioned by the latter diseases, such as *cough* and *dyspnea*, may completely veil any symptoms that may be due to the hypertrophy. *Discomfort* in the cardiac region should, however, arouse suspicions of the existence of the latter condition. When *dilatation* of the ventricle supervenes, as is usual, and the clinical evidences of tricuspid incompetency develop, then pulmonary symptoms, due to venous congestion, are prominent; there are bronchial catarrh, shortness of breath, and the like. Later, general cyanosis and edema appear. As pointed out in the discussion of Mitral Stenosis with permanently heightened tension and overgrowth of the right ventricle, the lung vessels become atheromatous and the lung tissue the seat of brown induration. Owing to the fact that the sclerotic vessels are easily ruptured, *hemoptysis*—a not uncommon event after sudden great exertion—is to be expected; intense pulmonary congestion and apoplexy may also be met with in hypertrophy with dominant dilatation.

Physical Signs.—These have been in the main detailed in speaking of affections of the mitral valve. *Inspection* discloses bulging of the sixth and seventh left costal cartilages and of the lower sternum. In the angle between the ensiform cartilage and the seventh rib an epigastric impulse may be visible, but more commonly the impulse is in the sixth interspace, close to the left edge of the sternum. It is also very generally seen to the right of the sternum, in the third and fourth interspaces, and particularly in this case in eccentric hypertrophy, forming a highly characteristic sign. The apex-beat is therefore diffuse, the radial *pulse* is small, and in dilated hypertrophy it is increased in frequency, and is small, unsustained, and irregular.

Percussion shows the extension of cardiac dulness to a point 1 inch (2.5 cm.) or more beyond the right sternal border. When there is great increase transversely, dilatation is most probably associated and may predominate over hypertrophy, though Mackenzie has shown that the dulness to the right of the sternum is largely auricular, and that right ventricular hypertrophy or dilatation is accompanied by a pushing over to the left of the area of cardiac

dulness with the apex displaced down and outward. The *auscultatory* signs are not distinctive unless dilatation also exists, when the first sounds are clear and sharp. In simple hypertrophy the first sound is slightly prolonged and lower than in health. Owing to the high vascular tension throughout the lungs the second sound at the pulmonary valve is accentuated, and reduplication of the second sound may occur for the same reason.

It must be kept in remembrance that when advanced emphysema is present all the physical signs will be greatly modified, and may even be entirely negative, though the heart be of large size. Under these circumstances venous pulsation in the neck would be diagnostic of dilated hypertrophy of the right ventricle.

Hypertrophy of the Left Auricle.—This may be assumed to occur in mitral stenosis and incompetency in order to compensate for these lesions; it cannot, however, be recognized positively by physical signs. When the chamber is at the same time extensively dilated, the dulness may be extended upward to the left of the sternum, passing over the third and even second interspaces. At this point—the second interspace—a presystolic wave may now be noticeable.

Hypertrophy of the right auricle, associated with dilatation, is perhaps more common than its counterpart on the left side. It is secondary to tricuspid incompetency (rarely stenosis) and enlargement of the right ventricle, and hence has the same etiology as the latter conditions.

The *physical signs* are—systolic jugular pulsation, sometimes a presystolic wavy pulsation over the third and fourth interspaces to the right of the sternum, extension of cardiac dulness to the same interspaces, and other signs of tricuspid regurgitation.

Diagnosis.—The recognition of cardiac hypertrophy is possible only by attention to the physical signs and by means of the electrocardiograph. Next to these, in point of diagnostic value, come the causes, which should therefore be diligently searched for; the rational symptoms are least in value, though usually corroborative. It is difficult to establish a diagnosis, even approximately, when extensive emphysema coexists. The size of the heart and the characteristic change in shape produced by hypertrophy, a dilatation of the various portions of the organ, can be accurately determined by the use of the roentgen rays, or, at all events, by means of the orthodiagram. By means of the electrocardiograph it is possible to diagnose absolutely right- or left-sided hypertrophy. The R wave in lead I is directed downward in right ventricular hypertrophy; in left ventricular hypertrophy the R wave is directed downward in lead III. Hypertrophy is also shown by the large size of the R waves, which in dilatation are usually small. In auricular hypertrophy there may be a large P wave.

Differential Diagnosis.—Conditions that cause an increase in the precordial area of dulness, except hypertrophy, must be eliminated. (1) *Pericardial Effusion*.—A careful analysis of the physical signs and the history will suffice. (2) *Aneurysm*.—In this affection the enlargement is altogether upward and to the left or right. This fact, joined with other evidences of aneurysm, should obviate error. (3) *Mediastinal growths* also enlarge the dull space mainly upward and to the right or left, though the point of cardiac contact may be increased and the heart carried forward. (4) *Displacement of the heart* does not give a heaving impulse nor an increased area of dulness; moreover, it usually furnishes its special cause (pleural effusion). (5) Abnormally narrow-chested persons present a considerably increased superficial zone of dulness, partly owing to the position assumed by the lungs and partly (perhaps chiefly) to their imperfect development. Since there is usually an

entire absence of all other physical signs of hypertrophy, ordinary caution will exclude the latter complaint. (6) *Affections of the Lungs and Pleuræ*.—Left-sided pleurisy with retraction may, by exposing a large part of the anterior surface of the heart, give rise to signs of moderate hypertrophy. The presence of the former condition, the lack of lung expansion on deep inspiration, the displacement of the heart to the left and upward, and an absence of the causes of hypertrophy should lead to a correct conclusion. (7) *Phthisis and cirrhosis of the lung*, with or without pleurisy, may in like manner produce apparent enlargement of the heart. It must also be remembered that cirrhosis of the lung is one of the causes of right-sided hypertrophy, and that the latter condition may therefore be present.

Prognosis and Course.—The course that will be pursued depends largely upon the stage at which the case has arrived and the character of its special cause. I have repeatedly found *postmortem* evidence of a moderate grade of hypertrophy in persons who died of other affections, and with especial relative frequency in those who had constantly followed manual pursuits. Simple cardiac hypertrophy, being compensatory as a rule, exerts in nearly all instances a salutary influence, and if the processes that constitute the causal factors are not steadily progressive, life may not only be curtailed, but be greatly lengthened by its existence. Even in organic valvular disease of the heart hypertrophy prolongs life by overcoming the ill effects of the valve lesion and by maintaining the normal circulatory equilibrium. But since in this class of cases the lesion is progressive despite treatment, a limit is reached sooner or later beyond which the increased vigor on the part of the heart cannot be maintained. The functional power becomes inadequate in obedience to a natural law, and muscular degenerations then occur, followed by disturbances of the circulation due to cardiac weakness and secondary dilatation. It must, however, be recollected that the heart may at no time, in the course of certain cases, fully compensate for the causal condition—*e. g.*, as when a valve ruptures with startling suddenness. Failure of the cardiac nutrition at once renders the prognosis unfavorable. The cardiac sounds now give notice that the hypertrophy no longer meets the requirements of the case. The systolic pause grows longer (with abbreviation of the first sound), and the diastolic shorter. Occasionally, as the result of undue muscular exercise, acute dilatation, followed by a speedy termination of life, is observed. I believe that hypertrophy of the left ventricle warrants a more favorable prediction than can be made in hypertrophy of the right, and this for two reasons: first, the increased capacity for work of the left ventricle; second, the milder character of the many factors that are productive of left ventricular hypertrophy, as compared with those of the right. In special instances, however, the reverse may obtain, as when left-sided hypertrophy is associated with or caused by general arterial degeneration. It may be of advantage to the student and junior physician to recapitulate here a few of the chief points that are prognostically favorable as well as those that are unfavorable: *Favorable Conditions*.—(1) When the hypertrophic development fully compensates the causal lesion; (2) when the causes are removable or more or less amenable to treatment; (3) when the external conditions under which the patient lives, his habits, and general nutrition are good; (4) when the tests of functional efficiency of the heart show but little evidence of insufficiency. *Unfavorable*.—(1) When signs of cardiac insufficiency arise upon very slight effort; (2) when evidences of advancing cardiac dilatation (dyspnea, rapid, irregular pulse, edema) show themselves; (3) when poverty, poor food, intemperate habits, and an unhygienic environment are all combined; (4) when apparent cardiac vigor suddenly gives place to dilatation and great cardiac weakness.

The **treatment** has for its prime object the prevention of failure of compensation on the one hand and overhypertrophy on the other (*vide* Chronic Valvular Disease).

Overhypertrophy, as indicated by certain cerebral and thoracic symptoms, may require the employment of measures to reduce the contractile energy of the left ventricle, although direct cardiac depressants (aconite and the like) are rarely needed. It requires careful dietetic and hygienic management. Briefly, the *diet* should be nutritious, but the more concentrated forms of food should be used very sparingly, and the daily quantity should be slightly less than that required in health. It must be non-stimulating, and tea, coffee, alcohol in all forms, and smoking must be prohibited. The physical exercise should be moderate in amount and of the gentlest sort; and if the patient's occupation tends to stimulate the heart, it must be immediately abandoned. A mild saline purge (ʒij to ʒss—8.0–16.0—of Rochelle salts once daily) is quite beneficial.

For relief of the cerebral symptoms (tinnitus aurium, vertigo, fulness) and the precordial discomfort the physiologic relaxants of the capillaries and the arterioles are of great service, particularly when arteriosclerosis is a traceable cause. Among them nitroglycerin in full doses and veratrum viride are most useful; the efficacy of both may often be enhanced by the addition of the bromids. In cases of nervous origin the bromids, with preparations of valerian, are the most valuable agents. Nothing, however, is of higher importance than the determination and removal of the cause when possible. After compensation has failed the further treatment is identical with that of cardiac dilatation.

DILATATION OF THE HEART

Definition.—By dilatation of the heart is meant an enlargement of its various cavities. The walls of the chambers may in consequence be thinner than in health, but much more commonly they are thicker, as in *dilatation with hypertrophy*. Both hypertrophy and dilatation are relative terms, but the latter has reference to that condition in which the cavities are distended out of proportion to the diameter of their walls.

Varieties.—(1) *Dilatation with Hypertrophy.*—Here there is a progressive increase in the capacity of the chambers until they attain to large dimensions. The cardiac walls continue of abnormal thickness, yet the vigor of the divisions affected may be relatively diminished to a remarkable degree, owing to the weakening influence of the degenerative processes that attack the hypertrophied muscles. In eccentric hypertrophy the heart cavities are dilated, but the hypertrophied cardiac walls are sufficiently vigorous to meet the demands of the circulation. This condition should not be regarded as identical with *dilatation with hypertrophy*, but frequently merges into the latter, the size of the cavities now being proportionately greater than is the thickness or the functional power of their walls.

(2) *Dilatation with Thinning of the Heart Walls.*—The diminution in the thickness of the cardiac muscles may be slight if the capacity of the chambers involved be only moderately increased. Instances of this sort are sometimes seen to follow prolonged fever (typhoid). On the other hand, the process of attenuation may reach a high grade, the greatly thinned cardiac wall being scarcely capable of holding the weight of the contained blood.

(3) *Dilatation with little or no variation from the normal cardiac wall* has also been described by some authors. It is to be observed, however, that

stretching of a cavity whose walls are of normal thickness must be attended with thinning of those walls.

Pathology.—Dilatation with hypertrophy is generally secondary to valve lesions, and affects more than one cavity as a rule. It may happen, as in advanced aortic regurgitation, that all the divisions are dilated. The right ventricle is somewhat more frequently dilated than the left, however, for reasons previously adduced. The auricles (especially the left) are more frequently expanded than the ventricles; hence of all the chambers the left ventricle is least apt to dilate. The extent of the relative increase in the capacity of the cavities is variable and often remarkable. As an example of extreme dilatation of a chamber, the left auricle in cases of mitral stenosis may be singled out; I have seen an instance in which this auricle was capable of containing 22 ounces of blood. The septum may be seen to bulge when one ventricle only is stretched. Extensive dilatation of the chambers produces a dilated condition of the auriculoventricular rings, which in turn gives rise to relative incompetency. Other cardiac orifices are found to be similarly dilated. Dombrowski has drawn attention to the fact, first pointed out by Wolf, that the surface of the mitral leaflets greatly exceeds the orifice, and Kirschner and Garcin contend that the anterior flap alone suffices to close the mitral orifice, "even when the left heart is considerably dilated." Dombrowski believes that functional incompetency is due, in many cases, "to muscular dilatation, producing a separation of the insertions of the papillary muscles, which in systole cannot approach each other near enough to allow the valves to close, the contraction of the papillary muscles only increasing the difficulty." Great dilatation of the left auriculoventricular ring is, however, probably an important factor in the causation of relative mitral incompetency. The tricuspid valves, being scarcely competent, normally, are unquestionably incompetent when that orifice is considerably dilated.

The *shape* of the heart is altered according to the seat and extent of the dilatation. When all the cavities are dilated the organ assumes a globular form, while dilatation of the ventricles only produces broadening of the apical region.

Condition of the Endocardium and Cardiac Muscle.—The muscular tissue generally exhibits degenerations (fibroid, fatty, or parenchymatous). Important as is the part played by the ganglia in maintaining the nutritive integrity of the heart by supplying nervous force, our knowledge of the alterations that may occur in them in this condition is as yet very imperfect. Ott and others have, however, found them to be degenerated. Opacity and patchy roughening of the endocardium are common. The parietes and endocardium may, however, have a normal color and structure.

Etiology.—Entering into the causation of cardiac dilatation there are two essential factors: (1) increased endocardial tension; (2) diminished resistance. These often act together. Broadbent contends that the special feature of dilatation is the imperfect emptying of the ventricles. Probably the most important factor is the disturbance of the coronary circulation that arises as a result of the increased tension in the right auricle, which impedes the return of the coronary blood into the right auricle (MacCallum).

(1) **Increased Endocardial Tension.**—It is to be premised that a primary and a secondary form occur, the latter being of greater importance clinically than the former. Primary dilatation occurs from a recent obstruction to the circulation of considerable magnitude and at any point throughout the blood-vessel system. A good example is afforded by aortic constriction, in which condition the obstruction of the aortic ring engenders dilatation of the left ventricle by raising the intraventricular pressure; this is quickly overcome

by compensatory hypertrophy. In the vast majority of these instances the nutrition of the muscular fibers eventually suffers, with consequent dilatation.

Other causes of augmented endocardial pressure have been considered in the discussion of Hypertrophy and Chronic Valvular Lesions. In eccentric hypertrophy dilatation is a compensatory arrangement, until finally the cardiac nutritive functions fail and dilatation at once predominates (dilatation with hypertrophy). Compensation has now been ruptured. Among the exciting factors that may precipitate this accident are—recurrent endocarditis, intercurrent febrile affections which overstimulate the heart and impair its muscular tissue, general disturbances of nutrition, and physical and mental overstrain.

Acute primary dilatation may be brought about by sudden, great exertion, as in ascending mountainous elevations, excessive bicycling, and the like. Under these circumstances the heart palpitates violently, and there are epigastric pulsation and often pain in the cardiac region—evidences of dilatation of the right ventricle. Although the heart's reserve capacity for work has been exceeded, rest followed by moderate exercise often restores the conditions to the normal. I have seen acute primary dilatation produced by strong emotion; here sudden contraction of the peripheral vessels occurs, attended with arrest of the heart's action; this soon gives place to violent palpitation and, rarely, to dilatation. *Angiospastic dilatation* is a condition due to acute transitory spasm of the vessels (Jacob).¹ Sudden fright may act similarly.

The remarkable endurance of the athlete and the gymnast is in part owing to the abnormal amount of physiologic cardiac reserve force which they naturally possess, but it is mainly due to the invigorating effect of training. If, however, the training be not so conducted as symmetrically to develop the entire muscular system, or if the exertion be in excess of the reserve functional power of the heart, then acute pathologic dilatation may suddenly arise. From this accident recovery may take place; sometimes, however, it initiates organic disease, and thus prohibits the further undertaking of unusual feats. However, in any severe prolonged physical effort (running or rowing a race) a certain amount of dilatation of the heart usually occurs which is not pathologic in the sense that it is no more than transitory. Lee has made a careful statistical study of Harvard oarsmen who have rowed in races, and concludes from this study that the effort made in the race has no permanent effect on the heart.

Apparently idiopathic cases of cardiac dilatation of indeterminate etiology rarely occur.

(2) **Diminished Resistance Owing to Weakened Cardiac Walls.**—The conditions that weaken the cardiac wall are numerous, and not a few lead to acute primary dilatation, such as *myocarditis* due to acute specific fevers (scarlatina, typhoid, malaria, typhus). It is especially prone to occur in *rheumatic endocarditis* and *pericarditis*. B. Robinson calls forcible attention to serious dilatation due to the toxic action upon the heart muscle of the rheumatic poison. The *chronic degenerations* (fatty, fibroid) impair the contractile power of the heart. *Nutritional disturbances* of varied origin, such as digestive disorders, ill ventilation, lack of open-air exercise, and improper or defective food-supply, may induce enfeeblement of the cardiac muscle. Dilatation is met with also in *diseases of the blood* (chlorosis, anemia, leukemia).

Clinical History.—In *acute* dilatation the *onset* is sudden. It is accompanied by rapidly augmenting dyspnea and cardiac palpitation, a feeling of coldness, and frequently by pain in the precordial region.

The **physical signs** may be incontestable. They are *venous pulsation* in the neck, a *rapid, feeble apex-beat*, and a *systolic murmur* at the tricuspid valves,

¹ *Ztsch. f. klin. Med.*, February 4, 1899.

all of which declare the presence of tricuspid regurgitation. In *angiospastic dilatation* the pain may begin in the extremities, and the second heart sound may be louder at the apex than the first. Among signs of subsidiary value are a venous turgescence, a marked epigastric pulsation, and a sudden extension of *dulness* to the right; the *pulse* is small, irregular, and exceedingly rapid.

In the more *chronic form* which arises from slowly acting causes, or in that which accompanies eccentric hypertrophy or follows simple hypertrophy due to left-sided heart or lung trouble, the manifestations in the earlier stages are not striking. They indicate weak heart walls, and such chambers expel their contents imperfectly during systole. With each subsequent diastole the abnormal amount of blood contained in them is increased. This blood-stasis often extends from the left heart to the pulmonary vessels, from the latter to the right heart, and finally to the general venous system. Both in the acute and chronic forms, however, *failure of the right ventricle* more often determines rupture of compensation. The symptoms are chiefly those of tricuspid incompetency. Dilatation of the right heart, without tricuspid insufficiency, is a frequent complication of pulmonary tuberculosis (Maisonneuve).

Physical Signs.—*Inspection* in dilatation of the left ventricle shows the apex-beat to be displaced outward and downward, and a diffuse, weak, fluttering, and often distinctly undulating impulse. The apex-beat will show a greatly diminished vigor in its normal area; or there may be no recognizable point of strongest impulse as in health. Distinct pulsation in the second left interspace is not rare. Its feebleness and diffuse character are confirmed by *palpation*. It may be quick and sharp, though always lacking in power. Walsh first made the capital observation—since abundantly corroborated—that the impulse may be visible, yet not palpable. There may be a mere vibration or an utter absence of the apex-beat in advanced cases. The pulse is small (rarely large), short, often rapid, and irregular. Palpation of the pulse should always be combined with the use of the sphygmomanometer, which may show an unexpected exaltation of the blood-pressure, especially when dilatation develops somewhat abruptly. *Percussion* shows a lateral increase in dulness to the left, to or even beyond the midclavicular line, upward to the second rib, and downward as far as, though rarely below, the sixth interspace, except perhaps, in rare instances, in dilatation with hypertrophy. In *em_h* hysema the lungs unduly overlap the heart.

Dilatation of the right ventricle demands separate consideration so far as the impulse and percussion-dulness are concerned. The normal impulse is largely replaced by the abnormal apex-beat of the right ventricle, which advances to the anterior chest wall. The chief impulse is now seen and feebly felt, as a rule, below the xiphoid cartilage or, less commonly, to the right or left of the latter. A wavy pulsation is seen to the left of the sternum, over the fourth, fifth, and sixth interspaces and close to its right edge. If dilatation of the right auricle be associated, as is often the case, a distinct pulsation also occurs in the third right interspace. Dulness reaches to a point 1 inch (2.5 cm.) or more beyond the right sternal border on a level with the fourth interspace.

On *auscultation* variable results are obtained according to the state and diameter of the cardiac walls. When thin and not much disorganized, the first sound is much shorter, sharper, and louder than in health. In advanced cases the systolic sounds may be feeble, though almost always audible in the aortic area (unlike the first sound in hypertrophy). The first closely resembles the second sound, the long pause being shortened, resembling the systolic pause (*fetal heart sounds*). This form of arrhythmia is a serious indication of failure of the ventricles. The *canter-rhythm* is equally common. Irregular

and intermittent cardiac action are usual phenomena. Reduplication may occur, but is not frequent.

Pre-existing *organic murmurs* obscure the sounds due to dilatation, and, on the other hand, the dilatation may also alter the murmurs (previously audible), and even cause them to disappear, as, for example, in mitral stenosis. Again, dilatation may induce relative incompetency or superadd a murmur, as in cases of chronic valvular disease at the auriculoventricular orifices. It is interesting to recall here that proper treatment may remove a murmur due to relative insufficiency, and that this treatment may, in turn, reproduce an organic murmur.

Diagnosis.—This is made readily when there is obtainable a clear history, together with the following characteristic features: a weak, irregular heart action (throbbing of the precordium); an extended, wavy impulse; a small, vigorless, and intermittent pulse; often an indistinct apex-beat; an outward, upward increase in the percussion-dulness on one or both sides, causing the outline to resemble a square; and a brief, sharp, yet feeble first sound that resembles the second, which is enfeebled.

Differential Diagnosis.—*Hypertrophy*, like dilatation, gives rise to an extended area of impulse and of percussion-dulness; hence by the careless observer these conditions are sometimes sadly confounded. From dilatations, in which the diagnosis rests upon the points above enumerated, hypertrophy is to be distinguished by symptoms of an opposite nature, such as indicate increased energy on the part of the heart. The latter are: a slow, heaving impulse; a full, sustained, regular pulse; an increase in the area of dulness, chiefly outward and downward; abnormal position of the apex-beat; and the prolonged, dull first and accentuated second sounds. To determine the point at which eccentric hypertrophy ends and dilatation (with hypertrophy) begins is often difficult; and I have already discussed the initial symptoms of dilatation following hypertrophy (chiefly of the right ventricle) in connection with Chronic Valvular Disease. Occurring in left ventricle hypertrophy, dilatation first betrays itself by a change in the position of the visible apex-beat and the palpable impulse. Thus, the maximum point of the apex-beat of hypertrophy very early becomes rounded and indefinite, and later is diffuse and wavy. The strong, heaving thrust of the impulse gives place to the shorter, more sudden shock of commencing dilatation, indicating weakness. These signs, together with a reduction in the strength and an increased frequency or irregularity of the pulse, show the condition to be dilatation with hypertrophy.

The **prognosis** is bad, as a rule, being that of the causative factors. Here prognostic information may be gained by a careful study of the functional efficiency of the myocardium. The gravity of the prognosis is in direct relationship to the severity of myocardial impairment. A dilatation occurring after sudden physical effort, for example, may be so mild that after rest for a period the heart may regain its full functional power. A dilatation that occurs in the course of chronic valvulitis may be so severe that even after prolonged rest the functional power of the heart never returns; the myocardium is inefficient.

Treatment.—This in all essential particulars is identical with the treatment of organic heart affections after rupture of compensation. The etiology in many cases differs from that of the organic valvular affections of the heart; and the removal of the remote and near causes of the dilatation is the most important part of the treatment. Individual cases frequently present special indications; but in all the work of the heart is increased and the propulsive power of the organ diminished. The indications are to diminish the heart's labor by bodily and mental rest, light diet, purgation and relaxing the pe-

ripheral vessels (T. A. Clayton), and to increase the functional power of the heart by the use of cardiants, baths, and massage. In cases of non-valvular origin digitalis and other heart stimulants may be omitted early, as a rule; though they should be resumed if there be a recurrence of serious indications of dilatation. When the dilatation has been overcome, careful attention is to be bestowed upon all the details of the patient's life and sanitary surroundings in order to force his bodily nutrition to the utmost. Every precautionary measure having for its aim the prevention of a recurrence of the dilatation must also be advised and enjoined.

MYOCARDITIS

(*Carditis*)

Definition.—An inflammation of the muscle substance of the heart. It may be acute or chronic.

ACUTE MYOCARDITIS

Pathology and Varieties.—(1) **Acute Parenchymatous Myocarditis.**—This is characterized by a granular degeneration of the muscular fibers of the parenchyma of the organ, with a numerical increase in their nuclei. The muscle structure throughout looks pale, is turbid, and very soft. Many cases of a severe type terminate in fatty degeneration.

(2) **Acute Diffuse Interstitial Myocarditis.**—Here the primary alterations affect the connective tissue of the myocardium; the histologic changes consist in round-cell infiltration.

(3) **Acute Circumscribed Myocarditis.**—In this variety the degenerative processes result in necrosis of the tissues over large or small areas, with abscess formation. Though usually multiple, these abscesses vary in number, and may rupture either into the various cardiac chambers or into the pericardium. Thus, the purulent contents of the abscess, when there is established a fistulous communication with an endocardial chamber, find their way into the bloodstream, frequently setting up embolic processes of an infectious nature in the various viscera. The blood, in turn, enters the abscess cavity, exerting pressure on its walls, and may either produce an acute aneurysmal dilatation of the heart wall or occasion fatal rupture into the pericardium. More commonly the connective-tissue wall of the abscess yields gradually during the ventricular diastole. Occurring in the vicinity of one of the auriculoventricular valves, abscesses may cause mitral or tricuspid incompetency. They may perforate the interventricular septum, thus creating a fistulous connection between the two sides of the heart, and resulting in an intermingling of venous and arterial blood. The abscess may become encysted, then caseous, and finally undergoes a calcareous process. Multiple abscesses usually affect the left ventricle.

Etiology.—*The causes of myocarditis are:* (a) endo- and pericarditis in the course of rheumatism; it is probable that rheumatic myocarditis may also exist without involvement of the endo- or pericardium, though most cases of rheumatism are associated with a pancarditis; (b) the infectious processes in acute specific fevers (influenza, diphtheria, typhoid); (c) infectious emboli, lodging in the branches of the coronary arteries in connection with septicemia, pyemia, and acute ulcerative endocarditis, and commonly terminating in abscesses (circumscribed myocarditis). The first two of these causes give rise to acute diffuse interstitial and acute parenchymatous myocarditis, as a

rule, although Freund calls attention to the frequency with which circumscribed myocarditis is associated with rheumatism and diseases of the joints. As compared with the female *sex*, the male suffers much more frequently.

Symptoms and Diagnosis.—The symptoms are practically negative. They point merely to great enfeeblement of cardiac function. When cardiac weakness, as shown by a rapid, small, compressible, and arrhythmic *pulse*, and by attacks of *cardiac palpitation* and *syncope*, comes on suddenly in the course of rheumatism, septicemia, or other causal affections, myocarditis may be suspected. Later, signs of *venous stasis* appear. The systolic blood-pressure is commonly low, though fluctuating, varying from 100 to less than 80 mm. Hg. The *mental symptoms* may suggest meningitis or salicylic acid poisoning. Koplik¹ calls attention to certain symptoms (pallor, faintness, vomiting, irregular, feeble heart action, disturbed respiration, and pulse-ratio) that should arouse suspicion of myocarditis in the course of an infectious disease in childhood.

The **physical signs** simulate those of dilatation, and may, indeed, be largely dependent upon the presence of the latter condition. Early the action of the heart is tumultuous; the sounds on auscultation are short, sharp, and finally very feeble. *Murmurs* in myocarditis are not rare, and are not necessarily dependent upon dilatation. Krehl's work shows the dependence of the valves for their complete closure upon a normal state of different portions of the heart muscles, and thus explains these murmurs. The special conditions rendering the murmurs audible are great dilatation, softening of the papillary muscle, and abscesses near the valves.

The great variability as to the intensity of these murmurs is an important point, especially in attempts to discriminate from murmurs due to *endocardial changes*. The latter usually coexist with a more marked accentuation of the second pulmonary sound. For the recognition of *cardiac aneurysm*, see p. 653. The symptoms of visceral or cutaneous *embolic processes*, combined with a murmur and a septic type of fever, are suspicious of the existence of circumscribed myocarditis. The murmur of relative tricuspid regurgitation and the venous pulse may eventually develop, accompanied by the symptoms of general venous engorgement.

Prognosis.—The diffuse forms are often fatal; the circumscribed form rarely eventuates in recovery. Myocarditis may end life suddenly.

The **treatment** is identical with that indicated for endocarditis and pericarditis—diseases of which myocarditis is usually a complication. The effects of digitalis, particularly when acute insufficiency supervenes upon old heart lesions, are quite unsatisfactory (insufficient intact heart muscle), but diffusible stimulants—*e. g.*, aromatic spirit of ammonia, brandy, and the like—are useful. When myocarditis is suspected as an independent condition absolute rest must be enjoined, the general nutrition maintained, and the more urgent symptoms relieved.

CHRONIC MYOCARDITIS

(*Fibrous Myocarditis*)

Definition.—A gradually developing inflammation of the cardiac interstitial connective tissue, resulting in induration.

Pathology.—The characteristic changes may be diffuse, though most frequently they are confined to certain portions of the muscular structure, the left ventricular wall, the septum, and the papillary muscles being the three favorite seats of the process. This is sometimes of antenatal development,

¹ *Med. News*, March 31, 1900.

and then its usual seat is near the apex of the right ventricle. The hardened spots take the form of more or less rounded patches or broad lines. In color they are gray, grayish-white, or grayish-yellow, the latter tint being due to the intermingling of fibers that have undergone fatty degeneration. Their size is exceedingly variable, some being so minute as to elude detection by the unaided eye, while others measure 1 or 2 inches (2.5–5 cm.) in diameter. Inflammatory induration (contraction) of the *conus arteriosus* of either ventricle causes narrowing of the pulmonary and aortic orifices, with the usual signs and symptoms. Similar changes, by disturbing the functions of the papillary muscles, produce valvular incompetency. Compensatory hypertrophy of the uninvolved portion of the heart is also observed; the hypertrophic enlargement may frequently be accounted for in part either by an associated chronic endocarditis or general arterial sclerosis. Dilatation of the ventricles follows, with fresh and grave disturbances of the circulation.

Chronic inflammation usually attacks early the intima of the coronaries, and leads to thrombosis, with the formation of anemic infarcts (*vide* p. 648). It is probable that most cases of localized fibrous myocarditis have their origin in an obliterating endarteritis. Pasquier offers proof that myocarditis results from chronic congestion due to stopping of the vessels. The calloused zone may yield to the endocardial blood-tension, and thus produce saccular dilatation (aneurysm). *Microscopically*, the affection is characterized by hyperplasia of the interfibrillar connective tissue with subsequent development of new fibrous tissue. Fatty degeneration and atrophy of the muscle-fibers (due to compression) are also observed. Fragmentation of the muscle-fibers (the *état ségmentaire* of Renant) has also been observed. This occurs as a *postmortem* change.

Etiology.—The disease is most commonly traceable to the action of one or more of the following factors: an *excess in the use of alcohol or tobacco, lead-poisoning, phosphorus, gout, rheumatism, diabetes, chronic nephritis, malaria, and syphilis*. Thus, it may be produced by many infections and chemical irritants, the latter, in most cases, first causing a sclerosis of the coronary arteries, to which the patchy fibroid degeneration is secondary. Some of the causes of acute diffuse interstitial myocarditis may by their more slightly irritant effect lead to the subsequent development of the general chronic form (*e. g.*, rheumatism). Certain irritants that engender localized lesions of chronic myocarditis may affect the entire myocardium (syphilis, alcohol, gout). Certain exhausting diseases, as dysentery, carcinoma, and the anemias, may act as causes. Longcope's studies show that repeated absorption of proteins from the intestines may injure the heart muscle. There is a small group of cases due to a primary local focus in some organ other than the heart, *e. g.*, the teeth, tonsils and, as pointed out by Babcock and Lichty, disease of the gall-bladder. Chronic myocarditis may arise in consequence of a *direct extension* of the inflammatory processes in chronic endo- and pericarditis; it may also follow *injuries* of the anterolateral thoracic region. *Sex* and *age* possess a predisposing effect, the disease being more common in males, and after middle life than before that period. The right ventricle is apt to be the seat of chronic myocarditis during fetal life, if at all.

Symptoms.—Extensive indurated myocarditis has been met with *post-mortem* in numerous instances that have been unattended by perceptible symptoms during life. In many of these cases the presence of compensatory hypertrophy accounts for the absence of any symptoms, and it may, therefore, be inferred that mild grades that fail to manifest themselves must frequently exist. The symptoms when present are, almost without exception, untrustworthy for diagnostic purposes, since they bear a striking resemblance to those

of the organic valvular diseases minus their more characteristic physical signs. Among the earliest phenomena that point merely to failing heart power are *dyspnea*, and sometimes also, on exertion, *palpitation* and a *sense of heaviness* or *constriction* in the precordia. The patient suffers from marked general debility, and becomes *fatigued* in consequence of the slightest physical exertion. *Mental inertia* is the rule, and *chronic mania* may come on and last to the close. Later, more positive disturbances of the circulation gradually arise, and when the breathing becomes more difficult (*cardiac asthma*) signs of *venous stasis* affecting the liver, gastro-intestinal tract, and kidneys, and edema finally appear.

Two symptoms that are frequently manifested, and not without some diagnostic import, remain to be mentioned: (1) *Angina pectoris*, which is attributable to the sclerosed condition of the coronary arteries. (*Vide Angina Pectoris*, p. 666.) It is often followed by some form of arrhythmia. Recurring paroxysms of angina pectoris, with or without arrhythmia, may be the only phenomena of the disease.

Bradycardia is associated as a rule, there being a reduction in the pulse-rate to 50 or even 40 beats. With this decreased rate various forms of disturbed rhythm are also observed—*e. g.*, the phenomena of the Stokes-Adams syndrome and extrasystoles. Slowing of the pulse does not prohibit the cardiac palpitation that is apt to arise during anginal attacks. Arrhythmia, however, may be entirely absent.

Chronic myocarditis may be the sole cause of the *pseudo-apoplectic seizures* that often terminate life abruptly. Preceding the unexpected attack the patient, usually advanced in life, may have experienced from time to time slight vertigo, syncope, and oppression. These seizures may also be caused by a heavy meal or intense mental or physical exertion, and may consist in a momentary loss of consciousness. At other times they last a number of hours, and are accompanied by paralysis which outlasts the coma, as a rule, by a few hours only. Convulsive twitchings may be present. During the attack cerebral hemorrhage may occur and leave the patient hemiplegic. It is highly characteristic of these pseudo-apoplectic seizures that they tend to recur, sometimes at intervals of a few hours for a day or two, but more commonly at longer intervals during many weeks or months.

Physical Signs.—The impulse may be feebly heaving (sometimes absent); the apex-beat is displaced downward and to the left, while the dull area is enlarged correspondingly in the same direction. The *pulse* is slow, irregular, and the blood-pressure more or less elevated. Should *fatty degeneration* be conjoined, the pulse may be quickened and irregular, and this effect likewise obtains when the patient escapes sudden death and the usual dilatation supervenes. Quite early the heart sounds may be clear and strong owing to compensatory hypertrophy of the healthy portion of the myocardium, but subsequently they become weak and muffled.

With the occurrence of dilatation comes an apical, systolic murmur (due to relative incompetency), with a gallop-rhythm of the heart. A contraction of the papillary muscles and of the chordæ tendinæ may cause mitral incompetency with its customary murmur during compensation.

Differential Diagnosis.—(1) *Chronic valvular disease* can, as a rule, be eliminated prior to the occurrence of secondary dilatation, in the course of fibrous myocarditis, but not after that, even though chronic endocarditis manifests the greater degree of hypertrophy. During the period of compensation murmurs do not occur in myocarditis unless the valvular adnexa (the chordæ and papillary muscles) are affected. In cases in which these structures are involved, the secondary alterations in the heart, the symptoms, and whole course of the complaint are the same as in certain chronic valvular lesions.

(2) *Idiopathic Hypertrophy*.—After the occurrence of *dilatation*, following indurated myocarditis, the differential diagnosis between the latter and hypertrophy, with secondary dilatation, so far as the physical signs and accompanying symptoms are concerned, is purely conjectural. A clear history may furnish differential diagnostic points before failure of compensation occurs; for example, evidences of decided arteriosclerosis, due to syphilis, would be in favor of chronic myocarditis.

(3) *Fatty overgrowth* must be distinguished from fibrous myocarditis, and is met with chiefly in brewers, publicans, and butlers. The disease is also found to be specially related to obesity, and sometimes to overeating and drinking, combined with indolent habits. These subjects suffer more frequently from bronchitis, emphysema, and nocturnal asthma than patients having chronic myocarditis alone. Slight vertigo is common, but true syncopal attacks are rare. In fatty overgrowth the heart sounds are weak and decidedly muffled throughout; the pulse is weak, though regular, as a rule, and of normal rate.

Prognosis.—Chronic myocarditis is a fatal disease. Its course and duration, however, are subject to great variations. Among unfavorable surroundings are certain causal and associated conditions, particularly arteriosclerosis, chronic interstitial nephritis, and diabetes mellitus. On the other hand, if syphilis has been the cause, hope for temporary improvement, if not for actual cure, may be reasonably entertained. Sudden death may result from a blocking of a vessel that is the seat of sclerosis. Functional tests are of value in determining the state of the myocardium. This, Mackenzie says, is the important factor in prognosis and treatment. The same authority says that in estimating the functional power of the heart greater dependence can be placed upon symptoms (*e. g.*, slight dyspnea, cough, gastric disturbances, and so on) than upon physical findings.

The **treatment** should be managed according to the considerations pointed out in the treatment of Organic Valvular Disease. Rest of body and mind is imperative. Next to this come the dietetic and hygienic details. Residence in a mild climate in winter and a change to the country or to a moderate elevation in summer are advisable. Cases caused by syphilis are favorably influenced by the iodids. Those rather frequent cases that present such closely united conditions as arteriosclerosis, gout, and chronic nephritis sometimes do well while sojourning at certain mineral springs, such as Marienbad, Carlsbad, Kissengen abroad, and Bedford or Saratoga at home. These waters must, however, be cautiously used. Bell,¹ after excluding advanced arterial fibrosis, aneurysm, and advanced cardiac insufficiency with dropsy, recommends saline baths administered in a manner similar to the artificial Nauheim baths (*vide* p. 626). The so-called "Karell cure" gives favorable results in that type of cardiac disease seen in senility, emphysema, chronic alcoholism, and cachectic states.² The Oertel cure (protein diet, restriction of fluid intake, graduated exercises up hill) may prove serviceable.

When dilatation arises digitalis is called for, but must be used with an unusual degree of caution. Strychnin has proved itself to be valuable as a general tonic and stimulant if perseveringly exhibited. For the angina pectoris morphin, administered hypodermically, is to be preferred. Recurrences of this distressing symptom may be averted by the cautious use of nitroglycerin, the use of which should, however, be limited to cases that seem to be dependent upon arterial degeneration with high tension. Attacks of syncope are

¹ *Med. News*, New York, May 7, 1904.

² See Goodman, "The Use of the 'Karell Cure' in the Treatment of Cardiac, Renal, and Hepatic Dropsies," *Arch. Inter. Med.*, 1916, xvii, 809.

most successfully met by the hypodermic use of the diffusible stimulants (ammonia, ether), and at the same time by putting the patient at rest with the head lowered.

DISEASES OF THE CORONARY ARTERIES

It has previously been noted that in pyemia and allied disorders septic emboli may block the branches of the coronary arteries, causing suppurative infarcts (acute circumscribed myocarditis).

It has also been shown that one of the chief effects of sclerosis affecting the coronary arteries is the production of *chronic myocarditis*. Sudden blocking of one coronary artery by an embolus causes instant death. In numerous instances in which death has occurred suddenly either thrombotic or embolic obstruction has been the only discoverable *postmortem* lesion. In others the pathologic evidences of local or general atheroma have coexisted. Ligation or plugging of the coronary vessels in the lower animals causes arrhythmia or even an abrupt arrest of cardiac action; a partial or even slight reduction in the lumen of the coronary vessels by diminishing the supply of blood to the heart muscle induces degenerations in the latter. Kronecker found that occlusion of the coronary arteries by injecting paraffin, even when it solidified in only the smaller branches, caused the heart to become irregular, and to stop almost at once. The anatomic peculiarity of the coronary arteries in that they are end-arteries is to be noted, since it affords a ready interpretation of the usual effects following total or partial occlusion. According to F. H. Pratt, however, the vessels of Thebesius, which extend from the auricles and ventricles to the myocardial capillaries and coronary veins, may rarely maintain the nutrition of the heart muscles even after occlusion of the coronary arteries.

The blocking of the terminal branches by emboli or by the formation of thrombi usually produces the so-called *anemic necrosis* or *white infarct*—a condition that deserves brief description:

Anemic necrosis (*anemic infarct*) is met with most frequently in the left ventricle and septum, which receive their blood from the anterior coronary artery. The involved areas are small and circumscribed, and present irregular margins that project slightly above the surface. Rarely the infarct is wedge shaped. Its color is grayish-white or grayish-red, while the central portion is often white and firm; less frequently it breaks down into a soft detrital mass (*myomalacia cordis*). When softening does not occur the fibers lose their nuclei, becoming first hyaline and subsequently sclerotic. The histologic changes are of two sorts: (a) the striæ of the muscle-fibers are lost, the latter becoming granular and breaking down; and (b) the fibers assume a homogeneous hyaline appearance, the nuclei having disappeared.

The *symptomatic* consequences of the lesions are often obscure and unreliable. Sudden death may take place, and rarely this accident may be due to rupture of the heart. Weak and irregular action of the heart, evidences of embarrassed circulation (especially in the cardiopulmonary circuit, as shown by cough and dyspnea), and finally angina pectoris, are among the principal features observed. Death may ensue in the first attack. The paroxysms are presumed to be due to sudden occlusion of a branch of the coronary artery; but it should be stated that occasionally in fatal instances of true angina pectoris a total absence of lesions, including emboli, has been noted. I desire to lay stress upon the medicolegal importance of coronary disease; it may be the only lesion found in cases of quick death.

DEGENERATIONS OF THE HEART

(a) **FATTY.**—The term “fatty heart” includes two pathologically distinct affections: (1) Fatty degeneration, in which the cardiac muscle-fibers have been converted into fat; and (2) fatty overgrowth, in which an abnormal quantity of fat is deposited in and about the heart. According to Leyden, the cases of “fat-heart” (fatty overgrowth) are divisible into two substances: (a) fatty overgrowth, and (b) fatty infiltration.

FATTY DEGENERATION

Pathology.—The condition may be either general or localized. Its most frequent seat is in the left ventricle, the papillary muscles and trabeculae, first appearing as yellowish spots or stripes beneath the endocardium. The affected portions are light yellow or yellowish-brown (faded leaf) in color, due to an associated brown atrophy; they are soft and friable, and are easily lacerated. The heart is enlarged and its walls lack firmness. The microscope reveals characteristic changes: the striæ and nuclei begin to fade, oil-drops and granules appear in the fibers, and finally the latter are occupied throughout by minute globules.

Etiology.—Fatty degeneration, as already mentioned, occurs in both the *primary* and *secondary* forms of *cardiac hypertrophy*. It is found, in association with fatty change in other organs, in severe forms of *primary* and *secondary anemias*. It is most common, however, in the *cachectic states* produced by such chronic diseases as carcinoma and phthisis, and in the course of *acute infectious diseases* of intense type. Warthin finds that focal or diffuse fatty degeneration of the myocardium may be associated with numerous spirochetes of syphilis without interstitial change. In poisoning by arsenic and phosphorus and in pernicious anemia it advances to a high grade. The various lesions of the *coronary arteries* previously considered bear the most significant causal relation.

Predisposing causes are: (a) *age*—it being most common after forty years of age; (b) *sex*—it occurs somewhat more frequently in men than in women, notwithstanding the fact that there are predisposing influences at work in the latter that do not obtain in the male sex, such as childbirth; and, lastly, (c) whatever may be its apparent etiology, it is invariably preceded by a defective nutritive supply to the muscle-cells; this may be dependent upon a narrowing of the lumen of the coronary vessels, or upon impairment of the oxygen-carrying power of the blood, as in the anemias. An excessive supply of glucose, glycogen, and nuclein may be a factor.

Symptoms.—The disease may exist in an advanced form without noticeable symptoms, though the conditions under which it is most liable to occur afford secure ground for suspicion. The evidences of *cardiac enfeeblement* are usually present, but in pernicious anemia and chlorosis the pulse may even be full and regular.

Dilatation is apt to supervene early, owing to the weakened state of the heart; and hence many of the symptoms are due to secondary dilatation. Among these are *palpitation*, *dyspnea*, a *small, irregular*, and somewhat *quickened pulse*, and *cool and clammy extremities*. The heart sounds are weak, as a rule, and the action of the heart often irregular. *Dropsy* is rare in uncomplicated cases. Sometimes sudden, great physical exertion produces equally sudden dilatation, whereupon a canter-rhythm and an apical systolic murmur develop. In most instances, however, the symptoms of dilatation are more gradually brought to light. *Breathlessness* on exertion is often a striking feature, and syncopal attacks are sometimes troublesome. The *pulse* often

becomes greatly retarded. The fatty *arcus senilis* is devoid of diagnostic value. There are frequent attacks of *cardiac asthma* in the mornings, and these are apt to be accompanied at intervals by *angina pectoris*. *Disturbance of the intellect*, sometimes taking the form of maniacal delusions, may come on and persist. Syncopal attacks occur. *Pseudo-apoplectic attacks*, such as have been described (*vide* Chronic Myocarditis), may occur. *Cheyne-Stokes breathing* is among the later manifestations. It happens that this symptom and pseudo-apoplectic seizures are found in association; they are more apt to be due to uremic toxemia, perhaps, than to fatty degeneration of the heart. Epileptiform attacks resembling *petit mal* may arise.

The **diagnosis** is sadly obscure. The history, the age of the patient, and the symptoms of cardiac weakness and subsequent dilatation, together with retardation of the pulse, apoplectic attacks, and Cheyne-Stokes breathing, in the absence of precedent hypertrophy merely justify a probable diagnosis. With a clear history and the presence of the more significant symptoms, including the signs of dilatation following hypertrophy, fatty changes may be inferred with some degree of assurance, although a positive opinion should be withheld.

The **prognosis** is as varied as the etiology. Death may come quickly, the process being commonly associated with sclerosis of the coronaries, though oftener the end is reached in a gradual manner, the signs and symptoms of advanced dilatation dominating the closing scene. The more corpulent the subject, the graver the prognosis.

Treatment.—The cause in each individual case should be determined, and when ascertained a bold attempt should be made to remove it. This course often places the patient in the most favorable position for the successful treatment of the cardiac condition. Anemia in one form or other plays an important rôle in the majority of the cases, and the particular variety present in each instance must determine the character of the remedies to be employed. In that large category of cases occurring in certain cachexias (cancerous, tuberculous) hematinics, arsenic, and strychnin are the remedies of choice.

A frequent, irregular pulse and other signs of cardiac failure indicate commencing dilatation, and under these circumstances digitalis should be employed in *small doses*. When found to be serviceable, its use should be continued until the dilatation is overcome; it may be conveniently combined with other cardiants.

I believe that gentle indulgence in physical exercise and light gymnastics is beneficial, since it tends to invigorate the heart muscle; it is to be increased in proportion to the manifest improvement in the patient's condition. It sometimes happens, however, that even gentle exercise is badly borne, and it should then be discontinued. Kinesitherapy, particularly the milder Swedish method of gymnastic exercises (alternating movements of resistance), increases the contractile power of the heart and at the same time lessens the peripheral resistance, and should be accorded a careful trial. I have been in the habit of advising daily inhalations of oxygen gas in this class of cases with good results. Recourse to massage is also in the line of sound practise, but the sittings should not exceed one-half hour in duration at the start. The more *prominent symptoms* may require special measures. The syncopal and anginal attacks are to be handled in the manner indicated for the same symptoms in chronic myocarditis. For the pseudo-apoplectic attacks rest in the recumbent posture, with the head slightly elevated, is useful. Therapeutic agents, as digitalis, ammonia, and ether, may be used hypodermically to stimulate the heart; it is also good practice to withdraw from 12 to 24 ounces (360.0–720.0) of blood directly from a vein. If the arteries be hard and tense, nitroglycerin is of distinct service.

A strictly horizontal posture and the application of ice to the precordial region often quickly terminate the attacks of cardiac asthma, and spartein sulphate, with nitroglycerin, is worthy of a trial. Hot toddy and other diffusible stimulants are valuable adjuvants. Should these remedies fail, hypodermic treatment by morphin is to be adopted.

FATTY OVERGROWTH

Pathology.—The normal fat, particularly in the auriculoventricular furrows, is increased. I have elsewhere suggested the term "subpericardial overfatness,"¹ to indicate the condition when unaccompanied by fatty infiltration. This overproduction of fat may become so excessive as to form a complete enveloping mantle measuring an inch or more in thickness. In these extreme grades the muscular fibers may, from too great pressure, undergo atrophy and thus become weakened.

Etiology.—The principal cause is general corpulency. (For a consideration of the factors predisposing to fat production, see Obesity.) In the cachexias of carcinoma and phthisis, and the general atrophy of old age, fatty overgrowth and fatty degeneration coexist.

Symptoms.—The condition may be unaccompanied by any symptoms. The muscle-fiber is weakened (not degenerated, as a rule), hence extra labor suddenly thrown upon the organ excites the clinical indications of a weak (dilated) heart, as urgent dyspnea, vertigo, syncope, palpitation and cyanosis. Later, recurrences arise on every provocation. Distressing attacks of asthma may develop after a full meal or without an apparent exciting cause. A passive form of bronchitis may supervene. The cardiac impulse is feeble and may even be missing. The pulse is, as a rule, regular and moderately tense. Slight intermittence and, in marked heart weakness, decided arrhythmia may be noted. In moderate grades the heart-sounds may be clear; in marked cases with ensuing dilatation a systolic, apical murmur may be audible.

The **diagnosis** rests upon the combined presence of marked obesity and cardiac enfeeblement. (For the **differential diagnosis**, see p. 647.)

Treatment.—I wish to advocate warmly the system of treatment introduced by Oertel, as I have seen excellent results from its employment. It should not be resorted to in chronic valvular disease, in the stage of broken compensation, nor in marked atheroma.

Oertel's method comprises three parts: (1) The reduction of the amount of liquid taken with the meals and during the intervals, the total for each day being 36 ounces (1 liter). Frequent bathing (including the Turkish bath in suitable instances) and pilocarpin are employed to promote free diaphoresis.

(2) The diet is composed largely of proteins, as follows: *Morning.*—A cup of coffee or tea, with a little milk—about 6 ounces (180.0) altogether; bread, 3 ounces (90.0).

Noon.—Three to 4 ounces (90.0–120.0) of soup; 7 to 8 ounces (210.0–240.0) of roast beef, veal, game, or poultry, salad or a light vegetable, a little fish; 1 ounce (30.0) of bread or farinaceous pudding; 3 to 6 ounces (90.0–180.0) of fruit for dessert. No liquids at this meal, as a rule, but in hot weather 6 ounces (180.0) of light wine may be taken.

Afternoon.—Six ounces (180.0) of coffee or tea, with as much water. An ounce of bread as an indulgence.

Evening.—One or two soft-boiled eggs, 1 ounce (30.0) of bread, perhaps a small slice of cheese, salad, and fruit; 6 to 8 ounces (180.0–240.0) of wine, with 4 or 5 ounces (120.0–150.0) of water (Yeo).

¹ *Amer. Jour. Med. Sci.*, April, 1901.

(3) Graduated exercise up inclines of various grades. The distance to be undertaken each day is to be carefully specified and frequently, though gradually, increased. A like plan is to be pursued with reference to the degree of inclination. This is the most important part of the system, since it directly invigorates the heart muscles.

Fatty Infiltration.—This condition may be associated with grave forms of myocardial degeneration, principally fibroid and fatty. In this place the term is limited in application to an infiltration or a dipping of fat between the muscle-fibers even to the endocardium, that is, *secondary* to extreme obesity (*e. g.*, the anemic variety). It is clearly a rare condition if we except the not uncommon instances in which the morbid process is limited to a thin layer of muscle-fibers situated directly beneath the epicardium. I have reported 5 and collected 7 additional cases from the literature. The subjects are extremely obese.

The *symptoms* may develop abruptly, after some unusual muscular exercise or after a profound systemic shock. More commonly, however, the clinical indications, which are not sharply defined as a rule, manifest themselves in a gradual manner. The principal features are *urgent dyspnea* (often an asthmatic form of breathing), and *utter exhaustion* upon muscular exercise, *precordial discomfort*, *pain under the sternum*, *cardiac palpitation*, *arrhythmia*, *syncope*, *vertigo*, *cyanosis*, and *angina pectoris*. Marked and constant disturbance of the cardiac rhythm is symptomatic of fatty infiltration. Hydrostatic *bronchitis*, with cough and expectoration, is commonly present. The *angina pectoris* may be dependent largely upon associated sclerosis of the arterial system. Emotional disturbance and mental apprehension were the chief nervous phenomena in my cases. The *physical signs* are neither constant nor characteristic; they are, in the main, those of cardiac dilatation. The *pulse* may be regular and of good tension, but after dilatation comes on it becomes irregular, frequent, and easily compressible. Moderate hypertrophy probably exists in the majority of cases, but cannot always be demonstrated owing to the extreme subpericardial overfatness. A basic systolic murmur may be heard; it is not due to valvulitis as a rule. The *prognosis* as to cure is almost hopeless, although marked improvement may follow appropriate treatment. A fatal termination is often due to spontaneous rupture of the heart. The *treatment* must be directed especially to the overfatness and the cardiac dilatation.

(b) BROWN ATROPHY.—A form of degeneration in which accumulations of yellowish-brown pigment-granules occur in the muscular fibers. The color exhibited by the heart muscle is a reddish-brown, and in pronounced cases a dark red brown. Brown atrophy is most commonly seen in the hearts of the aged, although also quite often in cases of chronic valvular disease that have reached an advanced stage.

(c) CALCAREOUS DEGENERATION (*Calcification*).—Calcareous infiltration of the muscular fibers of the myocardium has been noted, though very rarely. Somewhat more common are the bony callosities that result from myocardial abscesses (*vide* Circumscribed Myocarditis).

(d) AMYLOID DEGENERATION.—This form of degeneration is rare. It is limited to the blood-vessels and interstitial connective tissue; its causes are the same as those of amyloid degeneration of other viscera.

(e) HYALINE DEGENERATION.—This is sometimes seen in association with amyloid change. It also occurs independently in prolonged fevers (*hyaline transformation of Zenker*). The fibers are swollen, translucent, and homogeneous, and their striæ almost entirely disappear.

CARDIAC ANEURYSM

(Aneurysm of the Heart)

A cardiac aneurysm may involve either the whole diameter of the myocardium (aneurysm of the walls),¹ or merely the valves, together with a few myocardial fibers. Aneurysmal dilatation of the coronaries due to sclerosis or embolism is also recognized.

Aneurysm of the Walls.—This is not of frequent occurrence. Its most common seat is the wall of the left ventricle near the apex; it is quite generally a sequel to chronic myocarditis, which occurs oftenest at this point. In size cardiac aneurysms are exceedingly variable, and may either be very small or as large as the average-sized head of an adult. As to form, two types should be recognized: (a) an equable dilatation of a part of the ventricular wall, and (b) the sacculated form. Layers of fibrin are often found in these aneurysmal dilatations—an indication of Nature's attempt at a cure, and occasionally she is successful. Once an aneurysmal distention has begun, a straining effort may cause sudden increase of its dimensions or rupture it. The structures adjacent to the aneurysm exhibit fibrous overgrowth. This condition may rarely be congenital. Males are more commonly affected (74 per cent.—Hare).

Diagnosis.—Aneurysm of the myocardium has no characteristic features. Usually the *symptoms* and *local signs* of chronic myocarditis or *dilatation* are more or less conspicuous, but the presence of the aneurysm is not even suspected unless certain physical signs develop. These are: a *pulsating prominence* in the apex region that may even perforate the chest-wall, and a coextensive dulness. The abnormal area of dulness, which is peculiarly circumscribed, is best appreciated early by stethoscopic percussion. An aneurysmal dilatation may also be confirmed by the roentgen rays or the orthodiagram. The *course* of these cases is unfavorable, death ensuing (rarely) from rupture of the sac or (more frequently) from gradual cardiac exhaustion.

Valvular aneurysms sometimes arise in acute ulcerative endocarditis, which destroys the segmented endocardium and permits of dilatation as the result of the intracardial blood-pressure. They occur with much greater frequency on the aortic than on the mitral valves. They are spheroid in shape, and project into the left ventricle when found at the aortic segments, and into the left auricle when at the mitral. Rupture of these aneurysms is common, with the subsequent development of valvular incompetency. They cannot be *diagnosed* during life.

RUPTURE OF THE HEART

This rare and serious accident may either be *complete* or *partial*. The term "partial rupture" implies laceration of the trabeculæ ventriculi, whereby the chordæ are liberated. Rarely, the papillary muscles are torn, causing valvular incompetency. Complete rupture consists in a solution of continuity of the total diameter of the myocardium.

Pathology.—The chief seat of rupture is the anterior wall of the left ventricle, though it may also occur in the right ventricle and in the auricles. The rent runs parallel with the muscular fibers, and is to a certain extent the result of laceration, although chiefly of a separation, of the fibers. The fissural communication presents irregular edges, and at autopsy is seen to contain

¹ Of 87 cases collected by Pelvet, 57 were in this situation, and of 90 collected by Legg, 59.

blood-clots; the pericardial sac is also occupied by coagula. If pericardial adhesions have previously obliterated the cavity, the escaped blood-clots may occupy the pleural cavity. Histologic examination of the adjacent muscle structure shows the characteristic changes of fatty and other forms of degeneration.

Etiology.—Both *predisposing* and *exciting* causes may be at work. The former are the more important and, named in the order of their frequency of occurrence, are: disease of the coronary arteries (with anemic necrosis and abscesses), fatty degeneration,¹ fatty infiltration, chronic myocarditis, parietal tumors, and parasites in the heart wall.

The influence of *age* is notable; rupture of the heart usually occurs after the sixtieth year has been passed. Males suffer somewhat more frequently than females. The exciting cause is, as a rule, some form of muscular exertion, though it may occur during sleep.

Symptoms.—In the majority of instances rupture of the heart results in *sudden death*. Sometimes, however, the patient survives the accident for several hours or even for as many days. The symptoms are those of *internal bleeding*, and *pain* that may be agonizing and is referred to the heart. The body temperature falls, the skin surface becomes pale and cool, and it may be covered with cold perspiration, while the *pulse* grows small, very frequent, and finally almost vanishes. Occasionally gastro-intestinal symptoms and syncope tending to convulsions appear in consequence of the irritation of the vagus centers due to cerebral anemia. The *physical signs* of cardiac failure rapidly develop, and, if the leak be not too large, those of pericardial effusion more gradually.

Diagnosis.—Heart anguish, rapidly progressive cardiac failure, the evidence of internal hemorrhage, and the speedy development of the signs of pericardial effusion should always excite suspicion of rupture, and in many cases suffice for a correct inference.

The **prognosis** is hopeless. When immediately fatal, death is the result of heart shock; it may result from anemia of the brain or compression of the heart by the effused blood.

Treatment.—*Prophylaxis* is of the utmost importance. The physician should give ample warning of the dangers connected with muscular strain of whatever sort. If rupture has either occurred or is suspected, the patient must be put at complete rest in the horizontal position. Full doses of morphin should be given hypodermically, and the ice-bag locally applied. Warmth to the extremities may be useful. The use of cardiac stimulants will be attended with increased bleeding from the rent, but agents that relax the peripheral arterioles, such as nitroglycerin, may be employed with a view to diminishing the heart's labor without diminishing its power. Should rupture be partial and the hemorrhage slight, the patient's life may be prolonged, or even saved, by keeping him at absolute rest for a long period.

MINOR AFFECTIONS OF THE HEART

(a) **NEW GROWTHS.**—Primary carcinoma or sarcoma is rare indeed. Metastatic growths occur, but are very rarely sufficiently large (except perhaps the colloid variety) to be detected by *physical examination*, or to give rise to symptoms. Rarely, large tumors may weaken the heart. The separation of portions of the tumor may block one of the valvular orifices and cause sudden death, or

¹ According to Quain's statistics, about 75 per cent. of the cases are due to this cause.

more minute portions, becoming released, may give rise to embolism in distant parts.

(b) **PARASITES.**—Four forms may invade the heart muscle—the *Tania echinococcus*, actinomyces, *Cysticercus cellulosæ*, and the *Pentastomum denticulatum*. The former two only are productive of mischievous results. The echinococcus growths may attain to considerable dimensions and are often multiple; they are secondary to echinococcus cysts in other organs. Their effects are produced in a purely mechanical manner unless fragments become detached, when they may excite embolic lesions at different points in remote organs.

(c) **MISPLACEMENT** (*Transposition of the Heart*).—During intra-uterine life the heart (and rarely all the other thoracic and abdominal viscera) may either be transposed to the right side of the thorax, or the fetal position—in the median line—may be retained. The sternum may be missing in whole or in part, and the heart, which now lies immediately beneath the skin, can be seen and felt as a throbbing tumor. Recently an apparently healthy man of about forty years applied at the Medico-Chirurgical Hospital in whom the lower half of the sternum was absent; his heart occupied a position in the median line directly underneath the skin.

Very exceptionally other anomalous positions are acquired during antenatal development, and the heart may become displaced upward in the chest cavity even to the neck or downward into the abdominal cavity.

(d) **FLOATING HEART.**—The structures that serve to maintain the heart in its normal anatomic relations may become weakened and unduly lax, in consequence of which the organ may exhibit increased motility.

III. NEUROSES OF THE HEART

PALPITATION

Definition.—A more or less rapid action of the heart that is perceptible to the patient, and usually accompanied by an increased force of the cardiac contractions or a disturbance of the rhythm, including extrasystole (*vide infra*), and often also by precordial distress, anxiety, and dyspnea.

Etiology.—Chronic valve disease and other organic affections of the heart seldom produce palpitation. Among predisposing causes are: (1) Mental excitement, depression or emotion. (2) Anemia (from the local irritant action of the altered blood state). (3) The acute infectious diseases, in which the toxins in the blood irritate the cardiac accelerating nerves. (4) Dyspepsia, even in robust-appearing persons (as in the gouty) who wittingly or unwittingly commit dietetic errors. Special articles of diet may excite overaction (*e. g.*, strawberries, shell-fish), the palpitation thus arising from reflex irritation being dependent upon gastric catarrh. (5) The use and, more especially, the abuse of tea, coffee, alcohol, and tobacco. (6) The female sex manifests a greater disposition to the complaint than the male, especially about the period of puberty and the menopause. In the male it is most common at or after the middle period of life, a time when the effect of the work and worry of life show themselves. (7) Disturbances of the pelvic organs may possibly induce palpitation reflexly.

Symptomatology.—Cardiac overaction, as a rule, displays a definitely *paroxysmal* character. The *onset* is sudden, and immediately preceding the

attack there are often a blanching of the face and a slowing of the cardiac action, symptoms due to the momentary inhibitory effect of the nerve affections that cause the "palpitation." The patient's *perception* of increased force and rapidity of the heart's action is the essential symptom. The patient may complain of *palpitation*, with a normally acting (or, more rarely, abnormally slow) heart, the symptoms being wholly subjective in character. *Mental anxiety* is common, and dyspnea, the latter symptom assuming curious phases.

Physical Signs.—*Inspection* shows the impulse to be somewhat diffuse and forcible. Visible throbbing of the superficial vessels is also common. The *finger-tips* easily appreciate the increased strength of the impulse. At the wrist the pulse, though strong and full, as a rule is rapid, the rate varying from 120 to 160 per minute. *Percussion* does not show the area of cardiac dulness to be enlarged as a rule, while *auscultation* reveals louder sounds than the normal. Anemic murmurs may be present. The attack is usually of brief *duration*—but a few minutes—though sometimes it may last for hours or days.

Attention should here be called to the *irritable heart* described by DaCosta—a form of palpitation common among young soldiers during the late Civil War. It was caused partly by mental excitement and partly by inordinate muscular exertion. A minor part in its production was also played by diarrhea. The leading symptoms were palpitation, a very frequent pulse, dyspnea, and cardiac pains of varying intensity. Sir James Mackenzie has described a sharply defined clinical picture as follows: A sense of exhaustion, breathlessness on slight exertion, a rapid pulse, which becomes more rapid on the slightest attempt at action; pain over the precordial region or along the left costal margin, and a vasomotor condition of greater or less stability. The blood-pressure may be high and systolic murmurs heard in different regions. Mackenzie attributes the majority of the cases to bacterial and toxic influences.

Differential Diagnosis.—Nervous palpitation must be distinguished from the comparatively rare cases in which the heart contracts rapidly and irregularly, but does not excite subjective sensations. Some of the latter instances are to be looked upon as physiologic, while others are due to exhaustion and other causes. They do not constitute cases of palpitation, since they are unperceived by the patient.

Palpitation due to *chronic valve disease* should also be differentiated. Here chief reliance is to be placed upon the presence of a murmur and other physical signs during the intervals between the attacks. The presence of a diastolic murmur would exclude nervous palpitation.

Prognosis.—The condition is free from real danger to life. Most authors, however, are agreed that cardiac hypertrophy may be a sequel.

Treatment.—The chief indications for treatment are: (1) *The arrest of the paroxysm.* The patient must be put at absolute rest in bed in a large, well-ventilated, darkened chamber, and his clothing loosened so that the respiration is unimpeded. Pressure upon the vagus in the neck sometimes arrests the attack. An ice-bag applied to the precordial region is useful; it should be removed every third hour in protracted cases, and the patient be told to take large drafts of cold water or to swallow bits of ice. On the other hand, I have observed a few instances which were speedily relieved by the ingestion of hot and somewhat stimulating drinks.

Among the many drugs that have been employed, morphin alone has given good results, and particularly when administered hypodermically. However, before employing morphin, other sedatives and narcotics should be tried, such as the bromids (in large doses), hyoscyamus, hyoscin, and camphor monobromate. In hysteric subjects the bromids and the preparations of valerian are highly serviceable. I have found the following capsule of great utility:

R. Strychninæ sulph.,	gr. $\frac{1}{3}$ (0.02);
Zinci valeratis,	gr. x (0.65);
Extr. hyoscyami,	gr. v (0.32);
Extr. sumbul,	gr. x (0.65);
Extr. gentianæ,	q. s.
M. et ft. cap. No. x.	
Sig. One after each meal.	

If a special article of diet or an overloaded state of the stomach is the cause, an emetic may be given and the attack thus speedily controlled. Oxygen inhalations have been warmly advocated.

(2) *To prevent a recurrence of the paroxysms*, the causal conditions, some of which may long antedate the occurrence of palpitation, must be removed, if this be possible. All exciting factors must also be avoided. When cardiac palpitation occurs in neurasthenia and hysteria the Weir-Mitchell rest-cure should be advised. If the heart be weak, digitalis may be exhibited. I have observed good effects from the use of baths (carbonated).

TACHYCARDIA

(*Synchopezia; Rapid Heart*)

Definition.—A rapid movement of the heart directly dependent upon either paralysis of the pneumogastric, stimulation of the sympathetic nerves, or disease of the heart. Martius believes that the condition is attributable to sudden dilatation. Gordon¹ claims that tachycardia may be determined by dilatation of the splanchnic area, diminishing greatly the supply of blood to the left ventricle.

Pathology and Etiology.—It occurs as a physiologic condition in certain individuals; in such cases the pulse may range from 90 to 100 beats per minute or over. Certain persons can increase the pulse-rate by their own volition. The following table, modified from Mackenzie, indicates the various conditions which may be associated with a continuously rhythmic rapid heart rate:

(1) *Valvular Disease.*—A rapid heart rate associated with valvular lesions is usually an indication of failing muscle.

(2) *Myocardial Disorders.*—Weakness of the heart wall is usually first shown by a tachycardia, which may be induced by physical effort only and which is out of all proportion to the amount of work.

(3) *Exogenous Toxins.*—These include alcohol, arsenic, tea, coffee, tobacco, and the products of bacterial infection notably.

(4) *Endogenous Toxins.*—The toxic substance elaborated in the thyroid, an iodized protein, seems to have an almost specific stimulating effect on the cardiac accelerators of the sympathetic system.

(5) *Neurotic Conditions.*—The causes of this variety are identical with many of those that excite palpitation. Thus, among disposing factors are hysteria, anemia, neurasthenia. Violent exercise, intense mental agitation, fright, pain, grief, and other forms of shock are determining influences. Not a few cases are met at or about the menopause.

(6) *Lesions of the Nervous System.*—The lesions that induce this form are: (a) *central* and (b) *peripheral*. In the former group are especially to be placed

¹ *Brit. Med. Jour.*, March 12, 1910.

tumors, clots (due to hemorrhage), and softening of the medulla and cord; and in the latter, tumors, aneurysms, enlarged lymph-glands (which paralyze the vagus by exerting pressure upon it either in the neck or thorax), and neuritis, affecting the pneumogastric nerve. The latter lesion may be associated with polyneuritis (alcoholic or infectious).

(7) *Exhausting Diseases*.—Cancer, severe anemia, and other wasting diseases are accompanied by rapid pulse-rate.

(8) *Hemorrhage* if at all severe produces tachycardia probably as a result of the loss in blood mass at first, later as a result of nutritive changes in the heart and nervous system.

(9) *Pregnancy* is associated with tachycardia.

BRADYCARDIA

(*Brachycardia*)

Definition.—Slowness of the pulse. The condition may be physiologic, the rate of the pulse being sometimes 60 or less, and very rarely as low as 40 per minute during perfect health.

All cases of pathologic bradycardia fall naturally and conveniently into two groups: (1) those that are secondary to other complaints (*symptomatic bradycardia*), and (2) those that are due to neurosis.

Pathology and Etiology.—**Symptomatic Bradycardia.**—(a) Arising during convalescence from acute infectious diseases, especially *pneumonia*, *typhoid*, *diphtheria*, *influenza*, and *acute rheumatism*. According to Riegel, who analyzed 1047 cases, the *acute fevers* must be awarded the first place among the causal factors. I have met 3 cases of diphtheria in which the pulse fell to 30 a minute. That such instances are, as Traube contends, due to exhaustion is true of some cases, but not of all. The slowing of the pulse that is observed after premature or full-time delivery is similarly produced. (b) The second place belongs easily to gastro-intestinal and hepatic disorders (*chronic gastro-intestinal catarrh*, *ulcer*, or *carcinoma of the stomach*). (c) Bradycardia occurs in diseases of the circulatory system—in *coronary disease*, fibroid and fatty myocardial change, most frequently; and chronic valvular disease much less frequently, if we except aortic stenosis. It generally occurs with heart-block, whether organic, or functional, or from digitalis. In extrasystoles the premature contraction of the ventricle may be too weak to cause arterial pulsation. Some cases of auricular fibrillation show a slow pulse for the same reason or because of digitalis therapy. (d) Pulmonary complaints (emphysema and asthma). (e) Toxic agencies, as in jaundice, blood-poisoning, alcoholism, the unwonted use of tea, coffee, tobacco, and a few drugs (*e. g.*, coal-tar drugs). (f) Constitutional affections (anemia, chlorosis, gout, diabetes). (g) Rarely skin diseases and affections of the sexual organs, various grades of hypothyroidism, and commonly myxedema, are associated with bradycardia. (h) In various organic nerve affections (apoplexy, meningitis, epilepsy, tumors of the cerebrum and the medulla, injuries, and diseases of the cervical portion of the cord). Among soldiers in the trenches Binet's studies show that wounds of the skull and of the chest, when the heart is affected, cause bradycardia. Bradycardia is produced by direct or reflex irritation of the center or peripheral portion of the vagus except in cases in which it is brought about by exhaustion of the automatic motor apparatus of the heart. The condition is more common in men.

THE ARHYTHMIAS¹*(Irregular Heart- and Pulse-beat)*

Our knowledge of this subject has been advanced by the investigations of Wenckebach, Th. Lewis, J. Mackenzie, Walter B. James, Lewellys F. Barker, and others as the result of observations with the electrocardiograph. James suggests that the cases be classified into rhythmic irregularity and arrhythmic irregularity. The myogenic theory may explain the functional rhythmicity of the heart's action, but while the heart doubtless has the power of originating stimuli to cause contraction, it is held by many that the heart acts only in response to nerve stimulation under normal conditions—the neurogenic theory. Among recognized functions of the heart muscle are excitability, stimulus production, contractility, conductivity, and tonicity (Gaskell). As shown by Mackenzie and others, not all the heart muscles are equally endowed with these functions. The clinician must attempt to correlate the symptoms of the different forms of arrhythmia with condition of the different functions of the cardiac muscle. The arrhythmias include the following types of irregularity of heart action:

1. Sinus arrhythmia.
2. Extrasystole (premature contractions).
3. Auricular fibrillation.
4. Auricular flutter.
5. Heart-block.
6. Paroxysmal tachycardia.
7. Pulsus alternans.

SINUS ARHYTHMIA

(Juvenile, Respiratory, Vagus, Adolescent, etc., Arrhythmia)

This is a type of cardiac arrhythmia characterized by irregular ventricular contractions as a result of disturbances in the rhythm of impulses discharged from the sino-auricular node, termed by Lewis the pace-maker. The pace-maker is controlled by the vagus which inhibits its action. Stimulation or depression of the vagus is followed by slowing or increasing the heart-rate. In children and young adults there is an abnormal vagal irritability. As a result of this during respirations, particularly when deep inhalations are taken, the irritable vagus is alternately stimulated and depressed, and so from the pace-maker flow impulses which vary in the time interval of their discharge. Thus the pulse-rate, upon palpation of the artery, is found to vary during the respiratory phases. In adults sinus arrhythmia is indicative of vagus instability. This type of arrhythmia is normal in the young, while in adults it is of little diagnostic or prognostic importance. It is purely a vagus nerve condition and has practically no effect upon the heart itself.

EXTRASYSTOLE

(a) Intermittent heart-beat. This signifies a premature contraction generally arising in the auricle or the ventricle, and the response of the heart to this impulse. This response occurs at irregular intervals in most of the cases,

¹ An enormous amount of work has been done in recent years upon the cardiac irregularities as a result of the use of the electrocardiograph. Consequently, there is a large amount of literature to which reference might be made. Th. Lewis has summarized a large part of this in his excellent books—*The Mechanism of the Heart-beat* and *Clinical Disorders of the Heart-beat* (Shaw & Sons, London). To these the reader is referred for a more complete exposition of the subject than is possible in a text-book of this character.

though sometimes a cyclic irregularity is observed—*i. e.*, every second, fourth, sixth, or eighth beat being an extrasystole. To explain the premature contractions that arise in the ventricle it must be remembered that the ventricle contracts as a result of stimuli from the auricle. If an impulse arises in the ventricle a premature contraction occurs, which is followed by a long pause. As explained by Engelmann, this long pause is a consequence of the premature contraction, the ventricle being still in the refractory stage (lacking excitability) when the next physiologic stimulus reaches it, and it is not until the following stimulus arrives that contraction can again be produced. On the other hand, premature contractions arising in the auricle are followed by ventricular responses, as this ventricle always responds to auricular contractions placed in a series. The auricular extrasystole is followed by a pause which plus the preceding beat is, however, not equivalent to two full cycles of the normal rhythm as is the ventricular extrasystole with its preceding beat (period of disturbance).

The various forms of arrhythmia described below are due to the occurrence of these extrasystoles. (*b*) Twin pulse (coupled beats, allorhythmia). When two beats follow each other quickly (the diastole being shortened), and the next two not so quickly (the diastole being lengthened), we have produced the *pulsus bigeminus*. The first and second beats may be of equal strength, but often the second is relatively feeble. This is best determined by auscultation of the heart, since the second systolic contraction (of the ventricle) may, indeed, be so weak as not to give rise to a palpable beat at the wrist. I have frequently observed the *pulsus bigeminus* in mitral disease. With respect to the diastole, the approximated pulsations may be in blocks of three (*pulsus trigeminus*) or even of four (*pulsus quadrigeminus*).

Etiology.—Baumgarten's classification of the causes of extrasystoles (quoted by Osler) is the best, and is here given:

(1) Those due to central—cerebral—causes, either organic disease, as in hemorrhage or concussion, or, more commonly, psychical influences.

(2) Reflex influences, such as produce the cardiac irregularity in dyspepsia and diseases of the liver, lungs, and kidneys. Fatigue in those predisposed.

(3) Toxic influences. Tobacco, coffee, and tea are common causes. Various drugs, as digitalis, belladonna, and aconite, may induce it.

(4) Changes in the heart itself. (*a*) In the cardiac ganglia. Fatty, pigmentary, and sclerotic changes have been described in cases of this sort. (*b*) Mural changes are common in conditions of this kind. Simple dilatation, fatty degeneration, and sclerosis are most commonly present. In every case of extrasystole, no matter what the cause, reflex or otherwise, there must, of necessity, be some pathologic lesion in the heart or its nervous mechanism. A high blood-pressure may be associated with extrasystoles.

Excluding sinus arrhythmia, about 40 per cent. of the cardiac irregularities are caused by extrasystoles.

Symptoms.—Extrasystolic arrhythmia, particularly when functional or of reflex origin, may exist for many years. Symptoms referable to the heart may be absent, although in some instances the extrasystole causes a thud to be experienced, or the feeling as if the heart "had turned over"; a feeling of emptiness in the region of the pericardium sometimes follows the long pause of the ventricular extrasystoles.

Diagnosis.—Palpation and auscultation of the heart while examining the pulse are matters that should never be neglected if reliable results are to be obtained. A strip of tracing from the radial artery will suffice to show whether the extrasystole is auricular or ventricular in origin by measuring the distance between the beat preceding the premature combination and the end of the ex-

trasystole. In ventricular premature contractions the distance is equivalent to two full cycles; in auricular premature contractions it is not. The electrocardiograph will locate definitely the origin of the extra impulse, whether from auricle, ventricle, or some other portion of the heart.

It is important to differentiate functional extrasystole or that of reflex origin from that due to more or less grave myocardial disease. Important information is supplied by carefully reviewing the varied etiologic factors and close observation of the cardiac symptoms. Laubry and Harview have made a study of the modification of the heart rhythm by pressure on the eyeball, and explain the way in which this effects the contraction of the heart. It was found in one case in which repeated examinations failed to disclose organic trouble that pressure on the eyeballs caused the heart rhythm to change. The oculocardiac reflex may thus elicit symptoms that betray organic mischief otherwise impossible to detect.

The **prognosis** is variable. A gentleman with whom I am acquainted was rejected by a life insurance company twenty-five years ago on account of occasional slight extrasystolic arrhythmia, though he is still in active business life. When the myocardium is involved, as occurs in chronic valvular and coronary disease, the prospect is gloomy; on the other hand, when it is nervous in origin or due to extracardial causes, the course pursued is, as a rule, favorable.

Treatment.—There are many cases of the more benign form in which no treatment is required apart from methodic, physical training to improve the strength of the heart muscle and the general systemic development. Removal of the causal forces—tea, coffee, alcohol, indigestible food-stuffs, conditions acting in a reflex manner—must be executed promptly. There are no drugs known which have any direct influence on extrasystoles. Digitalis is contra-indicated if given for any direct effect. When the condition is associated with changes in the heart structures, cardiants, in addition to the general tonics, should be prescribed, of which I prefer strychnin, arsenic, and the dried sulphate of iron in combination. Nitroglycerin is of service if the arterial tension be high. If the arrhythmia be associated with cardiac dilatation, digitalis should be employed. If in functional cases, in which there is a predominating neurotic element, the subjoined formula has been useful in my hands:

R. Strychnin sulph., gr. j (0.065);
 Zinci valeratis,
 Ferri valeratis, āā gr. xxx (2.0).
 M. et ft. cap. No. xxx.
 Sig. One after each meal.

auricular fibrillation

Definition.—A condition due to abnormal impulses arising in different auricular areas, and replacing the normal regular stimulus which is produced by a single area.

The condition is closely connected with extrasystoles, auricular flutter, and heart-block. The systoles of the auricle and ventricle do not follow one another regularly. The ventricle receives instead of an abnormal stimulus or impulse, as in extrasystole, a variety of impulses, and in endeavoring to respond to these “increases its rate, and its contraction becomes entirely irregular” (Talley). There are no constant or definite morbid lesions, and in some of the cases apparently nothing abnormal is noted. Certain microscopic changes in the auricular tissue are most commonly met with—*e. g.*, atrophy of the muscle cells and a diffuse fibrosis.

Etiology.—Lewis' analysis of 126 cases showed an antecedent history of either rheumatism or chorea in 70 per cent. Among non-rheumatic subjects it was more frequent in males than females, and was commonest in advanced life. In the rheumatic type the vast majority of patients are from twenty to fifty years of age. Of Lewis' series of fibrillating cases, 52 per cent. presented mitral stenosis. Other cardiovascular conditions with which fibrillation is associated are mitral regurgitation, aortic disease (rare), myocarditis, and interstitial nephritis.

Auricular fibrillation constitutes over 40 per cent. of the various arrhythmias seen in a general medical ward.

Symptoms and Diagnosis.—In general, the ventricular rate varies from 100 to 160. With normal conduction the rate may reach 200 or over (delirium cordis), while impairment of this function may reduce it to 40 or even less. An accurate diagnosis requires the use of the electrocardiograph. Graphic curves, both arterial and venous, show an irregular succession of strong and weak contractions. The ventricular form of venous pulse is present, and is also found in tricuspid regurgitation.

Auricular fibrillation is usually recognizable by clinical observation. The pulse is rapid, usually over 120 per minute, and absolutely irregular in force, rate, and volume. The irregularity of rate and force is best appreciated by the stethoscope at the apex. The successive pulse-waves are so irregular that it is impossible to draw any definite conclusion as to the blood-pressure. Various methods (*e. g.*, Janeway's average pressure; pulse deficit method) of taking the blood-pressure have been recommended to secure information of functional ability of the heart. The associated phenomena and cardiovascular lesions, often grave and indicating cardiac failure, are of great diagnostic import.

From other forms of arrhythmia, such as extrasystoles and partial heart-block, auricular fibrillation is distinguishable by its greater persistence, by the effect of exercise, which increases the irregularity of the latter while it tends to remove that of the former. Similarly, drugs of the belladonna group aggravate fibrillation and diminish partial functional heart-block. The presystolic murmur of mitral stenosis generally vanishes in auricular fibrillation, but not invariably (Talley).

Prognosis.—This depends upon the associated conditions, the ventricular rate (the slower the rate, the better the prognosis), and the response to treatment. If the patient is willing not to make any unwonted exertion, a guardedly favorable prognosis is permissible in many cases. One of the authors has studied a case in whom the fibrillation apparently persisted for twenty years.

Treatment.—Rest is an important item of treatment. Digitalis acts most satisfactorily. It is in this condition that Mackenzie says it acts almost as a specific, and that as a result of the splendid results achieved from its use digitalis has secured the reputation it enjoys in the treatment of cardiac conditions. It acts by producing a block in the bundle of His which checks the numerous ventricular stimuli from the auricle. On the other hand, in cases of advanced myocardial degeneration this drug may fail. The rate of the pulse serves as a guide to its administration, and when normal again for the individual it should be discontinued. Bohan and others laud strophanthin, giving $\frac{1}{100}$ grain intravenously every four to seven days. The hygienic and dietetic details are quite similar to those recommended in chronic valvulitis (*vide supra*).

AURICULAR FLUTTER

This term implies extremely rapid action of the auricle in response to new, rhythmic, and pathologic impulses, the rate being usually between 200 and 330. The condition is closely related to auricular fibrillation and tachycardia of less rapid rate. It is always associated with heart-block, as it is impossible for all the auricular beats to get through the auriculoventricular bundle to cause ventricular contractions. It may be paroxysmal in character. In general, the ventricular rate is either one-half or one-fourth that of the auricle (heart-block), or the impulse to the ventricle may be quite irregular. Tallman¹ has studied 58 cases and demonstrated three different types: (1) flutter in an apparently normal heart; (2) auricular flutter supervening during the course of chronic heart disease; (3) auricular flutter preceded by partial and complete heart-block. In the large majority of cases clinical findings are of no avail in making the diagnosis; the electrocardiograph is necessary. Fulton² reports a case of paroxysmal type lasting seven years, with progressive improvement. Digitalis should be employed in the treatment, because if persisted in the auricles will go into fibrillation, which will cease when the drug is withdrawn and normal rhythm will appear (Lewis).

As a rule, with the showing of the ventricular rate the indications of flutter quickly disappear.

HEART-BLOCK

(Adams'-Stokes Syndrome)

The syndrome known by the above name was first recognized by Adams (1827), although more accurately described later by Stokes (1846). It is characterized clinically by bradycardia, vertigo, syncope, and auricular impulses in the veins of the neck. The Adams-Stokes syndrome may rarely be absent in fatal cases. While most common among adults, Frank and Polak observed a case in a girl of two and a half years of age.

Physiologic Pathology.—Physiologists have conclusively shown that the rhythmic contractions of the heart have as their basis a stimulus conducted not from nerve-centers of the organ, but from the sinus region to the auricle and ventricle. Gaskell's experiment elucidates the pathogenesis of the condition in man; he showed that constriction of the circular layer of muscle at the auriculoventricular junction in the heart of tortoises causes a cessation of the rhythmic action of the heart so that the auricles and ventricles become independent in their contractions, the former beating more rapidly than the latter. The impulse in the human subject flows through a bundle of neuromuscular tissue extending from the right side of the interauricular septum to the interventricular septum just below the *pars membranacea*; it is approximately 18 mm. long, 2 mm. broad, and 1.5 mm. thick. Now, if this pathway for the impulse is blocked the phenomena of Adams-Stokes disease may be produced. Erlanger has been able to gradually compress the bundle of His and bring about varying degrees of heart-block: *e. g.*, at first there occurs an occasional failure of ventricular contraction, then a ratio of auricular to ventricular beats of 2 to 1, 3 to 1, 4 to 1 (partial block), and finally complete block when the ventricles contract slowly and independently of the auricular rhythm. On the other hand, mild cases of partial block exist in which there is simply a delay in transmission of the auricular impulse through His' bundle to the ventricle (delayed conduction time—prolonged *a-v* interval).

¹ *Northwest Med.*, 1916, xv, No. 5.

² "Auricular Flutter," read by Dr. Frank T. Fulton before the *Amer. Climat. Assoc.*, May 6, 1913.

Various *pathologic changes* in the bundle of His have been found post-mortem, thus confirming the results of physiologic experiment. For example, Stengel found an atheromatous patch over the bundle of His; Ashton, Norris, and Laveson and others a gummatous involvement of this structure, while Walter James¹ noted recent ulceration. *Temporary and incomplete heart-block* has been noted in certain acute infections (typhoid fever, diphtheria, influenza, pneumonia, and others) and in the fibroid heart. It may also follow the prolonged use of digitalis.

Symptoms.—The important features are: (a) Bradycardia, (b) cerebral attacks, and (c) visible auricular pulsation of the cervical veins.

(a) Bradycardia—the slow pulse is a persistent feature in most cases, but it may be paroxysmal. The rate falls to 40, 30, 20, or even less beats per minute, and it often bears a definite relation to the normal for the sufferer. The pulse is scarcely influenced by exercise or drugs that quicken the heart action. Arrhythmia of the ventricular contractions may be noted, but is not common.

(b) We often observe a 2 to 1 or 3 to 1 rhythm on comparing the auricular impulses as noted in the veins of the neck with the ventricular systole. This is due to the fact that most of the former fail to cross the bundle of His. Feeble auricular sounds may be heard, when the ventricle is in asystole. The blood-pressure is notably increased (De Renzi).

(c) The cerebral attacks consist principally of vertigo, which is usually momentary, syncope; rarely convulsive seizures, and pseudo-apoplectic attacks. The attacks of unconsciousness may prove fatal. Heart-block is not necessarily associated with Stokes-Adams' phenomena (syncopal attacks). On the contrary, most cases of heart-block do not have the seizures.

Renal changes and albuminuria have been observed.

Diagnosis.—Bradycardia must be distinguished from Adams-Stokes disease. The former is characterized by a pulse below 48 beats per minute, with corresponding slowness of the systole and the auricular impulse, and it has a different etiology (*vide ante*). Doubtless, atypical cases of the Adams-Stokes syndrome occur, due to slight degenerative changes in the bundle of His, and these may exist for years before the clinical picture becomes typical. Krumbhaar reports a case of transient attacks of heart-block in which the right branch of the bundle of His was found completely obliterated; this condition alternated with normal pulse. There are instances in which the bundle of His shows no pathologic changes (Edes and Councilman).

Recurring extrasystole, simulating heart-block, may be due to hyper-rhythmicity of the atrioventricular bundle and not due to blocking of this stricture (*functional variety*). Here there occurs a forcible venous pulsation in the neck "without either a radial pulse or a discoverable pulsation in the innominate artery" (James). Seven cases have been recorded in the literature.² Clarac and Pezzi invite attention to contraction of the auricle coincidentally with the first part of the contraction of the ventricle, causing a explosive first sound, which testifies to total heart-block if the ventricle beat is regular.

The **prognosis** is grave in cases showing persistent heart-block of high grade. In young patients, whose heart muscle is functionally efficient, the prognosis is usually good. The functional form gives a favorable prognosis.

Treatment.—This consists in rest in bed and in overcoming the feeble condition of the circulation by free stimulation. In cases presumably due to syphilis, the iodids in massive doses should be given. In the functional form, atropin changes the ratio between auricular and ventricular beat, so as to cause

¹ *Amer. Jour. Med. Sci.*, October, 1908.

² See Pepper and Austin, *Amer. Jour. Med. Sci.*, May, 1912, p. 716.

the heart-block to disappear. During the syncopal attacks but little can be done for the patient, though nearly every type of drug which has any effect on the heart, directly or indirectly, has been recommended.

PAROXYSMAL TACHYCARDIA

Definition.—A condition characterized by the abrupt onset of extremely rapid heart rate as a result of “new, rhythmic, and pathologic impulses” (Th. Lewis).

Pathology and Etiology.—In the few cases that have come to autopsy, fibrosis of the heart wall has been the most frequent finding. Nerve lesions have been found at times, but it is questionable if they have had any direct association with the condition. In regard to etiology, males are more frequently affected than females. The condition may occur in any decade of life after the first. Rheumatic fever occasionally is noted in the history of these patients, and at times mitral stenosis or myocardial degeneration is associated with it.

Paroxysmal tachycardia is produced in the following manner: Normally, rhythmic impulses arise at the so-called “pace-maker” of the heart, located at the junction of the superior vena cava and the right auricle. At times an abnormal focus of impulse formation arises in the heart wall, usually the auricle, from which rhythmic impulses are sent out at a more rapid rate than the usual pace-maker rate, and which “dominate the movements of the whole heart.” Lewis says they may be regarded as a regular series of premature beats. As a result of these new formed impulses there is a sudden and marked increase in the heart rate.

Symptoms.—The clinical picture in most instances of the complaint is made up of recurring paroxysms of heart hurry. These attacks may come suddenly without prodromes. If the latter occur, they consist of vertigo, tinnitus, a sense of impending danger, and sometimes a “heart-flop” due to extrasystole. The “flop,” however, more commonly ends the paroxysm. With the onset of the paroxysms the *cardiac movements* leap to 150, 175, 200, and 250, or even to 300 beats per minute. The *pulse* is feeble, small, readily compressible, as a rule, and sometimes irregular. Rarely it is full, strong, and of good tension. The *respiration* may or may not be increased in frequency, but dyspnea is not common. At first pale, the *skin* soon becomes flushed, and the *countenance* may wear an anxious expression; but unless “palpitation” is associated there are no symptoms present that denote an intense degree of suffering. In many cases the patient is not conscious of palpitation, or there may be a sense of slowing of the heart, when in reality the cardiac contractions may be increased to 200 or more; this is *typical tachycardia*. Gallavardin claims that the temperature is liable to be higher and the tachycardia more pronounced in the early morning than in the afternoon. In a chlorotic girl I found that the pulse-rate increased from the normal rate to 200 beats, and lasted for a few minutes at each visit to my office. H. C. Wood reports a case occurring in a physician eighty-six years of age, who has had attacks since his thirty-seventh year, the pulse rising quickly to 200 beats per minute.

Physical Signs.—A diffuse, rapid, and regular impulse may be observed on *inspection* and *palpation*, but seldom is there an enlargement of the heart. The *sounds* are slightly modified, the first being accentuated and the second aortic diminished in intensity, owing to the lessened amount of blood thrown into the aorta with each systole; the intensity of the second pulmonic, however, may be increased. An apical *systolic murmur* is occasionally audible. The

carotids pulsate, and on ausculting over them a murmur is sometimes heard.

Diagnosis.—I would restate the fact that a high pulse-rate (200 or over a minute) and an absence or only a slight sense of palpitation or rapid heart action are the distinctive features of tachycardia. In *palpitation* (previously considered) the pulse-rate is not usually so high, while the associated phenomena of dyspnea, precordial constriction, smothering, and painful anxiety are correspondingly more pronounced.

Prognosis.—In the majority of cases no serious impairment of the general health follows, though the course is exceedingly chronic and recoveries are comparatively rare. At times death occurs during a paroxysm. The *duration* of tachycardia varies from one to two or more decades.

The **treatment** is to be conducted on the lines advanced for Palpitation (*vide* p. 656). Fairbrother has cut short the paroxysm in his own case by either walking or an exercise like a girl skipping the rope. An abdominal binder, with a view to emptying the splanchnic vessels, may reduce the excessive rate of the heart. The attacks can sometimes be averted by the taking of ice-water or strong coffee. Villacorta states that to abort the attack we can compress the pneumogastric or apply electric stimulation. The patient should be made to recline and take deep breaths, holding the lungs full of air for a few moments, or pressure may be applied to the eyeballs.

One of the principal aims of treatment, if the attack cannot be cut short, is to support the heart with some stimulant, such as digitalis, especially if a demonstrable organic lesion be present. Following the attack efforts must be made to strengthen the nervous system and to find the exciting cause of the attack when possible. An abdominal belt is advised by Lewis.

PULSUS ALTERNANS

This is an irregularity in which the ventricular discharge varies in force with alternate heart-beats, the rhythm being undisturbed. The condition is found, as a rule, in hearts which are extremely rapid or markedly injured. It was at one time thought to be extremely rare, but White,¹ of Boston, has shown in his electrocardiographic work that it is a relatively common clinical condition. Pulsus alternans is of serious prognostic import. Thus White found in his series of 71 cases, 25 dying within the first ten months they were under observation. Enlargement of the heart was a constant finding, while arteriosclerosis and hypertension were common. Unfortunately, the arrhythmia, though of great prognostic and diagnostic importance, is rarely recognizable by ordinary clinical methods, graphic methods being necessary except in marked cases.

ANGINA PECTORIS

(*Stenocardia, Breast-pang*)

Definition.—A paroxysm of violent precordial pain extending into the neck, back, and left arm, and at times attended by a sense of impending death. It scarcely deserves to be classified as a separate disease, being merely symptomatic of either cardiac or aortic lesions.

Pathology.—It is claimed to be a neurosis affecting the cardiac sensory filaments that are given off chiefly from the pneumogastric, and in many cases

¹ *Amer. Jour. Med. Sci.*, 1915, cl, 82.

² "Diseases of the Arteries, Including Angina Pectoris," McMillan & Co., New York and London.

the vasomotor apparatus is also involved. Allbutt,² in his delightful and stimulating exposition on arteriosclerosis and angina pectoris, holds that the symptoms owe their origin to disease in the aorta—acute and chronic aortitis. Sudden anemia of the myocardium consequent upon sclerosis of the coronaries (“vascular crisis”), and irritation of the ganglia and sensory nerves explain its origin (Leube). May¹ suggests chemical change in the myocardium as the stimulus to the nerve-endings, while Bramwell believes spasmodic contraction of the muscular fibers of the left ventricle, due to a sudden strain in cases of atheroma of the coronary arteries, to be the cause. By others it is held that the pain is due to acute dilatation of the heart. Heberden first made the observation that angina is essentially a vascular pain, and showed its extracardiac origin.

Etiology.—Cases of angina unassociated with *arterial sclerosis, hypertrophy, aortic regurgitation*, or adherent pericardium, are rarely encountered. With few exceptions sclerosis of the aorta and coronaries is present, and predisposes to the condition. This view receives some degree of color from the fact that angina usually occurs after the *fortieth year*, and principally in the *male sex*. Bramwell, however, analyzed 178 cases, and in 48, or 26.9 per cent., no definite lesions were detected either in the heart or aorta. Angina pectoris in the young should always suggest syphilis. Anders has collected 270 cases from the literature, of which 26.5 per cent. gave evidence of syphilis. These figures are much too low, as no mention is made of the Wassermann test in 250 of them, dependence being placed solely on the history. It may be a sequel of influenza. Dyspeptic disturbances may aggravate the disease. The *determining factors* of the attack are undue exertion and mental emotion.

Symptoms.—The *paroxysm* begins quite suddenly during the action of one or other exciting cause. There is excruciating pain of a grip-like character, affecting the entire chest and rendering the body motionless. The pain *radiates* most frequently to the left shoulder, though also to the right, and thence to the back, neck, and down the arms to the fingers. Not less agonizing than the pain is the awful sense of *impending death*. *Coldness* and *numbness* of the fingers or in the precordial area may be present. The *countenance* is frequently pale, and may assume a leaden hue, and is usually bathed in cold perspiration. The *respirations* are shallow or even temporarily arrested, and the patient's anxiety is extreme. The *heart's action* may be regular, and the arterial tension is generally increased markedly, though in many cases the systolic pressure may be lowered or normal. The *duration* of the paroxysm varies from a few seconds to a minute or two (rarely it lasts for hours), and after the attack, which subsides suddenly, gaseous eructations, vomiting, or the discharge of a large amount of clear urine may occur. Cheyne-Stokes breathing has been observed. After the seizure there may be an *absence of signs*, and, though there is weakness, this soon disappears. The attack may *recur* at intervals varying from a few days to as many years.

Varieties.—1. **Angina major**, or severe form, in which arterial disease is uniformly present. Its subvarieties are thus classified by Osler: (a) the fulminant or rapid form with one or two attacks only, or sometimes with the condition known as status anginosus; (b) the form with a duration of one and a half to two years and a varying number of attacks; (c) the chronic form, lasting upward of ten years with a varying number and growing intensity of attacks, that, for instance, of John Hunter, whose first seizure occurred twenty years before his death; and (d) lastly, the small group of cases which may last for months, or as long as two years, with attacks of great severity, and yet may completely recover.

¹ *Brit. Med. Jour.*, January 1, 1910.

2. **Angina minor**, or mild form, usually described as "false or pseudo-angina," with its subgroups, the neurotic, the vasomotor (Nothnagel), and the toxic forms. Mackenzie, among others, forcibly protests against this term, "pseudo-angina." He maintains that angina pectoris is an entity characterized chiefly by severe cardiac pain which is dependent upon lesion of the heart and blood-vessels; to term pain in the region of the heart unassociated with organic heart disease as pseudo-angina is but a confession of ignorance of the real nature of the condition which may ultimately be determined only by a thorough study of the case.

The term pseudo-angina pectoris is probably a misnomer in the present state of our knowledge, and apparently typical cases have been observed to merge into true angina pectoris (Anders).¹ It must be confessed that one meets with hysteric and neurasthenic females, in whom paroxysms of diffuse pains over the thoracic region, accompanied by restlessness and emotional disturbance, and lasting from one to several hours, occur. These cases, however, have nothing in common with angina pectoris.

Diagnosis.—The characteristic events are a sudden, intense pain in the substernal and left parasternal regions with marked constriction of the chest, the peculiar manner of radiation of the pain, and the fear of death. Less diagnostic, though of considerable value, are the brevity of the attack, its sudden cessation, the age and sex, and the anxious, moistened features. There are light forms, in which one or more of the diagnostic phenomena above described are absent. If they occur between the ages of forty and sixty years in persons in whom either arterial sclerosis or aortic regurgitation is present, this disease should be thought of; and after the exclusion of certain complaints in which paroxysmal pain is prominent, such as gastralgia, intercostal neuralgia, and locomotor ataxia, the diagnosis of angina becomes reasonably certain.

The **prognosis** is bad, yet uncertain. When the arteries are markedly sclerosed (particularly the coronaries) life is often suddenly terminated. Occasionally the sufferer dies of syncope. The nature of the causal and associated lesions must be considered, *e. g.*, when it accompanies aortic incompetency the prospect of life is bad. In the vasomotor angina of Nothnagel the outlook is less grave.

Treatment.—*Prevention* of the attacks in persons who are subject to them is of the utmost importance. The exciting factors are to be avoided. The patient should be instructed to carry constantly such agents as nitroglycerin and amyl nitrite *perles* (strength 3 to 5 drops), and instructed how to use them.

The *treatment of the attack* must be prompt and energetic, though carefully conducted, amyl nitrite being inhaled at once from a handkerchief in doses of 3 to 5 drops according to the severity of the attack. The patient should then be placed in a cool apartment at absolute rest in bed, with restriction of food. *Locally*, the use of the ice-bag may prove efficacious and should be tried at first. Rarely, hot applications (hot cloths or sinapisms) give better results than cold. If the pain is not controlled promptly by this method, the nitrite should be reinforced by the hypodermic injection of morphin (gr. $\frac{1}{3}$ —0.020) combined with atropin (gr. $\frac{1}{120}$ —0.0005). This usually brings speedy relief, and is best suited to those instances in which there is no increase of arterial tension. In cases exhibiting high arterial tension the spirits of nitroglycerin, hypodermically, should be employed (dose $\text{m}j$ —0.065, to be repeated once in a minute if needful). Soca² suggests a detoxicating treatment consisting of a

¹ "Angina Pectoris, True and False," *Jour. Amer. Med. Assoc.*, November 3, 1906.

² *Arch. d. mal. du cœur.*, August, 1905, p. 237, and *Jour. Amer. Med. Assoc.*, December 18, 1915, p. 2166.

special diet (first milk only for one to three weeks, then cereals and vegetables are added, finally eggs and a small amount of meat are allowed) and diuretics, as theobromin.

During the *intervals between the attacks* the aim should be not only to obviate the action of the exciting causes, but also to overcome any predisposing influences that may exist. Prolonged rest in bed should be enjoined in true organic cases, and in those who cannot walk without pain. Excessive tobacco smoking must be discontinued. Schott¹ prefers baths (effervescent) and passive movements to drugs or other methods. Passive movements alone should first be performed by an assistant, but later may be safely entrusted to the patient. In cases in which the arterial tension is habitually exalted, nitroglycerin in increasing doses is to be used perseveringly, beginning with mj (0.065) and increasing by mj (0.065) every five or six days until the physiologic effects are produced. Sodium nitrate may be employed alternately with the nitroglycerin, the dose being gr. j to ijj (0.065–0.18) three or four times daily. Says Kohn,² to ward off attacks theobromin has fully established its efficacy. Marked arterial sclerosis, particularly if there be a syphilitic history, is favorably influenced by a long course of potassium iodid. In cases in which there is quick recurrence, sodium nitrite in $2\frac{1}{2}$ -gr. tablets (dose, 1 to 4 tablets) is recommended. Allbutt lauds—(a) the high-frequency current, and (b) the administration of the lactic acid bacillus. When hypertrophy of the left ventricle is excessive, I use the following:

R. Sodii bromidi, ziv (16.0);
Tinct. aconiti, ml (3.3);
Elix. aromatici, q. s. ad $\text{f}\text{z}\text{ijj}$ (90.0).—M.
Sig. Teaspoonful in water after meals.

It may be omitted at the end of every two weeks for two or three days. The presence of a gouty diathesis would call for special treatment. Dyspeptic troubles should be rectified. For Cheyne-Stokes breathing Allbutt advises the inhalation of oxygen and carbon dioxid alternately. Venesection may be employed in high arterial tension.

IV. CONGENITAL AFFECTIONS OF THE HEART

These result from two leading causes: (1) Arrested development, and (2) fetal endocarditis. Occasionally, both these factors are operative. It is not infrequently found in patients suffering from congenital syphilis, as evidenced by a positive Wassermann reaction.

(1) **Arrested development** may produce a great variety of anomalies: (a) *Acardia*, absence of the organ. (b) *Cor biloculare*, or *reptilian heart*, in which the septum between the auricles and ventricles is absent, thus reducing the number of chambers to two. (c) *Absence of the interventricular septum*, the heart consisting of three chambers (*cor triloculare*). (d) *Patency*, or *incomplete closure of the foramen ovale*. Persistence of the foramen is, in the majority of cases, associated with obstruction of the pulmonary valve, though it may be solitary. (e) An anomaly known as *ectopia cordis* deserves mention. The sternum is usually divided vertically, and the heart is either entirely exposed or beating just beneath the skin in the cardiac, thoracic, or abdominal

¹ *Med. Record*, March 11, 1899.

² *Berliner. klin. Wochen.*, May 17, 1915.

region. The most common form of malposition, however, is *dextrocardia* (*vide supra*, *misplacement*, p. 655). (f) *Anomalies of the valves*. There may be either a numerical increase or decrease of the cardiac valves, particularly the segments of the semilunar valves of the aortic and pulmonary orifices. Supernumerary segments are usually rudimentary.

(2) **Fetal Endocarditis**.—The valve lesions originating during fetal life are most frequently situated on the right side. They may occur at the pulmonary, the aortic, or the auriculoventricular orifices. The changes are of the sclerotic form. The leaflets present smooth, thickened, and contracted borders. Union of the mitral segments is common, and the chordæ are often thickened and contracted.

The most frequent congenital valvular lesion is **stenosis of the pulmonary orifice** as the result of chronic endocarditis. Rarely, it is due directly to defective development, and perhaps more rarely still to endocarditis verrucosa. **Pulmonic constriction** of antenatal origin may be an associated lesion in other forms of valvular disease in the young adult. With stenosis at this orifice, there usually coexist stenosis of the conus arteriosus of the right ventricle, an open foramen ovale, and a patent ductus arteriosus; according to Peacock, "in 86 per cent. of the patients with congenital heart disease living beyond the twelfth year the lesion is at this orifice." **Atresia of the pulmonary orifice** occurs, though rarely.

At the **tricuspid orifice** there may be stenosis or contraction of the valves, producing either obstruction or regurgitation. Similar lesions of the aortic orifice are infrequent. **Congenital mitral disease** occurs only exceptionally; it is usually associated with tricuspid stenosis. Boys are more liable to congenital affection of the heart than girls.

Symptoms.—There is a constant and striking symptom in congenital heart disease—*cyanosis*. The *tint* of skin observed is variable, being at one time a general duskiness, at another a deep violet, and rarely almost black. This coloration is noted about the lips and mucous membrane of the mouth, the nostrils, conjunctivæ, the fingers, toes, and lobules of the ears, and, as a rule, is general, though it may be a local condition. The tint may grow less distinct when the child is in perfect repose or sleeping; excitants or efforts at coughing, however, increase the intensity of the discoloration. The cyanotic hue comes on almost invariably during the first week of life. The *fingers* present a decidedly clubbed appearance, and the *nails* are thickened and claw-like. The *temperature* is subnormal, while the extremities are cool to the feel. *Dyspnea* on exertion and *cough* are usual concomitants. Variot reports 2 cases, namely, interventricular perforation and narrowing of the pulmonary artery. Cyanosis was absent from one case, and "this disproves the two leading theories with regard to the origin of cyanosis—the mixture of the two bloods and the obstruction to the pulmonary circulation."

Physical Signs.—In the very young the impulse is feeble, the *percussion-dulness* is increased, especially to the right, and a loud *systolic murmur* is audible at the pulmonary orifice. When the auriculoventricular valves are the seat of endocarditis, the murmur may be apical. In pure pulmonary stenosis the second sound is feeble.

In older children the area of *dulness* is only slightly extended, particularly to the left, while the *murmurs* heard are loud and often musical.

In rare instances *cerebral abscess* is an associated condition.

Differential Diagnosis.—

CONGENITAL LESIONS

History of almost constant cyanosis, beginning in the first week after birth.

Slight enlargement of the heart. It is the right ventricle and non-progressive.

Loud and musical murmurs present, audible over upper third of sternum, with small area of transmission upward and to the left; second sound weak.

Deficient bodily development.

Mental faculties in abeyance.

ACQUIRED LESIONS

Not so; history of endocarditis or of rheumatism or other complaints in which endocarditis occurs as a complication.

Enlargement marked, frequently involving the left ventricle, and progressive.

Audible over apex or base; definite large areas of transmission. Second sound frequently accentuated.

Bodily development good, as a rule.

Mental faculties normal.

The **prognosis** is exceedingly grave. Many succumb within a few days after birth, more than one-half before the expiration of one year, and not less than three-fourths before the end of the third year. Few survive the first decade of life, and fewer still reach full adolescence. The form giving the most favorable prognosis is pulmonary stenosis with defective septa. There is a disposition to affections of the lungs (phthisis), nerve complaints (convulsions).

The **treatment** is, in the main, hygienic. The body must be warmly clad. The diet is to be judiciously arranged, yet liberal. Gentle exercise, when it can be taken, is valuable, as are also daily spongings of the surface followed by friction. Special therapeutic indications may arise, and must be met in accordance with general principles.

V. DISEASES OF THE ARTERIES

ACUTE AORTITIS

Pathology.—The morbid changes coincide with those noted in acute endocarditis, including the ulcerative variety.

Etiology.—The causes are not clear, but the condition generally follows the acute infectious diseases (typhoid fever, pneumonia, miliary tuberculosis). Alcoholism and syphilis are among the rarer causes. Various micro-organisms have been discovered to be causal irritants. Boinet and Romary have recently shown that in experimentally produced aortitis a point of lessened resistance (either from traumatism or other previous arterial lesion) is necessary.

The **symptoms** are *local* and *general*. Of the former, diffuse thoracic *pain*, with substernal *tenderness* under pressure and cardiac *palpitation*, are the chief. The pain may assume the type of true angina pectoris. Among the *general* symptoms a moderate febrile movement is almost constant. In a certain percentage of cases embolism is betrayed by the usual signs, as rigors, accompanied by a steep temperature-curve. These forms are analogous to the malignant variety of endocarditis. A cardiac murmur may be heard over the base.

Diagnosis.—All that the best clinicians can do is to establish a probable diagnosis even in the presence of the most frankly expressed features of the affection. From *acute endocarditis*, aortitis is to be discriminated by its diffuse pain and by the higher seat of its murmur.

The **prognosis** is serious, owing to the liability to infectious emboli and aneurysmal dilatation and the possibility of aortic rupture.

The **treatment** is similar to that of acute endocarditis.

ARTERIAL SCLEROSIS

(*Arteriosclerosis; Arterio-capillary Fibrosis; Endarteritis Chronica Deformans; Atheroma*)

Definition.—An atrophic degeneration of the median arterial coat followed by compensatory thickening (hyaline) of the intima.

Pathology.—The most frequent seat of the sclerotic process is the aorta, and the next most common the coronary arteries. Other vessels implicated are the arteries of the brain, the temporals, radials, brachials, ulnars, femorals, and iliacs. On the other hand, certain arteries, as the gastric, hepatic, and mesenteric, are rarely affected. Two forms may be recognized: (a) the circumscribed (atheroma) and (b) the diffuse. There is also a secondary variety due to hypertension, causing dilatation of the vessels, slowing of the current, and compensatory thickening of the intima.

(a) **Circumscribed Arteriosclerosis.**—Naturally, the intima presents a smooth internal surface, but when atheromatous changes occur it shows localized areas of thickening, often hemispheric in outline, yellowish-white in color, and their favorite seats are the orifices of the branches. They increase in depth and superficial area, and on reaching an advanced stage their interior disintegrates into granular material (*atheromatous abscess*).

Histologically, in circumscribed or nodular atheroma, the middle coat is the primary seat of the changes, which consist of localized infiltrations. These lesions weaken the media and then (as shown by Thoma) compensatory processes are set up in the intima and adventitia (Adami), which lead to the formation of the so-called *atheromatous button*. The latter consists in a hyperplasia of the intima with a deposit of round cells, which causes a gradual compensatory thickening. Josue and Pearce and Stanton¹ have confirmed experimentally Thoma's view of the nature and sequence of pathologic events in arteriosclerosis. When the prominences in the intima undergo softening or liquefaction, rapid dilatation (*aneurysmal*) of the affected vessels may occur; more commonly this accident arises early or before the intima has reinforced the other layers.

(b) **Diffuse Arteriosclerosis.**—The morbid process (histologically similar to that described above) is distributed throughout the greater part of the arterial system; the circumscribed form is generally "but not necessarily" (Councilman) combined with it in the aorta. Dilatation of the aorta and of its branches commonly coexists. Apart from the yellowish, translucent, elevated areas which, when suitably stained, are found under the microscope to be composed of cells loaded with fat, the intima may be smooth and the naked-eye appearances almost normal. Klotz's experiment shows that increased intravascular pressure alone may be the cause of the medial degeneration and weakening in the first place; of the giving way of the arterial wall in the second; and of the intimal hypertrophy in the third. The primary cause of arteriosclerosis is degeneration and exhaustion of the elastica (W. E. Sanders²). Sheffer holds that hypertension is the cause, rather than the result, of arteriosclerosis. *Microscopically*, there is observed an extensive proliferation of the subendothelial connective tissue and a hyaline transformation of the entire media, particularly in the larger vessels. The muscular fibers and elastic tissue have in *advanced cases* almost totally disappeared. Necrotic degeneration of the media, especially in the smaller arteries, is also observed, and calcareous deposits, causing rigidity of the walls, occur. This is particularly true of the so-called *senile arteriosclerosis*. In this variety the larger arteries are elongated and tortuous, with thin, stiff (calcified) walls. Atheromatous abscesses that burst, forming

¹ *Jour. Exper. Med.*, 1906, vol. viii.

² *Amer. Jour. Med. Sci.*, November, 1911.

atheromatous ulcers, are likewise common pathologic events in the aged. There may be associated atrophy of the heart, liver, and kidneys, due to a lack of nutritive supply in consequence of the narrowing of the vessels.

Sclerosis of the pulmonary artery exhibits all the changes observed in connection with atheroma of the systemic arteries, including aneurysmal dilatation. From the terminal tributaries the process may extend to the capillaries, and even to the pulmonary veins (*angiosclerosis*).

The *effect of arteriosclerosis* upon the physiologic functions of the vessel walls are of first importance. The elastic coat is either destroyed or impaired; this predisposes to dilatation of the vessels (aneurysm).

Another result of extensive atheromatous degeneration of the vessels is an increase in the resistance to the blood-current, and a consequent hypertension. As a consequence, the left ventricle generally becomes hypertrophied (especially if the splanchnic area is involved), "provided the general nutrition of the patient is still well maintained" (Strümpell).

The reduction of the lumen of the vessel, owing to the thickening of the intima, must lessen the blood-supply to the various viscera, and thus are explained such secondary affections as fibrous myocarditis, renal cirrhosis, chronic interstitial pancreatitis (Opie), and cerebral softening.

Syphilitic arterial disease, while classified and considered under arteriosclerosis, produces a different pathologic picture than true arteriosclerosis. The most characteristic change is the production of minute gummata in the arterial wall involving chiefly the adventitia and the media, which are absorbed, and by the production of scars cause marked distortion of the artery. The first part of the aorta is the portion of the vascular tree most pronouncedly affected, but all the arteries may be involved. From these atheromatous and gummatous lesions spirochetes may be isolated.

Sclerosis of the veins (phlebosclerosis) may accompany arteriosclerosis. It is often found in association with hepatic cirrhosis and mitral disease (due to increased tension) when the portal system and pulmonary veins are involved. Arteriosclerosis apart from sclerosis of the peripheral veins may be encountered, though rarely. *Microscopically*, thickening of the intima and atrophic degenerative changes in the media are commonly observed. Calcification and hyaline degeneration of the layers also occur. Moderate dilatation is not exceptional.

Étiology.—The diffuse form has, in part, a special etiology. It may appear in the young, though rarely; I have met with a case in the Medico-Chirurgical Hospital in a man aged twenty-four years. It is, however, most frequent in strongly built, middle-aged men, and in the aged. At an earlier period it occurs as a result of *alcoholism*, *syphilis* (the overshadowing factor), *lead-poisoning*, *gout*, and *chronic nephritis*—agencies that subject the vascular system to undue wear and tear. Fremont-Smith has collected 144 cases in the young. Congenital syphilis may cause either diffuse or localized arteriosclerosis. In old persons atheroma is often *physiologic* and characterizes the natural involution period of life. *Heredity* may play no inconspicuous part in arteriosclerosis dependent upon the age. This fact furnishes the reason why senile changes in the arteries occur at a much earlier period of life in some families than in others. *Negroes* are more liable than *whites*, and *males* than *females*, though it is more frequent in the latter sex than the circumscribed variety. The frequent occurrence of emphysema and diffuse angiosclerosis has been noted (Anderson).

The *general causes* may be thus classified: (1) *Biologic irritants*, as the specific micro-organisms of malaria and syphilis or bacteria. Thayer¹ ex-

¹ *Med. News*, New York, November 21, 1903, p. 1004.

amined 182 patients who had had typhoid from one month to eighteen years previously, and found the blood-pressure in all cases somewhat high, and over 50 per cent. of the cases over twenty years of age showed palpable arteries. Klotz's experiments indicate that diphtheritic toxins lead to medial degeneration, while others—*e. g.*, typhoid toxins—have no effect on this coat, but induce a primary intimal degeneration. (2) *Exogenous and Endogenous Toxins* (chronic alcoholism, lead-poisoning, gout, diabetes, obesity).—The above toxic agents produce their effects partly by their direct irritant action and partly by increasing the resistance in the peripheral vessels and thus raising the arterial pressure. (3) *Bright's Disease*.—There is a class of cases in which arteriosclerosis is secondary to Bright's disease (primary arteriosclerotic kidney), but when found in association the former is more frequently the primary disease than the latter. The two diseases may develop independently of one another, and yet simultaneously, in consequence of the action of a common cause. (4) *Constant overfilling of the blood-vessels*, resulting from excesses in eating and drinking, also causes arteriosclerosis. (5) *Muscular overstrain*, which augments the blood-pressure while at the same time obstructing the peripheral circulation, is a leading factor. (6) Herz emphasizes the importance of *grief and worry*. (7) The main causes of sclerosis of the pulmonary artery are *mitral disease* and *emphysema*. (8) Experimentally it is difficult to produce constantly sclerotic changes in the arteries by the various methods employed. Alcohol, lead, and other types of exogenous toxins fed over long intervals of time may or, more likely, may not produce arteriosclerosis. Adrenalin is said to cause it if given repeatedly. The Russian school claim to have produced arterial lesions by feeding cholesterin. Repeated anaphylactic shocks produce arterial changes in the liver and kidneys. Bacterial toxins, notably those extracted from staphylococci, may produce it if given over a period of time.

No matter how produced, it seems, as MacCallum points out, that the continuous or frequently repeated action of the toxins of a chronic infection or a chronic intoxication or prolonged vasomotor irritation or stimulation is responded to by reparatory processes and by an accumulation of fats and fatty acids which may be protective.

Clinical History.—The disease may be latent for years; or it may be discovered at *autopsy*. In many cases the earlier symptoms resemble those of neurasthenia, and these are accompanied by a slowly progressive failure of the general nutrition. The accessible peripheral vessels (radial, temporal, femoral, and brachial) should be carefully felt when the presence of the disease is suspected. In early cases the artery may be felt as a thin ribbon-like structure. In developed cases the *walls* of the affected artery feel *hard*, and the *pulse*, owing to increased tension, is incompressible; as a result of this rigidity of the arterial walls the degree of vascular tension is difficult of estimation. In marked cases the pulse-wave may not be detectable on palpation. Again, the *tension* may be high, and yet sclerosis of the vessel wall be slight or absent. The blood-pressure is high, as a rule, in arteriosclerosis, depending more upon the degree of sclerosis of the smaller vessels than the larger palpable ones.

The increased resistance to the circulating medium (due to the sclerosis of the arterioles) calls forth a correspondingly increased cardiac action, and thus *hypertrophy of the left ventricle* is engendered, with its customary symptoms and signs, including the ringing, accentuated second sound. The balance of the cardiovascular forces may thus be maintained for a long period of time, during which the health of the patient often remains unimpaired. It happens sometimes that hypertrophy preponderates and veils completely the symptoms of arteriosclerosis. In elderly persons suffering from atheroma the first sound is often surprisingly feeble. A soft-blowing systolic basal murmur is usually

indicative of aortitis, frequently syphilitic. *Myocardial degenerations* frequently come on in the later stages, when dilatation of the left ventricle, accompanied by a mitral systolic murmur and marked rapidity of the pulse, may supervene. The *aorta* may be so dilated as to give rise to an abnormal area of dullness in the upper sternal region. *Palpitation, dyspnea on exertion, a feeling of precordial constriction, and light febrile attacks* are not uncommon. *Angina pectoris* is an infrequent symptom except in coronary atheroma. *Angina abdominalis*, sudden severe, sharp attacks of abdominal pain, is more or less dependent upon sclerotic changes in the splanchnic vessels. Spasm of the peripheral vessels after exercise may produce severe attacks of cramp-like pain, relieved by rest. In the leg such a condition is known as *intermittent claudication*. Certain writers have emphasized flatulence and other gastrointestinal features.

It cannot be stated that involvement of the *external arteries* implies a serious involvement of the aorta and its main branches. On the other hand, the circumscribed variety is not attended with characteristic alteration of the pulse. The *pathologic*, and particularly the *clinical*, events may be more pronounced at one portion of the body than at others, and this fact has given rise to several distinct or *special types*, as follows: (a) cerebral, (b) pulmonary, (c) renal, and (d) peripheral types.

(a) **Cerebral Type.**—In the milder grades of this type such symptoms as headache, tinnitus, vertigo, syncopal attacks, and local palsies are variously blended as a rule. Especially in the aged, the condition is apt to lead to *thrombosis* or *cerebral embolism*, emboli being detached from the aortic area and conveyed to the brain, with the development subsequently of the symptoms of anemic softening of the latter. The loss of elasticity of the vessel walls in atheroma renders them more liable to rupture than normal arteries, while the tension is much increased. Under these circumstances the danger from cerebral apoplexy is obvious. In persons under forty apoplexy is practically always due to a syphilitic arteritis.

(b) **Pulmonary atheroma** is considered in its clinical relations in connection with the diseases of the heart and lungs.

(c) The **renal type** includes those instances of kidney lesion that are associated with, precede, or follow general arteriosclerosis. The condition is essentially an atrophic nephritis due to the diminution of the blood-supply to the organs in consequence of the narrowed lumen of the renal arteries.

(d) In this *type* the peripheral arteries become obliterated and cause starvation of the tissue, with resulting cramps and even gangrene.

Diagnosis.—Hardened arteries, increased arterial tension, left ventricular hypertrophy, and marked accentuation of the aortic second sound form a group of clinical characters that leaves no doubt as to the diagnosis. It may be the occurrence of apoplexy, acute cardiac dilatation, or of some other such accident that leads to the discovery of general arteriosclerosis. Slight albuminuria is generally present. A murmur may be heard over the base. An ophthalmoscopic examination is of the utmost value as a diagnostic aid, showing sclerosis of the retinal vessels. In young subjects the finding of a positive Wassermann is an important diagnostic aid.

C. Beck and others have found that the roentgen rays are useful in determining the extent of arteriosclerosis (*e. g.*, whether local or general).

To **differentiate** the murmurs of dilatation of the left ventricle following the hypertrophy of this disease from *organic mitral lesions* is only possible by the history or the results of treatment. In *aortic stenosis* the second sound is weak and the pulse less voluminous than in arteriosclerosis (*vide Aortic Stenosis*).

Prognosis.—Arterio-capillary fibrosis is an exceedingly chronic, though usually a progressive, disease, and frequently it terminates life. The axiom that a man is as old as his arteries has been borne out by the test of extensive clinical observation. However extensive, sclerosis of the larger vessels has apparently little effect on decreasing longevity. The extent of kidney involvement has a very decided effect on prognosis, more so than any one other factor. Syphilitic arterial disease is usually of short duration as compared to other types, chiefly on account of the more serious arterial and other complications (aneurysm—aortic insufficiency). The condition may prove fatal either with great suddenness, as when it occasions apoplexy, or with unwonted slowness. Very rarely the aorta ruptures, causing instant death.

Treatment.—Though the progress of the disease cannot in most instances be successfully stayed, it can be retarded frequently by correcting aggravating habits and by removing the influence of ascertainable causes. The syphilitic taint, if present, requires the liberal use of the iodids and the careful use of mercury and salvarsan.

The diet must be simple and free from stimulating properties; skimmed milk is excellent, particularly if renal symptoms be manifested. The lactic acid and sour milk treatment may be employed in cases in which intestinal toxemia is an etiologic factor. A salt-free diet (green vegetables, fruits, fresh butter, cream, potatoes, rice, sugar, salt-free bread) is useful for a week or two at a time when the blood-pressure runs high. A low protein diet is distinctly indicated and should be followed continuously. Elimination should be maintained at its most efficient pitch. The skin should be kept actively functioning by frequent hot baths or sweat baths twice or three times a week; the kidneys should be stimulated from time to time, and one or two complete evacuations of the intestinal canal should be secured by mild salines if necessary. In the earlier stages potassium iodid is serviceable; it should be administered for several years, combined with appropriate physical exercise (*e. g.*, golf, horseback riding, walking) to regulate the bodily function. Small doses of potassium iodid reduce the viscosity of the blood by acting on the corpuscles without diluting it.¹ On the other hand, Schwalbe utters a warning against the routine use of iodine or the iodids in non-syphilitic arteriosclerosis on account of the danger of injury from the iodine, especially in regions where goiter is common.

For the increased arterial tension, more especially if due to temporary vasoconstriction, nitroglycerin or the other nitrites, or erythrol tetranitrate, because of its more lasting effect, should be employed, in increasing doses, until an impression has been made upon the blood-pressure, after which this effect should merely be maintained. Electricity in the form of high-frequency current reduces the hypertension to an appreciable extent, and also probably stimulates the metabolic processes. In persistent (chronic) hypertension the tincture of aconite is useful. Venesection has a more lasting effect than have any of the drugs used (Lawrence). The cases in which the blood-pressure is quite elevated in consequence of vasoconstriction due to nervous causes, combined with a mild grade of arteriosclerosis, need mental and physical rest, arterial relaxants, and liberal feeding. Attempts to reduce the pressure too markedly or too rapidly are often dangerous and a warning note should be uttered against such efforts.

For the local aortic symptoms (fever, pain) absolute rest, a liquid and unirritating diet, and a small blister are most efficacious, together with internal minute doses of calomel, quinin, and potassium iodid.

¹ E. Romberg, *Deutsch. med. Woch.*, August 31, 1905.

ANEURYSM

Definition.—A true aneurysm is a circumscribed dilatation of an artery, formed of one or more of its coats.

Classified according to their form, aneurysms are—(1) sacculated, (2) cylindric, and (3) fusiform. They are termed *axial* when the complete circumference of the vessel participates in this dilatation, and *peripheral* when a single sac is confined to the side of the vascular duct.

Miliary aneurysms occur along the course of the cerebral vessels. On the other hand, aneurysms may attain the size of the human skull.

By a *false* aneurysm is meant one in which the coats are ruptured.

A *dissecting* aneurysm is one that, owing to laceration of the internal coat, dissects between the layers of the vessel wall. For its *seat* it usually selects the aorta, and may traverse its entire length.

An *arteriovenous* aneurysm arises from a direct fistulous connection between an artery and a vein (*aneurysmal varix*), or an aneurysmal sac may intervene (*varicose aneurysm*).

Pathology and Pathogenesis.—The wall of the aneurysm is commonly the seat of arteriosclerosis, which Malkoff claims is a compensatory arrangement. Osler states that the origin of aortic aneurysm is to be traced to mesoarteritis, so different from chronic aortic degeneration. The common atheromatous disease does not often produce aneurysm. Extreme atrophy of both the intima and media is not uncommon in the later stages, the wall of the sac being formed chiefly by the adventitia. The intima (as in Daland's case of aortic aneurysm, in which there were both an old and a new transverse rent) may become lacerated, and finally the media and adventitia tear; this results in rupture unless the adherent neighboring structures compensate for the natural wall.

The blood in the aneurysmal sac is composed of old and new thrombi. The latter when comparatively recent may be soft, and when old may be firm or even calcified, yellowish in color, and adherent to the wall.

Etiology.—Among recognized *causes* are: (1) **Arteriosclerosis.**—Some of the conditions that originate the latter at all events also tend to bring about aneurysms. According to Rasch, syphilis was present in 56 per cent. of 25 aneurysms of the aorta discovered in the course of 3165 necropsies at Copenhagen, and Annsperger found it in 48.6 per cent. of 37 cases. Heller has found 85 per cent. of aneurysms due to syphilis. Since the advent of the Wassermann reaction more and more is syphilis being recognized as the one outstanding etiologic factor, so that at the present time there are some who teach that syphilis is the cause of all non-traumatic aneurysms. In a series of 621 cases, 58.5 per cent. were of luetic origin. In view of the fact that some of these cases had not been submitted to the Wassermann test, this percentage is too low. (2) **Sudden Great Strain.**—This may be productive of aneurysm, particularly in an artery weakened by pathologic changes such as are induced by syphilis. Thus may the fact be accounted for that most instances of aneurysm occur during the period of greatest bodily activity in the male sex. (3) **Embotic plugging of a vessel**, if complete, may cause aneurysmal dilatation on the proximal side of the point of obstruction. The development of aneurysm may be facilitated by the mechanical efforts of the embolus, which may be of calcareous hardness, as when it comes from diseased heart valves. Infectious emboli set up inflammation and softening. (4) **Mycotic Aneurysms.**—That aneurysms sometimes owe their existence to mycotic origin was first pointed out by Osler, who found an abundant growth of micrococci in the aneurysmal sacs. They are met with in ulcerative endocarditis, and are often small and

usually multiple. (5) **Traumatism.**—Aneurysms have been produced experimentally by traumatism (Malkoff); hence it is obvious that it may become one of the assignable causes. (6) **Age and Sex.**—Aneurysms are most frequent between the *thirtieth* and *fiftieth* years, this being the period of greatest physical exertion. The *male sex* is more frequently affected than the *female* (ratio of 3 to 1—Lemann) owing to differences in occupation.

ANEURYSM OF THE THORACIC AORTA

(*Aneurysma Aortæ*)

The *thoracic portion* of the aorta is involved in about 75 per cent. of the cases, and the *abdominal aorta* and its branches in 25 per cent. Within the thorax nearly 60 per cent. of the cases originate in the *ascending portion of the aorta* (Lyman). Hare and Holden collected 570 cases of aneurysm of the ascending arch, of which 504 were of the saccular variety.

Symptoms.—Intrathoracic aneurysms may exist, particularly if they are small, without symptoms or noticeable physical signs. When they attain to any considerable dimensions, however, they usually excite characteristic signs and distressing symptoms, the latter being the results of direct pressure, and hence varying with the seat and direction of the progressive enlargement. In a few instances diagnostic symptoms are present in the absence of a detectable tumor or physical signs. Aneurysms of the **ascending portion** of the arch usually *compress* the vena cava, causing *distention of the veins* of the head and arms, though in a proportionately small number of cases the subclavian may be the only vein compressed, with resulting *enlargement* and *edema* of the right arm. The largest aneurysms may even compress the inferior vena cava, causing edema of the lower extremities. The *heart* is displaced outward toward the left pleura, and usually upward, and rarely causing erosion of the ribs and sternum. The right recurrent laryngeal nerve may be implicated, giving rise to *dyspnea* and *aphonia*. *Pain* is a constant feature.

Aneurysms of the **transverse portion** of the aorta, when they attain any considerable size, cause the most intense symptoms, owing to the relatively shorter anteroposterior diameter of the chest at this point, in consequence of which greater *compression* of the neighboring tissues takes place. By protruding backward they may exert pressure upon the trachea, causing paroxysmal *cough* and *dyspnea*, or on the esophagus, causing *dysphagia*; these are common events. The pressure may fall also upon the bronchus, inducing *dyspnea*, *bronchorrhea*, and *dilatation*, the latter in turn sometimes leading to circumscribed abscess. The left recurrent laryngeal nerve may be implicated, with resulting *aphonia*.

Upward extension of the aneurysmal process, with involvement of the coats of the carotid and subclavian on the left side, or of the innominate and carotid on the right, may occur. The *sympathetic nerves* in the cervical region may be irritated, causing dilatation; or they may be paralyzed, causing contraction of the *pupils*. Compression of the *thoracic duct* may occur, with resulting rapid emaciation. A *tumor* may appear in the jugular fossa.

The aneurysm may grow *forward*, in which event it lies directly behind the manubrium, which from the pressure becomes eroded and may finally disappear in part. In aneurysms involving the transverse portion of the arch, lateral pressure, both toward the right and the left, is also made, causing recession and compression of the lungs.

When the **descending portion** of the arch is affected the pressure is exerted upon the spinal column to the right, and upon the tissues as far as the shoulder-blade to the left. As a consequence of destruction and absorption of the ver-

tebræ, compression of the spinal cord may ensue, and is an intensely painful process. Pressure may be made upon the esophagus, causing *dysphagia*, or upon the left bronchus, causing *bronchiectasis*, with its usual *sequelæ* (bronchorrhea, fetid bronchitis, gangrene of the lung).

The *sac* may, in consequence of the slow ulcerative process that attends its progress, *rupture* (*vide* Prognosis). Frequently repeated small *hemorrhages*, due to weepings from the thinned walls, may precede the fatal rupture. I saw a case of aneurysm of the transverse portion in which rupture into the esophagus resulted, with instantaneous death.

When the tumor has reached the subcutaneous tissue and bulges externally, the skin covering it becomes tense and shining, and with increased pressure the surface becomes reddened and finally necrotic. The necrosed area is covered with a dry brown scab, which later is thrown off, leaving an oozing surface. Rupture soon follows.

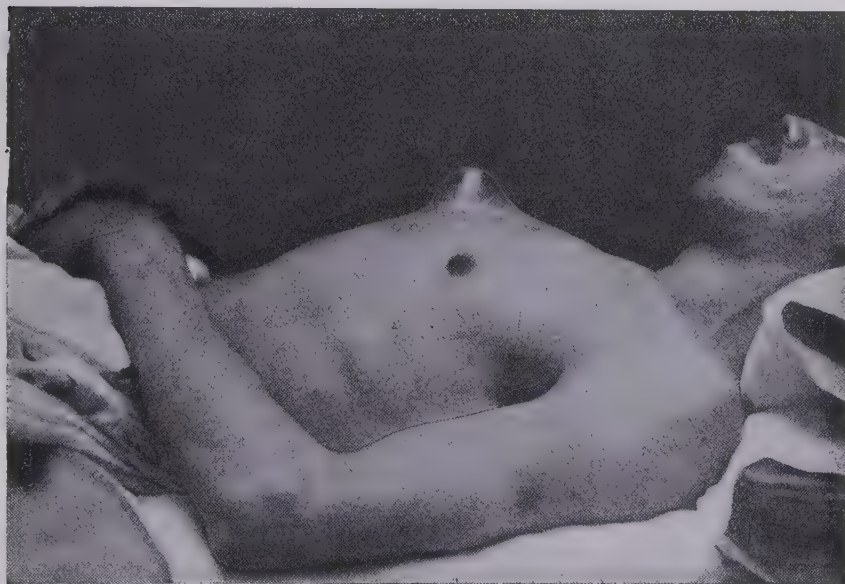

Fig. 51.—Aneurysm of aorta.

Leading Symptoms in Detail.—Among these *pain* stands primarily, being the first and most constant. It is of two kinds: (*a*) due to direct pressure upon and stretching of the nerves. When aneurysm is developed suddenly, a sharp, excruciating pain is felt in the upper sternal region, accompanied by a feeling of “something giving way.” In consequence of the stretching of the nerves a constant pain is experienced that is subject to exacerbations when the intra-aneurysmal pressure is raised. Pressure against the bony structures causes erosion, and usually produces a continuous boring pain. In a recent case of aneurysm shown in clinic at the Medico-Chirurgical College, however, a tumor of the size of a goose’s egg had given rise to no suffering whatever (Fig. 51). In latent aneurysm there is an absence of pain. Anginose attacks sometimes occur when the sac has its seat near the heart. (*b*) Reflected pains of a neuralgic character may be excited by aneurysm. This is true, in particular, of aneurysms situated in the transverse portion of the aorta, in which instances pain is commonly felt in the region of the neck and occiput

and down the left arm. When the growth is situated along the course of the descending aorta, intercostal neuralgia may be excited, due to pressure upon the nerve-trunks.

The *cough* is paroxysmal, and frequently has a peculiar brazen, ringing character that points to its laryngeal seat. Pressure upon the windpipe excites a paroxysmal dry cough. Compression of a bronchus may lead to bronchiectasis, and the cough then occurs only in severe paroxysms which recur at intervals of a day or even longer, and are attended with copious, ropy expectoration (*vide* Bronchiectasis).

Dyspnea is a conspicuous symptom in aneurysm of the transverse portion of the aorta (the aneurysm of symptoms—Broadbent). It arises (*a*) most frequently in consequence of pressure upon the recurrent laryngeal nerve, (*b*) direct pressure on the trachea, and (*c*) from pressure on the left bronchus. Marked stridor may accompany the first variety.

Paralysis of the vocal bands is occasioned by compression of the recurrent laryngeals, particularly the left, while a slight degree of compression or irritation of the same nerve causes *spasm* of the vocal cords. The symptoms of these conditions are hoarseness, cough, and aphonia respectively. The laryngoscope should be employed, since paralysis of one of the abductors may be present without giving rise to appreciable symptoms.

Hemorrhage may occur as a slow oozing, either from the point of compression in the trachea or externally; in either case the bleedings are small. Profuse bleedings (producing sudden death) take place in consequence of rupture of the sac into the lung, the bronchus, or the trachea.

Deglutition may be difficult owing to compression of the esophagus. When an aneurysm has been diagnosed or even suspected, the esophageal sound should not be passed, lest the sac be ruptured.

Compression and irritation of the sympathetic system of nerves cause pupillary changes that have already been mentioned. With dilatation of the pupil there may be observed pallor of one side of the face due to stimulation of the vasodilator fibers; on the other hand, with contraction of the pupil (due to paralysis of the constrictor fibers) there is hyperemia of one side of the face and unilateral sweating, with drooping eyelid. The most common cause of anisocoria is unequal blood-pressure in the ophthalmic arteries (Wall and Walker).

Clubbing of the fingers and incurvation of the nails (at times unilateral) are not rarely met with in thoracic aneurysm.

Physical Signs.—*Inspection.*—Visible pulsation is one of the earliest appreciable signs. It is most frequently observed at the right side of the sternum, above the level of the third rib (second interspace), and much less frequently on the left side over a corresponding area. In aneurysm of the transverse portion pulsation may be seen at the episternal notch, though an impulse here may be due to nervous palpitation, and have no connection with aneurysmal growths. When pulsation is associated with swelling, its diagnostic value becomes greater.

Involvement of the innominate artery produces pulsation in the neck above the sternoclavicular junction, or less commonly above the sternum. Corresponding to the site of visible impulse, there is, sooner or later, bulging in most instances. It may, however, be so slight as to elude detection unless the keenest observation be practised, and in not a few instances the tumor itself is invisible from the front of the body, but is recognizable on looking from behind or from either side. Again, on allowing the light to fall obliquely upon the chest, slight prominences may be brought to view that would otherwise be inappreciable.

When the aneurysm is situated in the ascending part of the arch, the most

frequent seat of the bulging—which varies in size from a hen's egg to a cocoon—*is* over the first and second right interspaces near to, and frequently involving, a portion of the sternum; when seated just beyond the aortic orifice a pulsating prominence may occupy the third interspace along the left sternal border; situated in the transverse section of the aorta, bulging of the upper part of the sternum is common. In the descending portion the swelling, when present, is in the second and third left interspaces near the sternum, or in the left scapular zone. The apex-beat is displaced downward and outward, chiefly from pressure, though also from hypertrophy (functional).

Palpation.—The protrusion presents a more or less yielding and elastic mass, and when superficially seated fluctuation may be obtainable. The degree and the rhythmic expansile character of the pulsation are to be noted, and also the fact that there is an alternate contraction and dilatation of the sac in every direction—a distinctive feature.

If the aneurysm is largely concealed, bimanual palpation should be employed, the palm of one hand being placed over the spine and that of the other over the sternum. In rare cases aneurysmal pulsation is only yielded when the finger-tips are used, and especially at the end of expiration. A diastolic shock is often perceived, and forms a sign of no little value. A distinct systolic shock, sometimes accompanied by a purring fremitus, can also be felt over the aneurysmal sac.

Percussion.—If the growth be deep-seated, percussion may give negative results; when, however, the tumor causes bulging or comes in contact with chest wall, a proportionate area of flatness is presented. The abnormal field of dulness may be the only symptom present; it is the most frequent sign. Aneurysms of the ascending arch give flatness to the right of the sternum; those of the transverse arch, over the upper part of the sternum and to the left; while those of the descending portion are revealed by a flat area between the spine and the left scapula. With flatness of the percussion-note there is a sense of increased resistance. There is generally a moderate increase in the area of cardiac dulness. Conversely, the left ventricle has been found of diminished size at necropsy.

Auscultatory percussion (practised after the method of Sansom and Ewart) quite often gives valuable results.

Auscultation.—Since murmurs owe their origin, in great part, to the presence of fibrin in the sac, they may be absent, and this even in the case of large aneurysms. When, as is usual, a murmur is present, it is systolic in rhythm, heard with greatest intensity over the flat area or body of the tumor, and is transmitted in the direction of the blood-stream, being, therefore, distinctly audible in the vessels of the neck and along the course of the aorta. The murmur has a booming quality.

Aortic regurgitation may be considered as associated with aneurysm near the aortic ring when a double murmur is heard. In a few instances the diastolic bruit alone is detectable. A much intensified, low-toned second sound is present (unless marked aortic regurgitation coexists).

The Peripheral Arteries.—The pulse in the vessels beyond the aneurysm is delayed. Hence the two radial pulses may exhibit differences in *time*. The *volume* of the pulse beyond the aneurysm is lessened, and in aneurysm of the abdominal aorta or the femorals it may be obliterated. Such differences as these will not only point to the existence of thoracic aneurysm, but also its *seat*. Thus, if there be dilatation of the transverse arch with no implication of the innominate, the pulse at the right wrist is strong and almost simultaneous with the cardiac impulse, while that on the left side is small, weak, and delayed. If the reverse be true with respect to the pulse, then the aneu-

rysm may be near or involve the innominate. O. K. Williamson has found a marked difference in the blood-pressure of the two arms in cases of thoracic aneurysm, a variation of more than 20 mm. Hg. being in favor of aneurysm.

Tracheal Tugging.—This sign may be practised while the patient is sitting or standing with the chin slightly elevated. The cricoid cartilage is grasped between the thumb and forefinger and pushed upward so as to stretch the trachea. The patient must cease breathing momentarily, when, if this sign be present, there will be a downward tugging at each systole. The transmitted pulsations from the cervical vessels must not be confounded with the vertical movement of the trachea. A new method of eliciting tracheal tugging, first suggested by Ewart, has been widely adopted and possesses the advantage of ensuring greater delicacy of touch than the old. He stands behind the patient, supporting the head of the latter against his body, and grasps the cricoid between the tips of the forefingers. The method is in other respects similar to that previously described. As shown by Toulmin, the tracheal tug may be present in health and in other diseases; hence it is of little value.

Diagnosis.—In the presence of the following points the existence of thoracic aneurysm may be confidently inferred: (1) Antecedent arteriosclerosis (with the appropriate causes of the latter); (2) history of other etiologic factors, as syphilis or the finding of a positive Wassermann in a young individual (between thirty and forty-five years) and occupation (such as entail unusual muscular strain); (3) pressure-symptoms, as pain, dyspnea, aphonia, cough (either laryngeal or bronchial), bronchorrhea, dysphagia, edema, vasomotor disturbances; (4) physical signs of a pulsating tumor (including the abnormal area of dulness, systolic murmurs, the systolic and diastolic shock, and tracheal tugging) somewhere along the course of the arch or its great branches, with or without differences in the blood-pressure, and in the volume and time of the radial pulses. There are, however, several classes of cases which offer difficulties that are sometimes insurmountable: (a) Those in which the aneurysm is small and deep seated. Here the symptoms and physical signs are indefinite. There may be thoracic oppression, in which pain may radiate to the left shoulder, and mild pressure symptoms—a group of suspicious features merely—sometimes appear. In one of my cases left-sided intercostal neuralgia was the only symptom present. (b) Aneurysm of the transverse arch, in which the pressure symptoms are more or less pronounced, but with no physical signs. In such, a clear history suffices to complete the diagnosis. Pressure symptoms without etiologic factors are just as likely to be due to other causes. (c) Those cases in which the more characteristic features are manifested intermittently. Fortunately, a proper diagnosis of aneurysm in obscure and latent cases can be usually made by the aid of the roentgen rays, and it can also be excluded, in suspected cases, by fluoroscopic examination.

Extremely obscure are many of the cases, in which the only symptoms manifested point to irritation of the trachea or bronchial tubes, with paroxysmal cough, or the signs of bronchiectasis. In a recent case of this sort tracheoscopic examination revealed compression of the windpipe. In another instance the laryngoscope determined the diagnosis, in that it brought to view bilateral paralysis of the abductors of the vocal bands. A symptom, which has been designated by its author, R. V. Hoesslin, as “diastolic expiration,” is due to compression of the trachea by an aneurysm, so that air can escape from the lungs only during diastole, when the sac diminishes in size.

Differential Diagnosis.—The affections from which intrathoracic aneurysm must be distinguished are *pulsating empyema*, *pulmonary tuberculosis*, *abnormal pulsation of the aorta*, and *solid tumors*. Of the latter, those simulating aneurysm are carcinoma, sarcoma, and enlarged lymph-glands. These *mediastinal*

tumors may duplicate all of the pressure-symptoms, though less apt to cause bulging, and less apt still to excite abnormal pulsation; when pulsation is noted it is quick, and not heaving and expansile, as in aneurysm. Solid growths also lack the characteristic shock—both systolic and diastolic—of aneurysm. The cardiovascular symptoms are usually wanting in the case of solid tumors, especially the moderate hypertrophy, accentuation of the second sound, tracheal tugging, and the difference between the radial pulses.

Carcinoma of the mediastinum usually gives a history of the disease in other parts of the body, with enlargement of the axillary or other superficial lymphatic structures, and later the characteristic cachexia, this being particularly marked in carcinoma of the esophagus.

Abnormal pulsation in the aorta is noted in neurotic subjects, mostly females, and in aortic regurgitation; less frequently it is associated with retraction of the right lung, with spinal curvature, and with displacement of the aorta. In the case of the latter two conditions a careful consideration of the causal states and the absence of the characteristic physical signs would lead to a correct diagnosis. *Aortic regurgitation* is frequently associated with aneurysm of the arch, and in its course there is often developed a dilatation of the ascending portion of the aorta. The diagnosis of aneurysm of the arch of the aorta should not be made, therefore, in these cases, unless the physical signs and symptoms be unmistakable. Dynamic pulsation of a neurotic origin is seen and felt in the episternal notch, as a rule, and a correct appreciation of the nervous element will prevent the observer from committing an error.

Pulsating empyema can only be confounded with large aneurysmal growths, and, as pointed out by Wilson, it does not have the same definite relation to the central long axis of the body as do aneurysms. The abnormal field of dulness is situated at the base of the lung in empyema, and is less circumscribed than in aneurysm. In empyema, moreover, the pulsation is not expansile, but is caused by pressure of the respiratory movements. Auscultation in empyema renders audible neither a bruit nor the double shock of aneurysm; the pressure-symptoms and pulse characters are also entirely wanting.

Pulmonary tuberculosis may be mistaken for thoracic aneurysm. When an aneurysm compresses a bronchus, bronchiectasis, attended with cough, bronchorrhea, fever, and emaciation, may be the result; but in phthisis the fever and emaciation are more pronounced, tubercle bacilli are present, while the cardiovascular signs of aneurysm are absent.

Prognosis.—The occurrence of perforation and consequent speedy death in unsuspected cases must be recollected. In other instances the end is approached in a very gradual manner, and cases in which rupture does not supervene sometimes pursue the general course of chronic valvular affections of the heart. The condition ends in death as a rule, and the *immediate causes* of the fatal issue are as follows: (1) Rupture of the aneurysm, followed by hemorrhage into any of the adjacent cavities or organs (pericardium, heart, large vessels, mediastinum, trachea, a bronchus, esophagus, lungs, pleura, spinal canal); it may, though rarely, rupture externally, in which case slight hemorrhages occur and life may last for weeks. Lemann's statistics show that in 592 autopsies rupture occurred into the pericardium 148 times, equal to 25 per cent.; externally only 35 times, equal to 5.9 per cent. (2) Gradual asthenia. (3) Direct pressure. (4) Independent diseases, either primary or secondary to, and induced by, the aneurysm. Among these, *pulmonary complications*—fibrinous pneumonia, abscess, gangrene, tuberculosis—are of first importance.

Treatment.—There are two main objects of treatment—first, the promotion of coagulation of the blood, and second, the contraction of the sac. The clotting of the blood within the growth may be greatly favored by retard-

ing the blood-current. Nothing so well accomplishes this object as *absolute rest* in the recumbent posture. This cannot always be rigidly enforced, but muscular exertion must be minimized, mental application regulated, and emotional excitement avoided; stimulants, arterial and nervous, are to be eschewed for like reasons. Palpitation of the heart, when present, is to be allayed by the local use of the ice-bag. The coagulability of the blood is also increased by removing as far as possible the liquid portion of the diet. The measures already indicated tend to lessen the volume of blood and the intra-aneurysmal pressure, thus inviting **contraction of the sac** as well as consolidation of its contents. A. E. Wright has insisted upon the value of calcium salts to increase the coagulability of the blood (gr. x to xv—0.6–1.0, t. i. d., may be given). T. R. Boggs¹ thinks calcium salts increase the coagulability of the blood, the best for this purpose being the acetate and lactate of calcium. More recent work does not confirm this.

Among medicinal agents, potassium iodid has been employed with good effects. The exact manner in which the iodid produces its favorable results in these cases is probably because the disease is so frequently of syphilitic origin; this view accords with my own personal experience. I would advise against the prolonged internal use of ergot. Numerous observers have resorted to the use of horse-hair, fine wire, fine catgut, slender watch-springs, with a view to coagulating the blood as it comes in contact with these foreign bodies. Electrolysis is a method that has been warmly advocated (Loreta).

Combined wiring and electrolysis (Corradi's method) has been successfully employed by Rosenstein, Kerr, D. D. Stewart, H. A. Hare, and Herchy. The details of the method are, briefly, as follows:

A piece of fine wire, several feet in length, is passed from a spool through a small insulated canula, so that the wire curls up within the sac. It is attached to the positive pole, while the negative is connected with a surface pad placed over the abdomen. The current is then passed through, and gradually increased in strength to 40 to 80 milliampères. Before stopping the current its strength should be slowly decreased. Each application of the current should last from one to two hours. It is not, however, without serious dangers (hemorrhage and embolism).

Galvanopuncture has long been resorted to, and in some instances with encouraging results. The cases that receive most benefit from the above measures belong to the saccular variety; this is also true of the plan first commended by Tufnell, which is especially applicable in the earlier stages. Tufnell's method is founded upon two principles—absolute rest in the recumbent posture, and a much-restricted, dry diet. A quiet mental state should be conjoined. The diet is as follows: Breakfast, 2 ounces (60.0) of bread and butter and 2 ounces (60.0) of milk; for dinner, 2 or 3 ounces (60.0–90.0) of meat and 3 or 4 ounces (90.0–120.0) of milk or claret; for supper, 2 ounces (60.0) of bread and 2 ounces (60.0) of milk.

The chief advantages growing out of this method are the lessened number and force of the heart-beats in consequence of the bodily rest, and the diminution of the blood volume in consequence of the dietetic restrictions. It should be persevered in for several months. The bowels should be regulated, and straining at stool prohibited. Lastly, it is to be recollected that an early diagnosis, *e. g.*, in cases due to syphilis, may enable prompt antisiphilitic treatment to arrest the aneurysmal process.

Special Symptoms.—Pain is often relieved by potassium iodid. When arterial sclerosis is present I have seen relief from pain afforded by the use of nitroglycerin (m̄j to ij—0.065–0.13, four times a day). In the later stages

¹ *New York Med. Jour.*, February 1, 1908.

morphin should be given. When there is bulging the pain may be relieved by the ice-bag or by a belladonna plaster.

Dyspnea and great venous congestion are to be met by venesection, and tracheotomy may be required in bilateral paralysis of the abductors. In dyspnea from pressure on the trachea or bronchus, however, tracheotomy would be a valueless expedient. When the aneurysm forms a large external tumor the application of an elastic bandage to the chest may be both agreeable and advantageous, as in a case referred to by Osler.

Among subjects of arteriosclerosis, tortuosity and elongation of the aorta may exist and give rise to some of the signs of aneurysm of the arch. Holzknecht¹ was the first to point out this pseudo-aneurysmal dilatation, but he classified them as dislocations of the aorta. Joseph Sailer and G. E. Pfahler² have made fluoroscopic and radiosopic examinations of 18 cases, some of which were autopsied at a later date, and showed that pulsating hemispheric shadows above the heart were not always aneurysms, but often mere tortuosities of the aorta, which cast a shadow from $\frac{1}{2}$ to 2 inches to the left of the fifth and sixth dorsal vertebræ.

The *symptoms* of atheroma with tortuosity are for the most part negative, but certain physical signs which strongly suggest aneurysm are commonly observed. "Probably it would be justifiable to suspect tortuosity in cases in which there is inequality of the radial pulse, slight tracheal tugging, dyspnea, and in which the symptoms are stationary for a considerable period of time and the fluoroscope shows a projection to the left of the descending portion of the arch of the aorta that has no true expansile pulsation" (Sailer and Pfahler).

ANEURYSM OF THE ABDOMINAL AORTA

The vicinity of the celiac axis is the favorite seat of abdominal aneurysm, which is less common than intrathoracic aneurysm, though not rare. It may assume a fusiform or saccular nature.

Symptoms.—The tumor may grow backward; but more frequently it grows forward. Projecting from the *posterior wall*, it usually erodes the vertebræ, and compression of the cord is apt to take place, producing *paraplegia*, preceded by *tingling* and *numbness of the legs*.

Pain is the leading symptom. It may be neuralgic or of a boring or gnawing character, due to destruction of the bone. Rarely, the aneurysm perforates the diaphragm, and finally *ruptures* into the lungs or pleura. Arising from the *anterior wall*, it may early form a well-defined tumor. It may, however, when situated high up or near the diaphragm, conceal itself until it has attained a comparatively large size, as in a case under my care at the Medico-Chirurgical Hospital. *Vomiting* and *gastralgie seizures* may be troublesome, and the fact that *embolism* of the superior mesenteric artery may occur and give rise to severe colicky pains must be recollected. *Jaundice* has been observed.

Physical Signs.—Epigastric pulsation may be *visible*, and occasionally an epigastric swelling. The *palpating* hand detects a heaving, expansile pulsation that may be accompanied by a thrill. When the tumor hugs the diaphragm the pulsation may be double. The femoral pulse is diminished in volume and delayed. An abnormal area of dulness may be present. In most instances a *soft bruit* is audible. The diastolic murmur and shock of *intrathoracic aneurysm* are usually absent.

Diagnosis.—A certain diagnosis demands the presence of a definite growth that is seizable and has a heaving, expansile pulsation. Mere pulsation attended with a thrill and a systolic murmur are insufficient.

¹ *Wien. klin. Wchnschr.*, 1900, No. 10.

² "Tortuosity of the Aorta," *Amer. Jour. Med. Sci.*, October, 1903.

Differential Diagnosis.—A *throbbing aorta*, as met with in neurotic females and in anemia (particularly in instances of the traumatic form), is sometimes distinguished from aneurysm of the abdominal aorta with great difficulty. It does not, however, present a pulsating tumor that can be held in the grasp, as in aneurysm.

When *solid growths* lie upon the aorta the latter may manifest pulsation, a thrill, and a systolic murmur, but the very general absence of pulsation (when the patient is placed in the knee-elbow position), owing to the fact that the tumor falls forward, suffices usually to differentiate the condition from genuine aneurysm. Again, expansile pulsation is not evinced by a solid growth.

The **prognosis** is very gloomy. Very rarely, however, nature effects a cure if the conditions be favorable. "Death may result from (a) the complete obliteration of the lumen by clots; (b) compression paraplegia; (c) rupture either into the pleura, retroperitoneal tissues, peritoneum, the intestines, or, very commonly, into the duodenum; (d) embolism of the superior mesenteric artery, producing infarction of the intestines" (Osler).

Treatment.—Apart from the measures indicated for thoracic aneurysm, there is one means of cure that may be tried if the growth be low down—viz., *pressure*. This must be maintained for twenty-four hours at least under an anesthetic. It is best to make steady pressure on the proximal portion of the vessel, and unless practised with great care the sac will be damaged and death ensue.

ANEURYSM OF THE PULMONARY ARTERY

Dilatation of the pulmonary artery is of frequent occurrence in affections that oppose obstruction to the lesser circulation (*e. g.*, mitral disease, emphysema, phthisis). Very rarely extreme dilatation of the vessel is followed by semilunar incompetence, when a diastolic murmur at the pulmonary orifice (second left interspace) becomes audible.

Aneurysms involving the pulmonary artery are quite rare: such as occur are small and of the saccular and fusiform varieties.

The **symptoms** resemble those of *intrathoracic aneurysm*, though they are rarely well marked, owing to the fact that they remain of small size as a rule.

Physical Signs.—Pulsation (and, rarely, a small tumor) is detectable in the second left interspace. *Palpation* may also render appreciable a thrill and diastolic shock. Coextensive with the area of pulsation there may be *dullness* on percussion, and over the second interspace to the left of the sternum a loud *superficial systolic murmur* is heard on auscultation, together with a diastolic shock. Before attaining to a large size, these aneurysms usually *rupture* into the heart itself.

The **prognosis** is altogether unfavorable, the treatment having reference to the principles that are appropriate in thoracic aneurysm.

The **coronary arteries** may be the seat of aneurysm, though exceptionally. The condition arises in consequence of weak points (due to arteriosclerosis) in the course of the vessels, and is unrecognizable during life.

ANEURYSM OF THE CELIAC AXIS

This condition is sometimes observed in combination with aneurysm of the upper portion of the abdominal aorta.

ANEURYSM OF THE SPLENIC ARTERY

This branch of the celiac axis is occasionally the seat of aneurysmal dilatation. It may be single or multiple, and while it is small, as a rule, may in rare cases be quite large.

The **symptoms** are indefinite, but distressing. Deep-seated abdominal pain, which shows a tendency to radiation, forms, with *vomiting*, and rarely *hematemesis*, the main features. By *percussion* a tumor may be mapped out in the left hypochondriac region, the dulness merging with that of the spleen and the left lobe of the liver. Usually, pulsation, and, rarely, a tumor can be felt, and *systolic murmur* is often heard. The condition may be confounded with *gastric ulcer*.

ANEURYSM OF THE HEPATIC ARTERY

This is exceedingly rare, the total number of cases on record being about 20. H. B. Schmidt has recently reported a case associated with symptoms of gall-stones, in which, as shown by the autopsy, death was caused by rupture of the sac into the bile-ducts. Schmidt found records of but 5 cases of this mode of termination. Osler and Ross have reported an instance associated with multiple hepatic abscesses.

The **symptoms** are, in the main, *colicky pains*, *vomiting*, *hematemesis*, and *obstructive jaundice*. A tumor is rarely discernible, though an abnormal area of pulsation is relatively more frequent. The recognition of the condition during life is entirely conjectural.

Aneurysm of the superior mesenteric artery is of rare occurrence. Pain in the epigastric and lumbar regions, and *demonstrable tumor* near or directly over the median line of the abdomen, are the symptoms displayed. Detached fragments of the clot may produce *embolism* of the terminal branches of the mesenteric arteries. The condition terminates usually in rupture into the peritoneal cavity.

Aneurysm of the inferior mesenteric artery runs a course similar to the above. It is quite rare and possesses slight interest.

Aneurysm of the Renal Arteries.—Small multiple dilatations are occasionally seen, but large ones are of great rarity. They are prone to rupture into the retroperitoneal cavity.

ARTERIOVENOUS ANEURYSM

Definition.—An artificial communication between an artery and a vein. A sac may intervene between the two vessels (*varicose aneurysm*) or there may be a direct fistulous communication without an intervening sac (*aneurysmal varix*).

In varicose aneurysm the sac is developed from the structures that mark the boundaries of the communicating duct. The majority of cases are caused by the simultaneous wounding of an artery and a vein. Their most frequent seat is at the bend of the elbow. Pepper and Griffith have analyzed the records of 29 cases in which the ascending portion of the aortic arch had opened into the vena cava.

The **symptoms** are largely *aneurysmal*, and, in addition, there appear in rapid sequence *great swelling of the veins*, *cyanosis*, and *edema* of the upper portion of the body. A continuous *thrill* and *buzzing murmur*, with systolic intensification, are the chief signs.

In the **treatment** of thoracic arteriovenous aneurysm the same general plan is to be pursued as advised in the purely arterial variety.

CONGENITAL ANEURYSM

This condition arises because of a defective antenatal development of the elastic coat. It is often multiple, and the tumors are, as a rule, small in size, ranging from that of a pea to a hazelnut. The most common situations for these growths are the coronary and pulmonary arteries. To Eppinger belongs the credit for having pointed out the fact that the aneurysmal walls consist only of the adventitia and intima. *Peri-arteritis nodosa*, a rare condition, which Eppinger holds to be a form of congenital aneurysm, presents the symptoms of general infection rapidly developed. "On examination after death the arteries are found beset with nodules of active inflammatory products, chiefly on the outer coat" (Allbutt). The condition may be met with in children and rarely in adults.

PART VIII

DISEASES OF THE DIGESTIVE SYSTEM

I. DISEASES OF THE MOUTH

STOMATITIS

CATARRHAL STOMATITIS

(*Stomatitis Erythematosa*)

Definition.—A simple, acute inflammation of the buccal mucous membrane. It is more commonly met with in children than in adults.

Etiology.—As a *primary* affection its causes are mainly mechanical and chemical irritation, such as the presence in the mouth of hard and sharp bodies, dental caries, acids, hot or cold food, condiments, tobacco, certain drugs (as mercury), eruption of teeth, and bad feeding, particularly in ill-nourished children. It is the result often of a neglect of the mouth toilet, leading to the decomposition of accumulated bits of food and mucus, and many cases probably owe their origin to infection. *Secondarily*, catarrhal stomatitis may be associated with certain of the eruptive fevers (scarlet fever, measles, typhoid), also with gastro-enteric derangements, and may follow, by direct inflammatory extension, ulcerative tonsillitis and pharyngitis.

Symptoms.—The *local symptoms* of this affection are those usually seen in an inflammation of a mucous membrane—redness, heat, swelling, and dryness, soon followed by increased secretion and soreness. The lips and gums only, or the membrane of the whole mouth, may be inflamed, and the swollen lips, cheeks, and furred tongue may be indented by teeth-marks. Enlarged and reddened papillæ on the tongue and minute vesicles inside the cheeks and lips from projecting mucous follicles are sometimes seen to terminate in small ulcers. A craving for cold drinks is nearly always noted, and distress, pain on taking food, and a disagreeable taste due to the perverted buccal secretions. Microscopically, desquamated epithelium that has undergone partial fatty degeneration, leukocytes, and occasionally red blood-cells are seen. The *Leptothrix buccalis*, micrococci, and bacilli are also present. Aside from restlessness and the symptoms common to slight febrile disturbances, the *constitutional condition* is rarely disturbed, except when the stomatitis is secondary either to inflammations lower down in the digestive tract, or to the specific infectious fevers.

The *course* of the disease is usually acute, and the duration about one week.

The **differential diagnosis** of catarrhal stomatitis is easily made by inspection of the membrane.

The **prognosis**, though favorable, will vary as to time and severity according to the cause.

Treatment.—After proper attention to the hygienic surroundings of the patient and the removal of all irritant influences, the treatment is mainly local. The first indications are to cleanse the mouth and allay the pain, and these may be met by the use of cool solutions of boric acid, sodium bicarbonate, or potassium chlorate, 5 and 10 grains (0.3–0.6) respectively to the ounce (30.0) of glycerin and rose-water, as mouth-washes, or for swabbing in the case of infants. When iced drinks are ungrateful and the inflammation is more intense and protracted, the use of hot milk and lime-water, mucilaginous decoctions, and sedative and antiseptic sprays of 1 or 2 per cent. solutions of cocain or carbolic acid are often beneficial; or mild astringents may be needed, as $\frac{1}{4}$ to 1 per cent. solutions of silver nitrate, alum (5 to 10 grains—0.3–0.6—to the ounce 30.0—of honey), and glycerite of tannin (2 drams to the ounce—8.0 to 30.0—of water), especially if there is a tendency to chronicity of the trouble, as in toppers and inveterate smokers. Tender and spongy gums may be relieved by the application of equal parts of the tinctures of myrrh and rhatany on a camel's-hair brush (Strümpell). *General symptoms* must be met as they arise. Small doses of aconite or potassium citrate for the pyrexia, with a minimum dose of bromid for irritability and sleeplessness, may be all that is required. The internal use of potassium chlorate in children is not to be recommended in this affection, both because of its deleterious action upon the kidneys, and also because it seems to be unnecessary (Forchheimer, Blackader). Sometimes an associated gastro-intestinal catarrh needs correction by the use of laxatives. The administration of bland foods and mild ferruginous tonics should be continued throughout convalescence.

APHTHOUS STOMATITIS

(*Follicular Stomatitis; Stomatitis Aphthosa*)

Definition.—A variety of catarrhal stomatitis characterized by the eruption of one or more vesicles upon the edges of the tongue, the cheek, or the lips, rapidly passing into small round or oval discrete spots that are slightly raised and surrounded by yellowish-white bases with narrow red areolæ.

Etiology.—Though more common in children between the ages of two and six years, it is by no means rare in adults. Predisposing influences may be found in the seasons (spring and autumn), malnutrition, tuberculosis, dentition, persistent gastro-enteric disorders, anemia, and the acute exanthemata. The *exciting causes* are supposed to be certain deleterious substances, bacterial or toxic, though no special parasite has yet been isolated.

Symptoms.—The herpetic vesicles soon rupture, leaving the aphthous ulcers as described. They are found singly, or at times as many as twenty in number, pin-head to split-pea in size, inside the lips, especially near the frenum, along the tongue edges, and sometimes inside the cheeks near the edges of the back teeth. They are exquisitely *tender*, so that almost any motion of the affected parts causes sharp burning pain; nourishment is therefore difficult. Patches of *catarrhal stomatitis*, and even of gingivitis, are seen adjacent to the aphthous spots. There is an increased flow of the secretions of the mouth, and the breath is heavy, but seldom offensive. *General symptoms*, as slight fever, anorexia, and furred tongue, constipation or diarrhea, and irritability, are usually present, with the additional symptoms of any associated disease that may coexist. Gastro-intestinal affections, though often associated with aphthous stomatitis, are most probably due to the common cause, and are not necessarily the cause of the stomatitis in these instances. In some of the specific infectious fevers many aphthæ may appear and tend to run together; these form large irregular ulcers, and give rise to the *confluent*

form of stomatitis aphthosa. The special form known as *Bednar's aphthæ*, occurring in young marantic babes, is a rare condition in America. Large white patches are seen on both halves of the posterior part of the hard palate near the alveolar processes, and these may cause large ulcers and involve the bone. Pressure of the tongue upon the thin mucous membrane during nursing, or other forms of traumatic irritation, appear to act as causes.

Aphtha Cachectica (Riga's Disease).—Fede has described a form of aphtha, occurring principally in Southern Italy (a raised, gray swelling), situated on the frenum and under surface of the tongue. It affects children soon after the eruption of the lower incisors. A severe type is sometimes met, and this may terminate fatally.

The average *duration* of the ordinary discrete aphthous eruption is from four to seven days; in very ill-nourished and poorly cared for cases the appearance of successive crops of aphthæ will prolong the distress.

Diagnosis.—This is based upon the characteristic appearance of the ulcers and the degree of soreness. Aphthæ must be differentiated from *thrush* (see page 694), where the distinguishing features will be dwelt upon in the description of the latter affection. Herpes of the mouth, so called, and aphthous vesicles are probably identical in most cases.

Prognosis.—The discrete form is mild, and favorable in its course toward recovery; confluent aphthæ is more troublesome, and follows a prolonged course on account of the general debility induced by the associated disease (Starr). In certain cases the affection is apt to recur; relapses are also frequent in those having weak digestive and imperfect assimilative functions. Recovery from Bednar's aphthæ is rare.

Treatment.—It is first necessary to remove all irritating influences, and in order to minimize the intense pain of the aphthous spots the blandest liquids and the softest foods that are consistent with the sustenance of the patient are imperative. Absolute cleanliness of the mouth, the foods, and the vehicles of administration, especially in bottle-fed children, is important. Local applications are of obvious value. Demulcents, as mucilage of sumac, or of marshmallow, with boric acid (gr. v to ʒj—0.3–30.0), sodium bicarbonate gr. v to ʒj—0.3–0.6 to 30.0), carbolic acid, or potassium permanganate (gr. iv to ʒj—0.25–30.0), are invariably useful. Swab applications of wine of opium (m̄v to ʒj—0.3–30.0) or of cocain (4 per cent. solution) may be necessary when the pain is intense, and prior to taking food.

To promote the healing of the ulcers a very light touch with the silver-nitrate stick or solution (gr. x-xxx to ʒj—0.6–2.0 to 30.0) is often beneficial. Much favor is deservedly given also to potassium chlorate in solution (gr. x to ʒj—0.6–30.0), or applied in the dry powdered form. In the confluent aphthous ulcer the use of sodium salicylate (ʒj to ʒj—4.0–30.0) has been recommended, while an ethereal solution of iodoform (ʒij to ʒj—8.0–30.0) has been advised by J. Lewis Smith. For bleeding and spongy gums the mild astringents mentioned in the treatment of catarrhal stomatitis are indicated. Stronger astringents may answer for application to sluggish ulcers; thus copper sulphate, either solid or in solution (gr. x to ʒj—0.6–30.0), and zinc sulphate (gr. xv to ʒj—1.0–30.0) are useful. Potassium chlorate acts as a specific in ulcers of the mouth, and is eliminated by the buccal secretions, which keep the ulcerated surfaces constantly bathed with the drug, so that its internal use is to be recommended, though in very small doses in children, well diluted, as in the following formula for a child three years of age:

R. Potassii chloratis, gr. xxiv (1.5);
Syr. aurantii, q. s. ad fʒiij (90.0).—M.
Sig. Teaspoonful in water every three hours.

Constitutional symptoms are to be combated on general principles and require careful attention. Remedies directed to the correction of digestive derangements and to the stimulation of assimilation are also often required. Good food and ferruginous tonics are necessary.

MEMBRANOUS STOMATITIS

(*Stomatitis Crouposa*)

Definition.—In this form of stomatitis the inflammation is more intense and more extended in area than in the aphthous form, being also attended with the formation of a false membrane.

The **pathology** of these membranous patches, which are very seldom confined to the mouth alone, is embraced in the article on Diphtheria. If in the latter disease the typical false (diphtheritic) membrane is removed, it leaves a deeper ulcer than does the removal of a croupous membrane, in which the coagulation-necrosis involves the more superficial layers only.

The **etiology** of membranous stomatitis is usually specific (diphtheritic, streptococcic). Membranous stomatitis may also be due to gonorrheal or syphilitic infection of the newborn.

Symptoms.—Some of these cases are, doubtless, true diphtheria of the oral cavity (usually secondary from extension), and an account of the symptoms presented may be found in the chapter on Diphtheria, p. 147. The writer has seen instances of extensive membranous stomatitis in which bacteriologic examination showed the presence of streptococci (principally) and also staphylococci. The symptoms were analogous to streptococcic membranous pharyngitis with the difference, in my cases of membranous stomatitis, that salivation was marked and distressing. The *general features* may be quite pronounced.

ULCERATIVE OR FETID STOMATITIS

(*Stomatitis Ulcerosa*)

Definition.—A specific ulcerative inflammation of the buccal mucous membrane and gums, attended with marked fetor of the breath, and having a tendency to extend widely and deeply.

Etiology.—The predisposing causes of this malady are principally as follows: Childhood, after the commencement of the first dentition, and usually between the ages of three and eight years; damp weather, especially during spring and autumn; unhygienic surroundings, particularly the lack of pure air, of good and abundant food and clothing, and the added detriments to health for which neglect and filth, specific infectious diseases, uncleanness of the mouth, caries and loosening of the teeth, and congenital heart disease (Duckworth) are responsible. An endemic type of this affection has been observed among soldiers in camps and barracks, among children in crowded eleemosynary institutions, and in jails. Its epidemic and contagious character likewise points to a microbic origin. The specific *exciting cause*, it has been held, corresponds to the hoof-and-mouth disease of cattle, the poison being conveyed in milk. Payne suggests the identity of the virus with that of impetigo contagiosa. The careless administration of mercury may also be followed by this affection. Scurvy (*scorbutic stomatitis*) and the persistent use of lead and phosphorus are also excitants.

Clinical Symptoms.—*Locally*, the disease starts, as a rule, at the edges of the gums opposite the lower incisor teeth, gradually spreading backward and to the adjoining portions of the lips and cheeks. The gingival mucous membrane is deeply red and swollen; the gums soon become spongy, bleed easily, and break down into thick, soft, grayish sloughs, which leave deep

and ragged ulcers surrounding the necks of the teeth. The latter even become loosened, and in protracted cases the alveolar periosteum may become inflamed and cause necrosis of the bone. Profuse salivation, a foul breath (that once earned for the condition the term of "putrid sore mouth"), occasional slight hemorrhages from the gums, and excessive discomfort, or even pain, on mastication are nearly always present. The tongue is coated, swollen, and tooth-marked; aphthæ are sometimes seen, and the submaxillary glands are generally swollen. The *general symptoms* attending this ailment are those of a lowered state of vitality, produced by an unhygienic environment, or cachexia, or severe illness primary to it, with, usually, moderate fever. Nausea and vomiting or an offensive diarrhea may supervene as the result of swallowing the putrid discharges.

Course and Duration.—Usually acute in its course, the highly debilitating character of the disease may tend to make it chronic, especially when there is alveolar necrosis and a neglect of proper treatment. Ordinarily, with careful management, convalescence may be established in from four days to a week. Goodhart regards the occasional termination of the pyrexia by lysis, with an accompanying improvement of the local symptoms in such cases at least, as suggestive of the specific nature of ulcerative stomatitis.

Neurotic Ulceration.—Under the head of *stomatitis neurotica chronica* Jacobi describes a herpetic (rarely pemphigoid) eruption in neurotic subjects. Sibly has met 3 cases, all of which occurred in women beyond middle age. In all the condition has lasted for a number of years and produced great difficulty in talking and mastication.

Diagnosis.—Upon examining the mouth and noting the characteristic ulceration, the fetid breath and saliva, and the cachetic appearance, the disease is usually recognized, and should not be confounded with the dark, extensive, gangrenous sloughs of noma.

The **prognosis** is favorable in typical cases, though less so in marasmic and neglected cases. When cancrum oris or necrosis of the jaw occur, chronicity, deformity, and even death may take place.

Treatment.—It is well in nearly all ill-nourished, uncleanly kept, and sickly children, as well as in cases in which mercury is to be administered for any length of time, to prescribe mouth-washes of potassium chlorate (gr. xv to ʒj—1.0–30.0), in order to prevent the occurrence of mercurial or ulcerative stomatitis. The *hygienic treatment* of ulcerative stomatitis is important. On account of the contagiousness of the disease cases occurring in a family or in institutions should be isolated, and fresh air, light nourishment, and cleanliness are *sine quâ non* of recovery. The *local treatment* is virtually a specific one in the use of potassium chlorate washes (gr. x—xx to ʒj—0.6–1.3 to 30.0—of rose-water or demulcent), aided by the internal administration of the same salt in small doses. For the disagreeable fetid odor the alternate use of antiseptic washes is indicated. Solutions of carbolic acid or potassium permanganate, in strength equal to or slightly over that indicated in the treatment of aphthæ, or hydrogen peroxid (ʒj-iiij to ʒj—4.0–12.0 to 30.0), or alkaline antiseptic solution and water (equal parts), are useful. Penciling the spongy gums with such astringents as tincture of rhatany, silver nitrate (gr. x to ʒj—0.6–30.0), alum, and also with tannic acid solutions, may be necessary. Loosened teeth should not be disturbed, as they may grow firm with convalescence, though surgical interference may be required in cases of necrosis of the alveolar process. Kissel's method in obstinate cases is to curet the ulcers and rub into them powdered iodoform once daily. Careful attention to the teeth is always requisite. During the height of the disease constitutional treatment may have to be directed toward stimulating the languid and lowered vitality. For

this purpose either whisky or brandy, in half- or teaspoonful doses in milk, is extremely useful; the elixir of cinchona, with some vegetable salt of iron, as the citrate or tartrate, also forms a useful combination. When there is pyrexia or a diminished urinary secretion the internal use of potassium chlorate must be cautiously employed. The following prescription is almost specific for a child three years old (Starr):

R. Potassii chloratis, gr. l (3.3);
 Acidi hydrochlor. dil., fʒj (4.0);
 Syrupi, fʒvj (24.0);
 Aquæ, q. s. ad fʒiij (90.0).—M.
 Sig. Teaspoonful in water every two hours.

The prolonged use of tonics and cod-liver-oil emulsion with lime-salts in scrofulous, rachitic, and scorbutic subjects must be carried on in order to prevent relapses of ulcerative stomatitis.

PARASITIC STOMATITIS

(*Thrush; Stomatitis Mycosa*)

Definition.—A specific, contagious fungous disease, characterized by the rapid formation upon the oral mucous surfaces of small, whitish, soft, and lightly adherent spots or flakes, tending to coalesce and spread throughout the entire buccal cavity.

Etiology.—*Predisposing causes* are—infancy with its concomitant disorders of the gastro-intestinal tract (especially when unhygienic surroundings prevail), congenital syphilis, tuberculosis, and the exanthemata. The disease may attack adults and complicate the typhoid and cachectic states, as in the final stages of low fevers, carcinoma, chronic tuberculosis, and diabetes. The growth of thrush patches is due, specifically, to the *Saccharomyces albicans*, though micrococci have also been found. It is a characteristic of this fungus to develop from round or oval spores in the formation of long-branching mycelium filaments, from the ends of which a multiplication of ovoid torulæ cells takes place by the process of simple budding. The mycelia exhibit a tendency to penetrate the deeper layers of the mucosa of the mouth and also into the mucous glands (Starr). Since the growth of this organism requires both an altered condition of the mucous membrane and an acid medium, the primary or exciting cause of thrush is to be found in whatever produces such a favorable nidus. Most important in this connection is uncleanness, particularly in the case of poorly nourished and bottle-fed children. The development of catarrhal stomatitis and the acid fermentation of remnants of food (especially of saccharine substances), which impair the nutrition of the mucosa and acidify the normally alkaline oral secretions, are common causes of thrush. The further growth of the fungus patches also contributes to the acid state of the already abnormal buccal fluids. The fact that the spores of thrush may be transferred to other cases by bottle-tips, spoons, and ill-kept feeding-bottles is well recognized as an explanation for the occasional endemic character of the malady.

Symptoms.—Any marked local symptoms are due rather to the coexisting stomatitis than to the thrush itself (Allchin). There will be some *soreness, heat, persistent dryness, and lividity* of the mucous membrane. Thrush spots, slightly raised above the surface, begin to appear on the tongue, and grow into patches that may coalesce and spread to the cheeks, lips, and hard palate: they may even invade the tonsils, pharynx, and esophagus, and, rarely,

the true vocal cords, the stomach, and cecum (Parrot). At first pearly white in color, the curd-like flakes may become yellow and even brown, owing to slight hemorrhages caused by the irritation. Though early adherent, in a few days they become loose, and when brushed off leave a smooth surface; when complicating some serious gastro-intestinal disease or dyscrasia, however, their attachment is deeper, and the deposit may sometimes appear in successive crops. A *microscopic examination* of the thrush patches shows interlacing, irregular, and branched mycelial threads, spores, occasional bacilli, and leptothrix filaments embedded in a mass of granular debris and fetid particles. The buccal fluids are acid in reaction. The *general symptoms* depend upon the associated disease, and are usually those of wasting, artificially nourished children having digestive troubles or a constitutional taint.

Diagnosis.—This may be accurately made upon the discovery of the fungus by microscopic examination. Only very rarely are portions of the thrush organism found in the false membrane of *diphtheritic stomatitis*. *Mild curds* may be readily removed, and are not necessarily associated with the stomatitis accompanying thrush or the grave systemic states. The important point of differential diagnosis arises in the case of *aphthæ*. The following table will express the main points:

PARASITIC STOMATITIS (THRUSH)	APHTHOUS STOMATITIS
Dryness of the mouth.	Salivation.
Whitish, raised spots or patches with no red areola; these are easily removed, leaving no ulcer and causing no bleeding.	An ulcer with a yellowish-white, depressed base, surrounded by a red areola. The base is removed with difficulty by forceps, and bleeding results.
Spots are numerous.	Usually few in number and discrete.
Begins in the form of minute spots.	Not so; ulcers appear, preceded by the formation of herpetic vesicles.
Ulcers not painful. Discomfort depends on the associated stomatitis.	Ulcers exquisitely tender.
The characteristic thrush-fungus is always detectable with the microscope.	No specific micro-organism determined, though probably present.

Prognosis.—This is favorable as regards the thrush alone, but, occurring in marantic children and cachectic adults, its appearance is of grave significance, and may portend a speedy death.

Treatment.—Prophylaxis is of great moment, since it is much easier to keep the mouth clean and the secretions normal, and to attend to proper food, and thus avoid creating a soil for the growth of the vegetable parasite, than it is to prevent absolutely the entrance of thrush spores. Efforts directed toward preventing acidity are especially indicated. This is to be done by the use of mild alkaline mouth-washes, as soda-water and lime-water. The dietary should be carefully looked after, and should exclude sugars and all starchy food; the addition of lime-water to the milk (about 1 part to 4) is a desirable precaution to take, particularly with children. Cleansing the feeding apparatus and the mouth after each feeding is essential both in the prevention of the formation, and in decreasing the further growth, of thrush when present. The local treatment consists in the use of alkaline and antiseptic applications, preferably by means of the spray. Solutions of boric acid or sodium hypsulphite (3j—4.0—of either to 3j—30.0—of water, with the addition of a little glycerin), potassium permanganate, or hydrogen peroxid, are useful. Syrupy excipients are to be excluded. Potassium chlorate may exert a beneficial effect in those cases in which stomatitis is associated, as may also penciling with a solution of silver nitrate. Concetti urges the use of a 3 to 5 per cent. solution of silver nitrate instead of the weaker strength usually employed. The use of the galvanocautery is often serviceable.

When esophageal obstruction exists it may be necessary to gently force a rubber tube through the mass of thrush deposit in order to give nourishment (Forchheimer).

Medicinal treatment embraces the administration of nourishing and easily digestible food, occasional stimulation, and the correction of gastro-intestinal disorders. Attention must also be paid to the primary affections to which the thrush is superadded. Iron, cod-liver oil, and acid and bitter tonics in palatable form are usually indicated in debilitated subjects, along with general hygienic measures. The internal use of small doses, frequently repeated, of calomel or mercuric chlorid may also be tried for a possible specific effect in combating thrush.

LA PERLECHE

This contagious disease is confined to the angles of the mouth. It was first described by Lemaistre in 1886 as prevalent among the children of Limousin in France. It was found that the drinking-water in that locality contained cocci similar to the spherobacteria that infested the epithelial thickenings, and that these were probably conveyed to human beings by drinking-vessels. Little elevations and fissures, said to resemble those of congenital syphilis, were seen around the oral angles. The latter were the seat of smarting pain, particularly on opening the mouth suddenly or too far, and caused the patient to lick (*perlicher*) them constantly. The disease seemed to be entirely local, and lasted from two to three weeks. Alum and copper sulphate solutions were most useful.

GANGRENOUS STOMATITIS

(*Noma; Cancrum Oris*)

Definition.—A rapidly spreading gangrenous affection of the cheek and gums, of rare occurrence, usually asymmetric, and ending fatally in most cases.

Pathology.—In addition to the necrotic changes in the cheeks, the process may extend to the jaws and lips. The blood-vessels contain thrombi, thus preventing hemorrhage from the sphacelus. The submaxillary and cervical glands may be slightly enlarged and soft. Blood changes of an uncertain character have been noted. Hemorrhagic infarctions, aspiration bronchopneumonia, or gangrene by inhalation of gangrenous particles or metastasis, may be met in the lungs. Wharton has described an associated membranous form of colitis, and a metastatic infiltration of the cardiac muscle and purulent pericarditis may also be seen *postmortem*. Klementorsky met with a peculiar and fatal form of gangrene limited to the gums of babes and occurring a few days after birth.

Etiology.—*Predisposing Causes.*—This uncommon affection attacks girls more frequently than boys, usually between the ages of two and five years; it appears to be endemic in low, moist countries, as Holland, though apparently it has not been regarded as contagious in the past. Children suffering from the effects of overcrowding and previous disease are especially liable to noma. Most often, however, it is secondary to measles; it may also follow scarlet fever, typhoid, small-pox, or less frequently pertussis. The causative influence of mercurialization and ulcerative stomatitis has been overrated.

Bacteriology.—Jos. Sailer¹ recovered diphtheria bacilli from the gangrenous areas of noma of the buccal cavities. Guzzetti found pseudodiphtheritic bacilli together with staphylococci and streptococci. More recent studies have shown that fusiform bacilli and spirilla are often found in association, as in Vincent's angina, together with numerous types of pyogenic organisms.

¹ *Phila. County Med. Soc.*, November, 1901, p. 301.

Symptoms.—The mucous membrane of one cheek, near the corner of the mouth, is usually first affected, a *dark, ragged, sloughing ulcer* appearing and spreading insidiously for two or three days before the substance of the cheek is involved. A *hard and sensitive nodule* may then be felt by grasping the thickness of cheek between the thumb and finger. Brawny induration of the skin over this nodule soon becomes manifest, and then there appear collateral edema and an unctuous looking, deeply livid, gangrenous spot, soon becoming bullous and leaving a black eschar. Perforation of the cheek may occur on the third day, though usually not until a week has passed. There is an *ichorous discharge* of shreds of gangrenous tissue from the unhealthy wound. The *fetor* of the breath is almost intolerable and characteristically gangrenous. The necrosis may extend over one-half the face of the side affected, and may involve the gums and jaws, but seldom does it attack the opposite side of the face. The *general symptoms* of such a grave malady may be slight at a very early period, but with the formation of the eschar they become rapidly severe and typhoid in type. Great prostration, delirium, pyrexia (104° F.—40° C.), diarrhea, and edema of the feet are common. The course rarely extends beyond two weeks.

Complications.—Septic lobular pneumonia may occur from aspiration of gangrenous particles; colitis and gangrene of the genitalia in females (*noma pudendæ*) are also seen. In those very rare cases that recover, granulations form, the gangrenous edges become clean, and cicatrization follows, often with great disfigurement of the face and even restricted jaw motion.

Diagnosis.—The disease when fully established is easily diagnosed by its characteristic origin, the gangrenous ulcer-nodule, the eschar formation, and perforation, associated with a previous history of measles or other acute infectious fever of childhood. The offensive fetid odor and severe constitutional depression are also of great value.

Differential Diagnosis.—From *anthrax* it differs in that the latter affection is more common in adults, with a history of contagion, and in the fact that malignant pustule starts on the exterior of the cheek, and perhaps in a previous abrasion in the skin. The discovery of the *Bacillus anthracis* in the blood and discharges is conclusive. *Ulcerative stomatitis* of a severe and neglected type may be confounded with cancrum oris, but in the former the destruction of tissue is mainly of the gums and alveoli, the cheeks being simply ulcerated and no extensive sloughing taking place; the breath, though fetid, is not gangrenous, and the oral discharge, though sometimes bloody, is not mixed with shreds of gangrenous tissue (Starr). Finally, the course of ulcerative stomatitis is less severe, a fatal termination being extremely rare.

Prognosis.—Noma is seldom recovered from, the mortality being about 80 to 90 per cent (Bogel). When recovery does take place the development of ectropion, facial deformity, and local disability, with a protracted convalescence, render life burdensome.

Treatment.—Quarantine all cases until they are proved by bacteriologic study to be of a non-diphtheric nature, and the avoidance of mercurialization will also be of undoubted use. The primary indication in the *local treatment* is the arrest of the gangrenous process, thus causing, if possible, a healthy reaction on the part of the surrounding tissues. All sloughs should be cut away, followed by cleanliness of the mouth and wound; and by the application of strong caustics, as fuming nitric acid, and the acid nitrate of mercury, solid zinc chlorid, silver nitrate, carbolic acid, a concentrated solution of perchlorid of iron, Vienna paste, and the actual cautery. For the protection of the healthy parts and for efficiency the Paquelin or the galvanic cautery is probably best. Anesthesia is requisite for such strong measures. Milder applications,

however, seem to be quite adequate in some cases. Thus, bismuth subnitrate, potassium chlorate, and aristol, or the following formula by Dr. Coates, may be tried:

R.	Cupri sulph.,	ʒij (8.0);
	Cinchonæ pulv.,	ʒiv (16.0);
	Aquæ,	q. s. ad fʒiv (120.0).—M.

As a mouth-wash employ mild antiseptic washes of carbolic acid, hydrogen peroxid, Labarraque's solution, potassium permanganate, etc.; and for the diminution of the fetor, antiseptic charcoal poultices containing boric or salicylic acid are useful. Mild antiseptic and astringent lotions of boric acid, zinc sulphate (gr. ij to ʒj—0.13–30.0), or balsamic ointments with vaselin, may aid in healing the granulating surfaces in favorable cases. The internal treatment must be directed toward sustaining the strength of the patient by the administration of the most nourishing food, stimulants, and tonics. Rectal feeding may be necessary. Plastic operations may be needful after recovery to mitigate oral disabilities or facial deformities. W. C. Cahall has successfully treated a case of noma with antistreptococcus serum. Antitoxin should be given early where the diphtheria bacillus is found.

MERCURIAL STOMATITIS

(*Mercurial Ptyalism*)

Definition.—An inflammation of the mouth and salivary glands caused by the excessive use of mercury; a similar condition is rarely seen as a result of the therapeutic use of other drugs.

Etiology.—Predisposing causes are dyscrasia and occupation, mainly. The peculiar individual susceptibility of these subjects to dyscrasia will not permit the use of even minimum doses of mercury without serious and almost immediate symptoms of ptyalism. This is also seen in barometer-makers, mirror-silverers, chemists, and others who handle mercury in their daily work. The exciting cause of ptyalism is the ingestion, inhalation, or cutaneous absorption of mercury.

Symptoms.—A *metallic taste* in the mouth is first noticed by the patient. Soon the *gums* become "touched"—i.e., red, swollen, tender to the touch, and sore during the act of mastication. A marked secretion and *flow of saliva*, with *fetid breath* and swollen tongue, follow. Very rarely in this disease the affection passes into an *ulcerative stomatitis*, and causes loosening of the teeth and necrosis of the maxilla. *General symptoms*, as constitutional depression, anorexia, diarrhea, mental anxiety, and nervousness, may supervene.

The recognition of the foregoing causal factors—predisposing and exciting—renders the *diagnosis* easy. The *prognosis* is favorable, and, although the local symptoms may be harassing, recovery is attainable within a few weeks as a rule.

Treatment.—The toxic action of mercury in the production of ptyalism can be avoided by a knowledge of individual susceptibility and by the local and internal use of potassium chlorate. Upon the first appearance of the symptoms there must be a prompt withdrawal of the mercurial influence, and a change of occupation if that be the predisposing cause. Locally, soothing, alkaline, and mildly antiseptic mouth washes, as in the treatment of catarrhal stomatitis, may be all that is necessary. For the fetid breath solutions of boric acid or potassium chlorate may be used. Ulcers may be brushed with silver nitrate solution. The internal treatment should be directed toward keeping the bowels soluble; in addition, alkaline mineral waters may be used, and in severe cases potassium chlorate in 5- to 10-grain (0.3–0.6) doses.

Atropin (gr. $\frac{1}{100}$ —0.0006) and opium have been recommended to decrease the excessive salivary secretion and to allay pain, and hot baths will aid the treatment materially. In severe cases the resulting debility and anemia should be met by the use of highly nourishing liquid foods and by tonics.

Osler points out that the condition of the teeth known as *erosion*, which sometimes follows infantile stomatitis, and especially the mercurial form, is to be discriminated from the deformed teeth of congenital syphilis. In the former the first permanent molars, and then the incisors, are observed to have small pits or discolored and eroded spots, due to a morbid deficiency in enamel formation. The notched and irregular teeth of hereditary syphilis in children (Hutchinson) are sufficiently distinctive.

PYORRHEA ALVEOLARIS

(Riggs' Disease, Fouchard's Disease, Alveolitis)

Definition.—A chronic progressive disease, commencing usually as a gingivitis, and advancing along the root of the tooth into the alveolus, with destruction of the tissues of the peridental membrane, and the formation of an abscess cavity as well as an inflammatory absorption, which results in progressive loss of the alveolar bone. The adjacent soft tissues are the seat of cellular infiltration which often tends to clear away after surgical removal or successful treatment of the diseased tooth or teeth.

Historic Note.—In 1865 J. M. Riggs forcibly called the attention of the dental profession to the subject, while William Hunter was the first to insist upon the importance of mouth sepsis, with absorption of pus, as a cause of many septic conditions—*e. g.*, gastritis, enteritis, appendicitis, and pleuritis.

Etiology.—It is probable, as shown by the labors of Rosenow and his associates, that the streptococcus-pneumococcus group of organisms are of especial etiologic importance. Recent investigations by Hartzell and Henrici and others ascribe the principal rôle to the *Streptococcus viridans*. The pyogenic staphylococci, fusiform bacilli, and other organisms have been found in the lesions, but some of these at least may be looked upon as secondary invaders.

In 1914 Smith and Barrett insisted upon the etiologic importance of certain parasitic amebas (*Endamæba buccalis*), but their specificity has not as yet been proved.

Symptoms.—The onset is without striking local features. At first the gums become abnormally reddened and slightly swollen and spongy, bleeding when the teeth are brushed. With the progress of the condition these symptoms gradually become more pronounced, with tenderness to pressure and pain, and on inspection a purulent material may be seen exuding either spontaneously or on slight pressure from the orifice at the gingival margin. In well-marked cases the peridental ligament is more or less extensively involved, and retraction of the gum with exposure of the tooth-root is quite common. The tooth or teeth affected may loosen.

In all cases that first fall under the care of a physician he should associate with himself a skilled dentist in their diagnosis and study. A roentgen ray examination should not be omitted from consideration. (*Vide Focal Sepsis*, p. 166.)

Treatment.—This is both local and general, but since the systemic features are due to septic absorption from the oral lesions, the germs causing the latter must be either destroyed *in loco*, or eliminated by the removal, surgically, of the primary pathologic focus, but it is not necessary to sacrifice all of the teeth involved, as the recent results of expert specialists and dental surgeons, confirmed by roentgen ray findings, clearly show.

Among local preventive and corrective measures I would emphasize the importance of the systematic removal of tartar from the teeth and the use of antiseptic mouth-washes. Emetin, locally and by hypodermic injection, has its warm advocates, although it has not invariably been found useful. A specially skilled dentist should conduct the local treatment whenever practical.

The general treatment consists in meeting the indications presented by associated conditions, some of which are caused by factors apart from the mouth condition, in accordance with accepted therapeutic principles. The bacterial origin of the complaint has shown the way to successful vaccine treatment in some cases at least. For this purpose an autogenous vaccine is always to be preferred, since it has yielded more brilliant results than the stock vaccines in this truly obstinate condition.

II. DISEASES OF THE TONGUE

GLOSSITIS

ACUTE GLOSSITIS

(*Glossitis Acuta*)

Definition.—An acute parenchymatous inflammation of the tongue, sometimes ending in abscess.

Etiology.—Predisposing causes are supposed to be an impaired general health and exposure to cold, humid weather. The exciting causes are most frequently the stings and bites of insects, or burns, scalds, and the action of corrosives. I believe that many cases follow slight injuries to the tongue that allow of the introduction of inflammatory poisons or microbes. A. J. Hall describes a case of membranous glossitis complicating acute nephritis.

Symptoms.—These come on *rapidly* and with more or less local severity and danger. The *tongue* becomes much swollen, and may even protrude beyond the lips. It is very *tender* and *painful*, and coated with a thick, soft yellowish-white fur, and it may also be dry, cracked, and ulcerated. *Catarrhal stomatitis* is often associated, salivation is usually profuse, and talking, swallowing, and even breathing are rendered difficult and distressing. *Dyspnea*, even to suffocation, may be imminent. The cervical and sublingual glands may be swollen, moderate *fever* is always present, and the obstruction to breathing and administration of nutriment may assume a dangerous aspect.

The inflammation reaches its height in about three or four days, tending to subside almost entirely about the seventh day. Not rarely the inflammatory infiltration passes into suppuration with the formation of a circumscribed abscess of variable size in one-half of the tongue; fluctuation may not, however, be obtainable, spontaneous rupture being sometimes the first indication of abscess. The **prognosis** is favorable, except that serious obstruction is likely to remain.

Treatment.—When the case is seen quite early and during the congestive stage, the topical use of ice, allowed to slowly dissolve in the mouth, is serviceable. Mucilaginous mouth-washes, containing some mild antiseptic, as sodium borate with sodium bicarbonate (gr. v–xx to ʒj—0.3–1.3 to 30.0), should also be employed. A brisk saline purge, given early, will aid in reducing the inflammation, and should the tongue become alarmingly swollen, deep scarification and the use of half a dozen leeches between the hyoid bone and the jaw angles may be of decided service. Steam atomization, medicated with

the compound tincture of benzoin or ammonium chlorid (3j to 3j—4.0–30.0), favors resolution (Cohen). Abscesses must be incised and washed out with antiseptic solutions. Tracheotomy is rarely called for to relieve the dyspnea. Rectal alimentation with predigested foods may be necessary, and during convalescence ferruginous tonics in glycerin and bland foods should be continued for some time, in order to prevent chronic inflammation and thickening. Any local source of irritation, as from carious or sharp teeth, should be removed.

CHRONIC SUPERFICIAL GLOSSITIS

Definition.—A chronic inflammation of the mucosa of the tongue.

Etiology.—This disease is often preceded by several acute attacks, the habitual use of tobacco, both in smoking and chewing, and of strong spirituous liquors being mainly productive of the original affection. The frequent use of irritating foods is also a factor in some instances.

Symptoms.—The surface of the tongue is continually sensitive and more or less reddened. Often there are seen ovoid patches of various size, smooth and shiny, on account of the loss of papillæ, and separated by furrows that extend to the depth of the mucosa itself. The tongue may also be slightly furrowed in intervening spaces, especially at the base. The general health is somewhat deteriorated.

Diagnosis.—This rests upon the history of the case and upon the results of examination of the organ.

The **prognosis** is favorable as to alleviation, but guarded as to cure.

Treatment.—The blandest dietary must be insisted on, as well as absolute abstinence from the causal irritants. The local use of demulcents and of mildly alkaline and antiseptic lotions, such as Seiler's tablets in solution, and of solutions of chromic acid or silver nitrate (gr. v-x to 3j—0.3–0.6 to 30.0) in water or honey, applied once or twice daily by gentle brushing, is to be recommended. General tonics and the avoidance of irritating drinks will be indicated.

GLOSSITIS DESICCANS

A rare disease, chronic in nature and of unknown causation. It is characterized by "the gradual development upon the surface of the tongue of a number of deep fissures and indentations, giving the organ an uneven and ragged look. The pain is due to the frequent presence of excoriations and ulcers in these fissures" (Strümpell). The *prognosis* of the affection is favorable as regards any danger. The *treatment* is hygienic, consisting of cleanliness of the mouth and the use of disinfectant mouth-lotions, together with the topical use of alterative or astringent applications, as silver nitrate or chromic acid, to any ulceration.

LINGUAL PSORIASIS (TYLOSIS LINGUÆ)

In this disease there are small regular areas of hyperplasia of the glossal epithelium, eventually causing a map-like appearance of the surface of the tongue—"lingua geographica." The trouble is obscure in its etiology and persists for years. Seldom is there any discomfort associated, although mental anxiety or hypochondriasis may develop.

LEUKOPLAKIA ORIS (BUCCAL PSORIASIS)

In this affection the mucous membrane of the mouth and tongue may be involved. On the lateral borders of the tongue white or bluish-white scar-like spots or patches, often slightly notched, make their appearance. Some of these pass away to be replaced by others, and the affection progresses despite all attempts to cure it. The true *cause* is unknown, but it has been suggested

that some irritant, as the use of a pipe, may account for the condition. The malady has, however, been seen in women. A syphilitic taint is said to especially predispose to the disease (Strümpell). The affection must be carefully diagnosed from the oral manifestations of syphilis, if for no other reason than to relieve the mind of a morbidly anxious patient. Excepting some pain connected with possible ulceration, there are no annoying *symptoms*, and the *treatment* suggested for glossitis desiccans is appropriate. Kyle touches the white patches daily with pure tincture of iodine.

In children a similar tongue affection has been named "wandering rash." The patches are circinate and enlarge peripherally, forming rings of epithelial hyperplasia, within which is a red, glossy center, "devoid of filiform papillæ, though the fungiform remain" (Allchin).

ANGINA LUDOVICI

(Ludwig's Angina)

Definition.—A rare acute phlegmonous inflammation of the floor of the mouth.

Etiology.—The condition is more common in males, and may be secondary to specific infections (scarlet fever, diphtheria). Thomas states that insignificant lesions in the mouth (*e. g.*, carious tooth, ulcer, tonsillitis) are the usual primary foci leading to lymphatic involvement. The specific organism is generally the streptococcus, though rarely the staphylococcus is found. It may result from trauma.

Symptoms.—These are *intense* at the *outset*, and begin with swelling in the region of the submaxillary gland, with a rapid involvement of the cellular tissue of the floor of the mouth as well as of the anterior portion of the neck. *Pain* is marked, and this, with the *acute swelling*, renders articulation, mastication, and deglutition extremely difficult. Compression or edema of the larynx may often cause dangerous dyspnea. The *constitutional disturbance* is usually febrile, and may either approach the typhoid type or may be septic. The condition generally terminates either in abscess or extensive sloughing (*cynanche gangrænosa*).

The **diagnosis** is easily made when complicating a specific fever.

The **prognosis** is always grave. Of 106 cases collected by Thomas, 43 died. Relapses may follow in weakly subjects.

Treatment.—The most that can be done is to sustain the strength of the patient and secure prompt surgical interference. Tracheotomy may be demanded if asphyxia threatens life.

III. DISEASES OF THE SALIVARY GLANDS

HYPERSECRETION

(*Ptyalism*)

Definition.—An abnormal increase in the secretion of saliva.

Etiology.—Salivation as an idiopathic affection is rare, and as such is considered to be a neurosis. Thus, it has been seen in emotional children of from two to eight years of age, though apparently in perfect health. According to Bohn, the secretion in these cases is mostly increased during active exercise, is reduced on lying down, and absent during sleep. Spontaneous recovery takes place in a few years. As a deuteropathic disease ptyalism may be the result of oral disease (*e. g.*, noma, ulcerative stomatitis), and also of

gastro-enteric, pancreatic, uterine (as gestation), centric (as diseases or tumors of the medulla or of the facial nerve), toxic, systemic (as small-pox, the use of mercury, iodids, pilocarpin, tobacco), and hydrophobic irritation and disease.

Diagnosis.—It should be pointed out that a failure in swallowing the normal quantity of saliva may cause dribbling from the mouth and simulate true hypersecretion.

The **prognosis** is favorable in itself, but dependent on the cause.

Treatment.—The causes are to be removed and the general health toned up. For stomatitic salivation potassium chlorate is first in rank as an internal and local remedy. Iron and arsenic are valuable in neurotic cases, and the bromids or hyoscin may be of supplemental use. Atropin (gr. $\frac{1}{200}$ to $\frac{1}{100}$ —0.0003–0.0006) and belladonna are almost uniformly successful in idiopathic as well as in central ptyalism.

XEROSTOMA

(*Aptyalism*; "Dry Mouth")

Definition.—A morbid arrest of the salivary and buccal secretions.

Etiology.—The disease is probably due to an affection of the nerve-supply of all the glands of the mouth (Harris). It may follow sudden mental phenomena as a temporary condition. A. J. Hall collected 39 cases, of which 32 occurred in females. In most of the cases the causes were unknown. Not uncommonly xerostoma is an effect of the febrile state, of mouth-breathing (due to nasal obstruction), and of diabetes.

Symptoms.—Apart from the sensation of dryness, mastication, deglutition, and articulation are difficult. The *local appearances* show a glazed, red, and sometimes cracked condition of the tongue and labial and palatine mucosa. The teeth may become diseased and crumble.

The **diagnosis** is made on inspection, the **prognosis** depending on the removability of the cause, and rightfully being guarded on account of the frequent obstinacy of the trouble.

Treatment.—Attention to the systemic condition is requisite. Small doses of potassium iodid and pilocarpin (gr. $\frac{1}{20}$ —0.003) in gelatin lamellæ or in lozenge form, allowed to dissolve in the mouth with the aid of a sip of water, have been productive of relief. In cases of centric origin the galvanic current should be tried.

Glassblowers' Mouth.—This condition is found among glassblowers and also among musicians. It occurs in about 2.5 per cent. of all glassblowers. Scheele,¹ who reports 2 cases, described the condition as a hernial outpocketing of the muscles of the cheeks. The epithelium of the mucous membranes shows the so-called *plaques opalines*. It is often combined with a distention of Steno's duct. In addition to a ballooning out of the buccal mucosa, there is likely to be a disturbance of hearing and cramp-like contraction of the cheek. The parotids may be emphysematous and crepitate on palpation.

SYMPTOMATIC PAROTITIS

(*Parotid Bubo*)

Definition.—A secondary inflammation of the parotid gland, generally due to septic infection and tending to suppuration.

¹ *Berliner. klin. Wochen.*, March 12, 1900.

Etiology.—Not being a primary affection, the causes giving rise to it may be mentioned as follows: (a) Acute infectious fevers, as typhoid, typhus, pneumonitis, pyemia, erysipelas; (b) injury or disease of the abdomen or pelvis (Stephen Paget), or of the genito-urinary tract, as mild traumatism or derangement of the testes or ovaries, or even menstruation or pregnancy; gastric ulcer may be accompanied by it; (c) peripheral neuritis with facial paralysis (Gowers).

Most of the cases are septic and indicative of an unfavorable course in the progress of the associated disease. The *symptoms, diagnosis, and treatment* of the parotitis itself fall under the scope of surgery.

Chronic Parotitis.—Mikulicz first described this condition and reported a case in which symmetric enlargement of the lacrimal, and subsequently of the salivary, glands occurred. Kümmel and Osler have also recorded cases. It may be caused by lead or mercury and may be secondary to mumps, inflammation of the throat, and chronic Bright's disease. The condition may be painless.

IV. DISEASES OF THE TONSILS

ACUTE TONSILLITIS

Definition.—An acute inflammation of the tonsil or tonsils, affecting either the mucous membrane, the follicles, or the parenchyma, and ending either in resolution, suppuration, or chronic enlargement.

Pathology.—In the *superficial variety* of acute tonsillitis the mucosa is simply red, swollen, and sometimes covered with a thin, soft exudate of mucus. The tonsil itself may also be swollen. In *follicular tonsillitis* the lacunæ become filled with a cheesy exudate which often protrudes from the tonsillar crypts; epithelial and pus-cells, cellular debris, and occasional cholesterol crystals are found in these cheesy masses. In older, darker hued masses an offensive odor is given off, and numerous bacteria are found. In adults, calcareous infiltration of the cheesy little masses may be met with. *Parenchymatous tonsillitis* is shown by a greater enlargement of the tonsil, due to a marked infiltration of all the tissues. Suppuration in the tonsil is frequent, the follicles usually bursting and uniting in abscess formation. Pus may burrow into the cellular tissue surrounding the tonsil, and find its way even down to the clavicle. The *herpetic* or *ulceromembranous form* of tonsillitis, in which an eruption of herpetic vesicles on the tonsils is followed by their rupture and the formation of a lightly adherent membrane, is rare. In *necrotic tonsillitis* (Strümpell) a grayish-white adherent necrotic membrane is observed, that is limited by the inflamed membrane surrounding the mucosa covering the tonsils. The latter are moderately swollen. A dirty ulcer often remains after the slough separates.

Etiology.—*Predisposing causes* are age, sex, temperament, and atmospheric conditions. The disease is most common in youth and in early adult life. Boys and young men appear to be attacked more often than the opposite sex. Tonsillitis is most prevalent during the spring season. The proportion of cases in which tonsillitis precedes rheumatism is probably over 30 per cent. It is certain that one attack of acute tonsillitis predisposes to subsequent ones, particularly when the first attack has left some enlargement of the tonsils. Sudden and extreme climatic changes predispose to the disease.

The *predisposing causes* of acute tonsillitis are most commonly the following: (a) Exposure to cold and dampness, or talking in a cold, moist atmosphere;

(b) exposure and talking in an overheated atmosphere vitiated with smoke or other irritating vapors or gases; (c) specific infectious fevers, as scarlatina, measles, and erysipelas; (d) irritation from hard and sharp foreign bodies or chemical irritants. The exciting cause is the presence of microbes (streptococci, staphylococci, pneumococci). Epidemics of streptococcic infection have been traced to the milk-supply (over 70 per cent. of the cases in Cortland and Homer, N. Y., epidemics occurred among the patrons of a certain dairyman). Capps and Davis¹ suspected that ice cream played an important rôle as a carrier in an epidemic which they reported. They found 11 cows with garget to account for infection of the milk, to some extent at least.

Clinical Symptoms.—Three principal varieties of acute tonsillitis occur clinically, the symptoms of which will be described separately.

(a) **Acute Catarrhal or Superficial Tonsillitis.**—This form is often associated with acute pharyngitis. The earliest *local symptoms* are pain and difficulty in swallowing, the former often becoming quite acute and radiating to the ear and lymphatics at the angle of the jaw, where tenderness on pressure may also be elicited. In speaking a nasal twang is often noticed. During the laborious act of swallowing the sensation of a lump in the throat, especially when the mouth is dry, is commonly complained of. Simple stomatitis may be associated, and rarely there is a slight cough with the painful expectoration of a sticky mucus which accumulates in the throat (Browne). There may be salivation, with fetor of the breath. *Inspection* shows the tonsil to be red and swollen. Though dry and glazed at first, the surfaces soon become covered with a thin exudate of mucus, which is easily detached by brushing, gargling, or "hawking" the throat. There is usually some accompanying redness, and also a *tumefaction* of the uvula and faucial pillars. The *constitutional symptoms* at the outset are mildly febrile. The attacks usually come on rapidly, and last but a few days. The pneumococcus variety, however, runs a longer and more rebellious course. *Otitis media* may follow the extension of the tonsillar inflammation.

(b) **Acute Lacunar or Follicular Tonsillitis.**—In this form, which is quite common in children, not only the mucous membrane lining the crypts is inflamed, but that covering the surface of the tonsils also, giving rise to more or less associated *catarrhal tonsillitis*. The *local subjective symptoms* are, as in the preceding variety, pain, tenderness, and difficult deglutition. The tonsils are seen to be covered with small, slightly prominent, whitish-yellow spots or patches of a characteristic creamy exudate corresponding to the position of the crypts and numbering from two to eight or ten or more. These little masses or plugs may be pressed out of the follicles with a spatula. A predominance of pus cocci and cells may rarely forerun the further formation of little follicular abscesses, and even of slight erosions and ulceration of the mouths of the lacunæ. Unlike simple catarrhal tonsillitis—at least in so far as simultaneous involvement is concerned (Cohen)—both tonsils are usually affected in this trouble, though one to a greater degree than the other. The whole tonsil is considerably swollen, and in severe cases the cervical lymph-glands also. The *constitutional symptoms* of follicular tonsillitis may be quite severe. The disease may be ushered in with a pronounced chill, headache, aching of the back and limbs, marked anorexia, and insomnia, along with a rapid rise in the temperature to 103° or 104° F. (39.4–40° C.)—in children as high as 105° F. (40.5° C.). Slight albuminuria is an exceptional finding, but acetonuria is more common (25.6 per cent.—Reiche). The general depression may be so great as to simulate adynamia. Though sudden in its onset and rapid and often intensely acute in its progress, the disease seldom lasts more than five or eight

¹ *Arch. Inter. Med.*, November, 1914.

days. Follicular abscesses complicate the case, while chronic swelling of the tonsils, desiccation, and bacterial degeneration of the lacunar masses may be sequelæ. Packard has reported 5 cases of endocarditis following acute angina. Pericarditis, pleuritis, nephritis, and skin lesions, particularly erythema nodosum, may occur as complications. The exudate may become calcified, and may be expectorated as concretions.

(c) **Acute Parenchymatous Tonsillitis** (*Tonsillar Abscess or Quinsy*).—In this form of tonsillitis, which occurs most often during adolescence and early adult life, the symptoms reach the most severe types.

Local Symptoms.—Complaint is first made of dryness of the throat, with painful and difficult deglutition. The pain is a prominent subjective sign, and may be referred to one or both ears according as one or both tonsils are inflamed. The secretion of a viscid mucus soon takes place, and as the tonsillar swelling increases, the husky voice of sore throat and difficult articulation supervene; in cases of aggravated swelling dyspnea may often appear later. On examining the tonsils they are found to be greatly enlarged, deeply red-dened, firm, and edematous. The surrounding soft parts, the faucial arches, pillars, and the uvula, manifest a deep congestion. In severe cases the tonsils may meet in the median line, pushing the uvula forward. Patches showing follicular tonsillitis are sometimes associated. The submaxillary glands may be engorged, and opening the mouth is often performed with difficulty; it is usually only partial on account of the fixation of the jaw.

In a few days, perhaps, softening and fluctuation may be detected in the tonsils, and spontaneous rupture and discharge of the pus may occur, with almost instant relief to the patient. Resolution, however, sometimes takes place in the milder cases. The abscess may open in one or more places, and should rupture occur during sleep it may, as in one of my patients, cause suffocation by the entrance of pus into the larynx. The tonsil may regain its original size in a few days after the discharge of pus, and all the symptoms subside. The *constitutional phenomena* of parenchymatous tonsillitis are usually severe from the start, even in children, and more so than in the follicular form (Mackenzie). The temperature rises to 104° or 105° F. (40°–40.5° C.), and the pulse-beats may reach 130 per minute. A polynuclear leukocytosis is a constant accompaniment of the other constitutional symptoms. Acetonuria is often present in this disease. There may be delirium, and the symptoms generally increase until the abscess bursts or is opened, when all symptoms abate.

Course, Duration, and Termination.—Though often severely acute in its course, quinsy seldom goes on to rupture in children, usually ending in resolution in from three to five days. If both tonsils are inflamed, only one suppurates as a rule, or but one at a time. The duration of an attack ending in tonsillar abscess is about eight or ten days in adults.

Complications and Sequelæ.—The tonsillar suppuration may invade the cellular tissue between the tonsil and the pterygoid muscles; a peritonsillar abscess may then result that may burrow as far as the clavicle. Ulceration into the internal carotid or internal maxillary arteries with fatal hemorrhage may occur, though rarely. Edema of the larynx is also an infrequent complication. French writers have reported cases of paralysis of the soft palate and pharynx following inflammatory throat diseases. On subsidence of the tonsillar inflammation the trouble becomes evident in the difficult swallowing and partial regurgitation of liquids and solids into the nasal passages, and in the nasal intonation of the voice. A frequent sequel is chronic enlargement of the tonsils.

(d) **Necrotic Tonsillitis.**—This affection is considered by Strümpell to be in some instances entirely distinct from diphtheria in its etiology. It is im-

possible to distinguish between the local appearances of the two conditions: these have been referred to under the heading of Morbid Anatomy. The *constitutional disturbances* are severe, especially in children, though they seldom last longer than a week, and are followed by a rapid convalescence. The cervical glands are not swollen to the same extent as in diphtheria. The occurrence later of palatal and pharyngeal *paralysis* in a supposed case of necrotic tonsillitis would point to its true diphtheritic origin.

(e) **Streptococcus Tonsillitis** (*Septic Sore Throat*).—An epidemic form, which was first observed in Christiania in 1908 and later in England, has more recently been described by certain American authors, *e. g.*, J. A. Capps, D. J. Davis and E. C. Rosenow, and C. E. A. Winslow. The onset is sudden, with or without a chill. The throat presents a diffuse redness with much mucoid secretion. The crypts of the tonsils are always filled with an exudate, and a grayish membrane resembling diphtheria may spread over a large part of the tonsil. "The fever, the muscular pains, the prostration, and the constitutional symptoms were out of all proportion to what one would expect from the amount of local involvement."¹ The pulse is relatively slow and the leukocytes are only moderately increased. The acute symptoms may subside in a few days, but at the end of a week or ten days the patient suddenly manifests great enlargement of the cervical glands without suppuration, as a rule. Visceral complications occur most often in the group of cases having little or no glandular involvement but marked constitutional disturbances. Otitis media is frequent and bacteriologic examination shows an encapsulated hemolytic streptococcus of high virulence.

Diagnosis.—The appearance of the several forms of acute tonsillitis, associated with the clinical history of each case, should enable a ready diagnosis to be made in the majority of cases. A difficulty may, however, arise in discriminating follicular tonsillitis from diphtheria, and apparently transitional forms are not uncommon. The appended table gives the important points of differentiation between these diseases:

FOLLICULAR TONSILLITIS

A soft, pultaceous, yellowish-white deposit occurs in spots or patches situated over the mouth of the follicles, with areas of redness intervening.

The exudate is easily removed, leaving a smooth surface.

The deposit is always limited to the tonsils (important).

If the creamy deposits unite to form a continuous layer, removal is either not followed by re-formation, or very late.

May have high temperature, lasting only a day or two, and falls after administration of sodium salicylate. Albuminuria extremely rare, if present at all.

Cervical lymphatic glands seldom or slightly swollen.

Complications rare and mild.

Bacteriologic test shows no special organism; often, however, streptococci and staphylococci.

DIPHTHERIA

A tough, ashy-gray, continuous, and uniform pseudomembranous deposit covers the tonsils, pharynx, or soft palate.

Very adherent, and can be torn off in strips only, leaving a bleeding surface.

The pillars of the fauces and uvula are involved as well.

Removal of the membrane is followed by re-formation within twelve to twenty-four hours.

Persistent elevation of the temperature, which is not materially influenced by salicylates; more or less albuminuria is common.

Usually markedly swollen glands.

Complications frequent and grave (cardiac failure and paralysis).

Bacteriologic examination shows presence of Klebs-Löffler bacillus.

Cases seen early, with severe constitutional symptoms and red and *swollen tonsils* having no deposit, may give rise to the question whether *simple angina* or *scarlet fever* is to follow. In such cases the latter disease may be excluded

¹ *Pract. Med. Series*, 1912, vi, 110.

by a negative history of exposure to contagion, by the absence of a very high pulse-rate, and by the non-appearance of the scarlatinal eruption. *Necrotic tonsillitis* may be discriminated from the lacunar variety in the same manner as diphtheria—*i. e.*, by its local manifestations (*vide* Morbid Anatomy).

The **prognosis** is good as regards life, and favorable as regards complete recovery. The occurrence of either fatal hemorrhage or asphyxia in *quinsy* is extremely rare. In debilitated and strumous individuals relapses are prone to occur, and successive acute attacks of tonsillitis tend to cause permanent hypertrophy of the tonsils. In cases of *necrotic tonsillitis*, especially during the earlier periods, the prognosis should always be guarded.

Treatment.—Particularly in the lacunar and necrotic forms of tonsillitis the patient should be kept apart from others as much as possible, since both types appear to be contagious to a certain degree. Individual susceptibility to frequent attacks of sore throat may be lessened by systematic cold bathing of the neck. Constitutional and local rest is a first and constant requisite. Efforts at swallowing and talking should be reduced to a minimum. Bland nourishing liquids, as milk, broths, and the like, should constitute the only nutriment during the attack.

Medicinal Treatment.—Early in the case a free evacuation of the bowels should be obtained, and small doses of calomel (gr. $\frac{1}{8}$ to $\frac{1}{6}$ —0.008–0.010, repeated hourly until about gr. 1—0.065—has been taken), followed by a Seidlitz powder or Rochelle salts in hot water, will be effective in most cases. In severe cases of quinsy relief from the pain is urgently called for, and either a Dover's powder or a hypodermic injection of morphin (gr. $\frac{1}{6}$ to $\frac{1}{4}$ —0.010–0.016) and atropin (gr. $\frac{1}{100}$ —0.0006) will probably suffice for their relief. A high temperature must be combated by small doses of aconite, frequently repeated: this drug has been much used in the follicular tonsillitis of children. Quinin, in solution with dilute sulphuric acid, is also often given.

The administration of sodium salicylate, of phenyl salicylate, acetosalicylic acid, or any of the salicylate preparations seems to lessen the duration and severity of tonsillitis, and even to cure some cases of the lacunar form within forty-eight hours and without local applications. The tincture of the chlorid of iron in glycerin (4 or 5 drops to the dram—4.0—given every two hours) is regarded by Bosworth as almost specific at the commencement of an attack of acute follicular tonsillitis. During convalescence soft, light foods may be allowed; and bitter tonics and iron are to be administered if there are depression and anemia. The following is a favorite prescription:

R. Strychninæ sulph., gr. ss (0.03);
 Syr. acaciæ, fʒss (15.0);
 Liq. ferri et ammon. acetat., q. s. ad fʒiij (90.0).—M.
 Sig. Teaspoonful in water after meals.

Local Treatment.—If the case is seen early, the use of cold is of great value in giving local relief and in shortening the attack. Ice may be sucked and flannel wrung out of ice-water may be applied around the neck, or an ice-bag used. Lozenges of guaiac (gr. ij—0.13) or the ammoniated tincture in 1-dram (4.0) doses in milk, and used as a gargle, are indicated early, and, according to Sajous, seldom fail to control or arrest the inflammation. Equal parts of the tincture of the chlorid of iron, glycerin, and water, applied gently with a camel's-hair brush, have long been used locally on the surfaces of the tonsils, and with marked benefit. Alkaline and mild antiseptic solutions, used as gargles or sprays (preferably the latter), are generally useful. Thus, Dobell's solution, or Seiler's tablets dissolved in water, or borax and thymol, or carbolic

acid, or potassium permanganate in weak solution, may be serviceable. Mild counterirritation at the angle of the jaw by means of iodine or slightly irritating embrocations is helpful.

Early scarification of the tonsils as a depletory measure and painting with cocaine (10 per cent.) I have found useful to bring about resolution.

Astringent sprays containing alum or silver nitrate are often efficacious after a day or two. When the case is fully developed, the atomization of a warm solution of cocaine (4 to 8 per cent.) or lime-water is useful. The external application of the ice-collar is indicated. Should gargling be possible, nothing is better than hot water or milk. If, in parenchymatous tonsillitis, fluctuation be detected or suppuration be even suspected of commencing, the prompt use of the bistoury (the blade being guarded by wrapping with cotton or adhesive plaster), with the production of free bleeding or the discharge of pus, will give great relief. The patient's head, especially if it be a child, should be tilted forward during the operation, so as to allow most of the blood and pus to pass into the mouth. When incision of the tonsil fails to bring pus, it has been advised to puncture through the anterior pillar, where pus may be formed in the cellular tissue in front of or behind the tonsil. When the tonsillar enlargement threatens life through suffocation, excision of the tonsils, laryngotomy, or tracheotomy may have to be performed.

VINCENT'S ANGINA

(*Ulceromembranous Tonsillitis*)

Definition.—An acute inflammation of the tonsil and, in severe cases, peritonsillar tissues, characterized by a pseudomembranous exudate and, later, ulceration.

Etiology.—The condition is much more frequent than was generally supposed before the introduction of laboratory methods of diagnosis. The disorder more frequently attacks children than adults, probably because hypertrophied tonsils seem to predispose to the infection. The specific organisms responsible for the condition are the elongated fusiform bacillus (?) and the *Spirochaeta anginae vincenti*.

Symptoms.—The most characteristic symptom is the severe pain in the throat. The breath is offensive and there may be considerable salivation. Systemic symptoms are usually lacking, but fever and tachycardia may be present in a mild degree. Prostration is sometimes out of proportion to the apparent severity of the other systemic manifestations of the toxemia. Upon examination there will be found upon the tonsil an ulcer about the size of a ten-cent piece covered with a dirty grayish-yellow membrane. Attempts to pull off the membrane will usually cause bleeding of the tissue to which the membrane is attached. The regional lymph-glands are enlarged and the muscles of the neck stiff and tender.

The **diagnosis** is of importance because of the necessity of differentiating the condition from diphtheria, particularly from the early stages of this latter disease. This may be done most readily by staining and examining under the microscope a smear from the lesion. Probably many cases are unrecognized, failing smear examinations when diphtheria is unsuspected, and are diagnosed acute tonsillitis.

The **treatment** consists in the local application of silver nitrate solution or tincture of iodine, together with the same general management as outlined in Acute Tonsillitis.

CHRONIC TONSILLITIS

(Hypertrophied Tonsils; Adenoid Vegetations)

Definition.—Enlargement of the tonsils (faucial and pharyngeal), due to chronic inflammation or hypertrophy, and usually associated with or causing a perverted local and systemic condition.

Pathology.—The faucial tonsils show a true chronic hypertrophy of the lymphoid and fibrous elements. If the latter predominate the organs will be smaller and more indurated. They may be rough on the surface from “distended lacunæ or ruptured follicles” (Berkley Robinson), the latter being in a state of chronic inflammatory thickening, and showing caseous degeneration of their contents. The growths in the vault of the pharynx are adenomatous papillomata; they are either sessile or pedunculated, and are fleshy in appearance and consistence and very vascular. They range in size from a grain of wheat to an almond kernel (Allen), and project from the pharyngeal vault, lying in the depression posterior to and on a line with the fossa of the eustachian tube (Rosenmüller’s fossa). “Hypertrophy of the pharyngeal adenoid tissue may also be present without great enlargement of the tonsils proper” (Osler). A congestive type of nasal catarrh in adults often accompanies, or is the result of, neglected adenoid growths and hypertrophied tonsils. Chronic pharyngitis may be associated.

Etiology.—The *predisposing causes* of chronic hypertrophy of the tonsils are: (a) heredity; (b) age, most frequently between five and fifteen years; (c) sex, boys appear to be affected more frequently; (d) hygienic surroundings.

The *exciting causes* are usually previous attacks of acute tonsillitis, either simple or that which is symptomatic of diphtheria or scarlatina. According to Harrison Allen, adenoid growths from the normal lymphoid tissue of the vault of the pharynx (pharyngeal tonsils) may be congenital, and are “in some way associated with the canal which is found in early fetal life penetrating the brain-case and uniting the anterior part of the pituitary body to the lining membrane of the pharynx.”

Symptoms.—*Local.*—With slight or moderate enlargement there may be few or no symptoms. There may be simply an increased secretion of mucus, and a susceptibility to fresh anginal attacks or to severe tonsillar manifestations in diphtheritic or scarlatinal attacks.

The first symptom to attract the attention is the direct effect of naso-pharyngeal obstruction—*i. e.*, *oral respiration*. This mouth-breathing is visibly labored and abnormally audible, and is especially marked at night, the child’s respiration being noisy, snorting, and irregular. Sleep is disturbed by paroxysms of dyspnea, sometimes due perhaps to reflex spasm of the glottis. Nightmare follows as a result of imperfect aëration of the blood supplying the brain on account of the obstruction to perfect respiration. The act of swallowing is rendered difficult by the faucial obstruction, and is often painful, owing to the superadded acute tonsillar trouble that is so liable to occur in the hypertrophied glands. Indirect results of chronic tonsillar enlargement are a *laryngeal stridor* and a *croupy cough*. Sometimes *asthmatic attacks* coexist, and seem also to be due to the hypertrophy. An excessive secretion of mucus in the pharynx is a common symptom, and causes hawking in subjects past young childhood. The *hearing* is often impaired, and *tinnitus aurium* is complained of, being the result of pressure of the growths against the orifice of the eustachian tube or of extension of inflammation from the nasopharynx. Absolute deafness may result, and the senses of taste and smell are likewise diminished or perverted. *Inspection* of the fauces will show the tonsils bulging

as two lumps covered with thick mucus, or the latter may ooze around the uvula from the pharynx. In mouth-breathers of long standing the superior dental arch is narrowed and the hard palate is highly arched. The breath is fetid, owing to the cheesy, inspissated exudate in the tonsillar crypts. In very old cases a tonsillar *calculus* may be felt, and is the result of calcification of the secretion.

The *facial expression* is characteristically stupid and apathetic; the disposition is dull, irritable, and stubborn; the lips are thick, and a vacant stare is in the eyes. *Speech* is slow, phonation nasal in quality and articulation of the nasal consonants *n* and *m*, *l* and *o* is changed or muffled. *Stammering* may be associated. The anterior nares may be dilated and present a pinched appearance above their openings.

The prolonged interference with respiration gives rise to a peculiar chest conformation simulating that of rickets (*chicken-breast*). The ribs are prominent anteriorly, and there is a marked forward angle at the manubriogladiolar junction, as well as a grooved depression at the ensiform cartilage. Depressions between the widely separated ribs exist anteriorly also. Posteriorly, and at the base of the chest in particular, the intercostal spaces are practically absent on account of the closeness of the ribs. The upper part of the chest is very narrow and the shoulder bones quite prominent. On percussion the hepatic area of dullness is diminished on the chest wall, but increased downward and to the left. The first cardiac sound is weak. On inspiration there is a retraction of the intercostal spaces in the lower and lateral thoracic regions.

The resulting thoracic deformity may express itself principally as an excavation of the lower sternal area (*trichter brust*). When chronic tonsillar enlargement leads to oft-recurring asthmatic attacks, the chest may become *barrel shaped*, as in emphysema, at an early period of life.

The *general symptoms* of tonsillar hypertrophy are more marked when the growths exist in the pharyngeal vault alone. Developmental processes in children, such as dentition, and at puberty, particularly when the voice changes are looked for, are often retarded or perverted. Anemia, headache, especially during study, cardiac palpitation, enuresis, and habit chorea of the facial muscles, may be associated with general capriciousness, mental dullness, indisposition to intellectual exertion, drowsiness, and sullen irritability. The term *aproxexia* has been given to the loss of power to concentrate the mind for any length of time that is so characteristic of these cases.

Diagnosis.—Inspection of the fauces will reveal enlarged tonsils. The act of gagging, however, often causes the tonsils to rotate forward and inward, making them appear larger really than is the case. Adenoid growths of the pharyngeal vault may exist without tonsillar enlargement, and can be detected by posterior rhinoscopy or by the insertion of the finger into the nasopharynx.

Differential Diagnosis.—It is important not to attribute the obstructive symptoms to *nasal hypertrophies* or *atresia* or to *malignant growths* in the nasopharyngeal space. The latter are infrequent at the ages at which chronic tonsillar enlargement of the fauces and pharynx is most apt to occur—*i. e.*, early in life. Again, palpation of sarcomatous or carcinomatous growths gives marked differences in consistence, and there are usually spontaneous hemorrhages and local pain in attendance upon these neoplasms. *Thumb-suckers* differ from mouth-breathers in that in the former the incisors are inclined forward and cause slight protrusion beneath the upper lip; the dental arch is flat. In mouth-breathers, however, the incisors are vertical or nearly so, or incline so as to overlap each other; the dental arch is high and curved (H. Allen). *Retropharyngeal abscess* may be confounded with tonsillar enlargement, especially in children. But in this disease the attacks of dyspnea, the

dysphagia, and the local distress are more marked. Again, in the pharyngeal disease the swelling is in the median line, pushing the soft palate forward perhaps, and on palpation it may give a sense of elasticity or fluctuation to the finger. Slight fever may also be present.

Prognosis.—Tonsillar hypertrophy is not a severe disease as regards life. There is, however, an increased liability to contract colds, to recurrences of follicular tonsillitis, attacks of diphtheria, and severe scarlatinal angina. Nor must it be forgotten that chronic tonsillitis leads to many other more serious conditions. The tonsils are a focus of infection within the body affording an entrance into the system of bacteria or their toxins which may cause severe systemic disturbance. The tonsils are probably the most frequently affected site for a focal infection. Through them, usually when chronically diseased, pass germs that may cause acute rheumatic fever, septicemia, chorea, chronic cervical lymphadenitis (bovine type of tubercle bacilli), possibly arthritis deformans, and many similar conditions. Toxins elaborated in diseased crypts may be responsible for many a vague ache or pain, for more severe neuralgias, neuritides, and so on. The prognosis in acute respiratory affections associated with chronic tonsillar enlargement is always more or less grave. Adenoid growths, even when neglected, tend to lessen in size after puberty. After removal the growths, as a rule, do not return.

Treatment.—The old-fashioned use of astringent applications is probably useless when there is any marked chronic enlargement of the tonsils, and active surgical treatment alone is to be recommended for the condition. The use of absorbents and caustics, either externally or by parenchymatous injection, is, I think, objectionable.

There are no more satisfactory means of doing radical good in cases of this kind than the galvanocautery, scarification, and the removal of the tonsils with the tonsillotome, snare, or bistoury. In offensive follicular disease applications of chromic acid may give good results. Adenoid growths may be removed by means of the finger, curet, or forceps.

Constitutional treatment is often necessary in improving the nutrition of the patient. Good food, a change of air, systematic bathing, prudent habits, careful dress, and medicinal tonics and alteratives, as cod-liver oil, iodid of iron, and the hypophosphites, are usually indicated.

V. DISEASES OF THE PHARYNX

PHARYNGITIS

ACUTE PHARYNGITIS

(*Pharyngitis Acuta Simplex*)

Definition.—An acute catarrhal inflammation of the mucous membrane of the pharynx.

Pathology.—The mucous membrane is congested diffusely or in patches, and there may be an inflammatory exudate in, and a consequent swelling of, the submucosa and the contained glandular structures. The surface of the membrane is more or less coated with a viscid mucopus.

Etiology.—*Predisposing causes* are: age, it being more frequent in adolescence and young adult life; a depraved constitution; digestive disorders, and a rheumatic, gouty, or scrofulous diathesis. The usual exciting cause

is exposure, particularly of certain portions of the body, as the neck and chest, to cold or to sudden changes of temperature and to irritating vapors. An acute nasopharyngeal catarrh, by bathing the pharyngeal mucosa with its irritating secretions, may set up the trouble. *Epidemic pharyngitis* is probably a manifestation of influenza. Acute simple pharyngitis may be a complication of scarlatina, measles, and small-pox (*exanthematous pharyngitis*). Micrococci are present, the streptococci often predominating.

Symptoms.—*Locally*, the affection is ushered in with a feeling of dryness and soreness, especially on swallowing. With the production of the mucopurulent secretion a tickling sensation provokes *hawking* or a slight *throat cough* and efforts at expulsion. The catarrhal process may extend to the larynx and cause some hoarseness, or to the eustachian tube, causing dulness of hearing. Movements of the neck are *painful* and *stiff*, particularly if there is, as is often the case, slight involvement of the lymph-glands. *Inspection* of the throat shows the pharynx, often the posterior pillars of the fauces and the soft palate, and even the anterior pillars and tonsillar surfaces, to be deeply reddened and tumefied; the coursing veins are enlarged, and particles of a yellowish-white secretion appear here and there. Sometimes the pharyngeal follicles become subject to acute inflammation, and appear as elevated, discrete, shiny spots (*herpetic pharyngitis*—Mackenzie).

At the *onset* of this affection there may be chilliness, followed by slight fever, headache, an accelerated pulse, a dry skin, and anorexia. The *pharyngeal symptoms* seldom last more than from three to five days, when resolution takes place, some tenderness of the pharynx, however, remaining for a time.

Diagnosis.—On examination of the throat there should neither be any difficulty in diagnosing the affection nor any likelihood of confounding the affection with simple tonsillitis.

The **prognosis** is always favorable. In weakly patients, however, there is a liability to subsequent attacks.

Treatment.—In the early stages sucking of small pieces of ice does much to allay the congestion and irritability. A spray of cocain or menthol in alcoholene (2 per cent.) may also be used, followed by a 4 per cent. solution of antipyrin. Eucaïn may be substituted for cocain (2 per cent. solution), and is preferred by Gibbs and others. Dobell's solution is always to be recommended for its alkaline, sedative, and antiseptic action. Swabbing the pharynx with a silver nitrate solution (gr. xl to the ounce—2.6–30.0) is, according to Sajous, of great benefit.

In well-established cases relief is often obtainable by medicated steam inhalation, as with the compound tincture of benzoin. In rheumatic cases lozenges of guaiac (gr. iij—0.19) are useful. The sipping of hot milk in which sodium bicarbonate has been dissolved is grateful.

The *general treatment* embraces measures directed at the fever and the diathetic condition. A hot foot-bath and a calomel purge, with belladonna, acetanilid, or aconite for the fever and pain, and sodium salicylate (gr. lx to lxxx—4.0–5.5—in the twenty-four hours), may be required. The diet, of course, should either be liquid or semisolid.

Persons susceptible to repeated attacks must exercise caution in regard to exposure to severe cold and weather changes, irritating vapors, and the like. Daily cold sponge-baths may be used to harden the skin. Tonic, nutrient treatment is also frequently called for.

MEMBRANOUS PHARYNGITIS

(Pharyngitis Crouposa)

Definition.—An acute superficial inflammation of the pharyngeal mucosa, characterized by the formation of a whitish false membrane, due usually to the streptococcus.

Etiology.—The principal causes of this form of pharyngitis are exposure of persons in debilitated health to cold or an impure or a septic atmosphere, particularly during epidemics of such diseases as scarlatina.

Symptoms.—The local and general symptoms are those of ordinary sore throat, though of a more severe type.

Diagnosis.—The pseudomembrane is thin, of a yellowish-white color, and appears in small patches over the pharynx. It is easily detached, and this feature, together with the presence of small vesicles or ulcers and the absence of grave constitutional disturbances, serve to differentiate this affection from diphtheritic pharyngitis.

The prognosis is favorable.

Treatment.—Local applications of solutions of hydrogen peroxid or potassium permanganate (gr. x to the ounce—0.6–30.0) are very satisfactory. For the painful dysphagia the sedative and soothing remedies suggested for simple acute pharyngitis may be used. Internally, sodium benzoate (gr. v to xv—0.3–1.0) in glycerin, elixir of calisaya, and phenyl salicylate have each been recommended. Tonic treatment is nearly always needed.

CHRONIC PHARYNGITIS

Definition.—A chronic inflammation of the mucous membrane of the pharynx. It may consist of either a hypertrophic or an atrophic involvement of the follicles, or both processes may coexist.

Varieties.—(a) Chronic nasopharyngeal catarrh; (b) chronic hypertrophic pharyngitis or nasopharyngitis (*pharyngitis sicca*); (c) follicular or granular pharyngitis. The last named is probably the result of, and nearly always is associated with, chronic simple (or hypertrophic) pharyngeal (or nasopharyngeal) catarrh.

Pathology.—The mucous membrane in simple chronic pharyngitis is either reddened, thickened, and viscid (hypertrophic form), or pale, thin, and dry (atrophic form); in both instances dilated and tortuous veins are prominently shown. In the follicular variety the pharyngeal mucous glands are swollen into little red, glistening nodules studding the congested membrane. The enlarged follicles are due to a hyperplasia of lymphoid cells and an accumulation of retained dried-up secretions.

Etiology.—A protracted impairment of the general health, especially in those who overexert mentally and are of sedentary habits, is a common *pre-disposing cause* of chronic pharyngitis. Repeated acute attacks may precede the affection. It is most common in adolescent and middle life.

The *exciting causes* are frequent and prolonged overuse and strain of the voice in clergymen, singers, teachers, army officers, and street venders; irritation from tobacco smoke, chemical vapors, and continued exposure to cold air. Among prevailing causes may be mentioned postnasal adenoids, deviations of the septum, and neoplasms. It may arise from gastric disorders.

Symptoms.—In all varieties of chronic pharyngitis the *local discomfort* is often very slight, and more annoying than painful, except when an exacerbation takes place. There is a sensation of *dryness* and *tickling* or *burning* in the throat and the desire to clear the throat of sticky mucus by *hawking* or a

short cough. These symptoms are usually worse on rising in the morning, especially if some unfavorable influence has been exerted during the night previous, the throat being dry and a viscid secretion having collected. Swallowing is seldom interfered with.

If the larynx is somewhat affected by extension of the pharyngeal inflammation, *hoarseness* and a *dry, hacking cough* are produced. After using the voice there is a sense of fatigue, with huskiness and irritability.

The *local appearances* of chronic pharyngitis vary according to the form of the affection present in the case. In chronic catarrh of the pharynx a considerable collection of mucus is seen adhering to the mucosa and extending downward from the posterior nares. The senses of hearing and taste may be impaired. The uvula is frequently elongated, and its tip may rest on the base of the tongue. A nasal intonation of the voice is sometimes provoked. The posterior nares as seen by the rhinal mirror are often stopped up by foul secretions or by hypertrophy of the nasal mucous membrane. Headache and attacks of vertigo may occur.

Chronic hypertrophic pharyngitis and follicular pharyngitis (*clergyman's sore throat*) are commonly associated. The thickened, reddened, pimply, vein-coursed appearance of the mucosa is characteristic. The follicles may be seen sometimes as polypoid elevations, and the pharyngeal tonsil may be found by the finger to be enlarged (Kölliker).

In the dry, *atrophic pharyngitis* that occurs more often in later life, and as a sequel of the simple chronic or follicular variety, a pale, smooth, relaxed, lustrous, and often quite painful membrane is observed.

The *general symptoms* are usually those of a weak, debilitated, nervous constitution, though in mild cases the general health may be unimpaired. In atrophic pharyngitis considerable cachexia may be present.

Diagnosis.—Care should be exercised in discriminating the variety of chronic pharyngitis present in any given case, so that the treatment may be planned accordingly. Careful and repeated inspection of the throat renders the diagnosis easy unless ulceration has taken place: in such cases a *tuberculous* or *syphilitic* sore throat must be eliminated by the superficial character of the ulcers, by their ready response to proper treatment, by the history of the case as to specificity, and by the absence of marked pain or symptoms pointing to tuberculosis. When due to gastric disturbance the lower throat will be deeply congested and the tongue will be irritable, with red papillæ standing over its base (Price-Brown).

Prognosis.—This should be guarded as to cure on account of the stubborn resistance to treatment and the difficulty in removing unfavorable influences. Acute exacerbations are liable to recur unless rigid caution is practised at all times in avoiding the cause of the trouble.

Treatment.—The local use of astringent and alkaline antiseptic sprays or the nasal douche is usually recommended, but has only a palliative effect. Silver nitrate cauterization may be tried. The only effectual means, however, of curing the follicular or hypertrophic variety is that used by most throat specialists, namely, the wire galvano- or actual cautery. Applications of silver nitrate (gr. x to the ounce—0.6–30.0) and the internal use of the oleoresin of cubebs have been recommended for the atrophic pharyngitis. Insufflation of powdered tannin or alum is also of service.

Systemic disturbances need attention according as they present themselves. Mineral baths are sometimes of great benefit, and tonics are usually indicated. All irritating causal factors must be removed or avoided before any favorable results can be hoped for from local applications. Tobacco smokers and topers must deny themselves their habitual luxuries.

ACUTE INFECTIOUS PHLEGMON OF THE THROAT

Definition.—An inflammation of the pharyngeal mucosa that passes rapidly into a suppurative process. It is exceedingly rare.

Its **etiology** is not definitely known. I have met with no cases except in my hospital wards, though they doubtless occur in general medical practice. The clinical features have been described by Senator.

The **symptoms** are *sudden in their onset* and quite intense. They are severe soreness of the throat, dysphagia, and hoarseness, as a rule; in advanced cases there has been difficult respiration. *Inspection* shows the pharynx to be deeply injected and the seat of marked inflammatory edema, the neck appearing greatly swollen as well. The general disturbance is correspondingly severe.

The **treatment** is wholly symptomatic.

RETROPHARYNGEAL ABSCESS

Definition and Pathology.—A suppurative inflammation (rare) of the glands or connective tissue anterior to the cervical spinal column.

Etiology.—The disease is relatively most common before two years of age. It is usually a primary affection, occurring without assignable cause, but a certain proportion of instances are doubtless caused by caries of the cervical vertebræ. It may rarely be secondary to any of the specific fevers. Traumatism causes occasional instances.

The **symptoms** are *pain in swallowing, impeded respiration*, soon becoming stertorous in character, the dyspnea meanwhile constantly increasing. There may be *cough*, and the voice may present abnormal characteristics. The signs of *stenosis* finally declare themselves with considerable violence, and an examination of the pharynx usually serves to make the diagnosis positive; the projecting tumor is visible, and the palpating finger readily detects fluctuation. In children the *general features* (slight fever, anorexia, languor) overshadow for days the *local*, while in adults the condition develops acutely with severe faucial symptoms.

The **course** of the disease may be acute, lasting one or two weeks; more frequently, however, it is subacute (rarely chronic), as, for example, when it is due to caries of the vertebræ.

The **prognosis** is favorable in all cases that are early diagnosticated. If unrecognized until the later stages have been run, suffocation may ensue, or rupture into the larynx may cause death by asphyxia.

Treatment.—As soon as fluctuation is detected the abscess should be freely opened, and preferably, as a rule, through the mouth by means of a guarded bistoury. The throat, after the abscess is thoroughly evacuated, should be washed out with some mild antiseptic solution (salicylic acid 2 per cent. or boric acid 2 per cent.). When pointing occurs at the side of the neck, as sometimes happens, the incision should be made through the skin in that locality. Constitutional indications are to be fulfilled in accordance with general principles, and the strength of the patient is to be maintained by a highly nutritious dietary.

VI. DISEASES OF THE ESOPHAGUS

ESOPHAGITIS

ACUTE ESOPHAGITIS

Definition.—An acute inflammation affecting either the mucous membrane or submucous tissues of the esophagus, or both.

Pathology.—The ordinary morbid changes of an acute esophagitis are those of a simple catarrhal inflammation of the mucosa. It is rather characteristic of the condition that there is no increased secretion, a sponginess and rapid desquamation of the epithelium taking place instead, and causing a granular appearance of the membrane. Occasionally the mucous glands are swollen, and may break down, with the formation of small follicular ulcers. Catarrhal erosions may also be seen here and there. A croupous or diphtheritic exudate is seldom found in the lower portion of the esophagus, and small-pox pustules are rarely, if ever, seen. A diffuse or circumscribed purulent inflammation of the submucosa may dissect up the mucous membrane so as to considerably diminish the esophageal caliber; pus is usually discharged into the tube. In severe cases of poisoning (*corrosive esophagitis*) sloughing may extend into the muscular layer, and may produce a foul, dark, hemorrhagic mass. A fibrinous cast of the gullet has been vomited up by a hysteric woman (Birch-Hirschfeld).

Etiology.—The causes of acute esophagitis, other than traumatic, are rare. Under the later are included the *mechanical*, *thermal*, and *chemical* irritants, such as the presence of foreign bodies and the swallowing of hot liquids, corrosive poisons, "concentrated lye," mineral acids, and arsenic. The condition may also be the result of the following: (a) an extension of catarrhal inflammation of the pharynx; (b) specific infectious fevers, as typhoid, typhus, and pneumonitis; (c) diphtheria (*pseudomembranous esophagitis*) by the extension of pharyngeal diphtheria; (d) small-pox, giving rise to a pustular inflammation of the gullet; (e) local disease, as carcinoma of the esophagus, glandular or vertebral abscess, or laryngeal perichondritis (Strümpell).

Symptoms.—*Pain* during deglutition may be referred to the region of the esophagus, and a steady, dull pain may exist beneath the sternum. *Dysphagia* and *regurgitation of food* may be caused by spasm in severe cases. Mucus, blood, and pus may be discharged later. The absence or mildness of pain is not a true indication of the gravity and extent of esophageal inflammation.

Sequelæ.—Simple catarrhal or follicular ulcers may appear, and the necrotic form of the disease may be followed by suppurating ulcers, which, if healing takes place, may cause cicatricial stenosis.

Diagnosis.—This may be based upon the localization of pain, especially during deglutition; upon the pain occasioned by the passage of the esophageal sound; and upon the mucus, blood, or pus adherent to its bulb on withdrawal, provided carcinoma at the cardiac orifice of the stomach can be excluded. The expulsion of a pseudomembrane (diphtheritic) from the gullet should be differentiated from esophagomycosis (thrush), especially in children. The diagnosis of the particular form of esophagitis will depend upon the facts elicited relating to the etiology.

The **prognosis** is good in mild cases, and should be guarded in those associated with grave disease. Death may occur in either the purulent or necrotic form.

Treatment.—This is entirely symptomatic, and in severe cases is of little value. A soft, bland diet, preferably of milk, may be borne in ordinary in-

stances; if not, rectal alimentation should be resorted to. For the mild cases swallowing of bits of ice, and later of warm demulcent drinks, should be recommended. In cases of marked pain and esophageal spasm relief may be afforded by a hypodermic injection of morphin and atropin.

CHRONIC ESOPHAGITIS

Chronic catarrh of the gullet may result from continued irritation by the causes of the acute form, and also from passive congestion due to hepatic cirrhosis, chronic cardiac or renal disease. The last-named conditions may also cause varicose esophageal veins, and fatal hemorrhage may result therefrom. Chronic alcoholism is a common cause. The increased mucous secretion may cause eructations and nausea.

Postmortem evidence of esophagitis, either acute or chronic, is found with extreme rarity.

ULCER OF THE ESOPHAGUS

This is a consequence of a simple or follicular catarrh of the gullet or of gangrene. "Catarrhal erosions" and follicular ulcers may occur, and also necrotic ulcers, in bedridden persons opposite the cricoid cartilage. The extensive purulent ulceration following the separation of necrotic sloughs may heal and cause stenosis of the tube, or it may rupture into the trachea, the posterior mediastinum, or the aorta. Pressure ulcers (*e. g.*, from aneurysm) occur. Ulceration may also be met in uremia. Ulcers simulating those occurring in the stomach (*ulceres ex digestionem*) may sometimes be found at the lower end of the esophagus. There may be localized points of pain on the passage of the esophageal bougie, with some pus and blood on the bulb after its withdrawal. Rest from swallowing should be secured as far as possible. The sipping of hot milk may be soothing, and the slow swallowing of mild boric acid and sodium bicarbonate solutions may be tried with benefit.

CARCINOMA OF THE ESOPHAGUS

This is the most frequent affection of the tube, and, as it is the commonest cause of stenosis, it is important from a diagnostic standpoint.

Pathology.—Carcinoma of the esophagus is primary and of an epitheliomatous nature, the mucous membrane here being composed of pavement cells. The new growth affects the mucosa first, and then, increasing in size and causing ulceration, it involves the entire circumference of the tube. This may either be hard and fibrous, or soft and jelly-like. The esophageal lumen is markedly diminished, though disintegrating ulceration or "flat" carcinoma may encroach upon the caliber but little. There may be a diffuse dilatation of the esophagus above the growth, as well as a hypertrophy of the circular muscular fibers. The cancerous tumor is found most commonly in the lower third of the esophagus (generally at the bifurcation of the trachea). A small percentage of the cases are surgically accessible, being situated in the neck.

Etiology.—The *predisposing causes* of esophageal carcinoma are age and sex, males past forty years of age being the usual subjects of this neoplasm.

Lerche emphasizes "hot fluids" as an important predisposing cause. The *exciting causes* are of uncertain origin. It has been alleged that various forms of protracted irritation of the mucous membrane may cause the development of carcinoma; and especially has this point been maintained in connection with the frequent occurrence of carcinoma of the gullet in topers. It is also believed by some that as gastric carcinoma may develop from the scars of old ulcers, a like condition in the esophagus may act as a nucleus for a carcinomatous growth.

Symptoms.—*Dysphagia* is the earliest symptom of esophageal carcinoma with beginning stenosis of the tube. This gradually and steadily increases, so that liquids alone can be swallowed, and later regurgitation even of small amounts (not above 3 ounces) of liquid foods takes place. Occasionally, at the start, dysphagia amounts to a brief choking sensation only. There may be considerable *pain*. I saw an instance with the late Dr. W. Frank Haehnlen, in which mucus was almost constantly regurgitated, and bronchiectasis developed near the close.

The *ejecta* may contain cancerous fragments, blood, and mucus. The dysphagic symptoms may subside spontaneously, owing to the disintegration and ulceration of the growth, or the dysphagia may be so slight as to be masked by the prominent symptoms of hepatic or pulmonary carcinoma and gangrene secondary to a very flat esophageal carcinoma. Or, without secondary manifestations of such a growth, the esophageal symptoms may rarely be latent. The cervical glands may be enlarged.

The most important *general symptom* of esophageal carcinoma, as of this malignant growth elsewhere, is the progressive emaciation, which increases with the stenosis and obstruction to the entrance of nourishment into the stomach. Though seemingly anemic, the patient's blood may contain an excessive number of corpuscles in a given bulk. This is due to inspissation from failure to absorb water and food into the body.

Course, Duration, and Termination.—The disease is chronic, becoming progressively worse, and is often beset with grave complications (*vide infra*). It seldom lasts longer than one and a half years, and the duration of medullary carcinoma of the gullet is usually shorter. A fatal ending is inevitable by inanition and exhaustion, or as the result of metastasis and secondary complications.

Complications.—These follow extension of the cancerous growth to neighboring parts. Thus, involvement of the larynx, trachea, and bronchi has been noted. The cancerous ulcer may also perforate the pleura, the pericardium, or the aorta or its branches, and cause fatal hemorrhage. The vertebræ have been eroded, and compression of the cord, with resulting paraplegia, may take place.

Paralysis of the vocal cords may be the effect of pressure by the growth upon the recurrent laryngeal nerve; most frequently pulmonary gangrene is due to perforation of the lung or to the inspiration of cancerous and decomposing particles that have been regurgitated.

Diagnosis.—All other causes of dysphagia must be excluded. *Enlarged tonsils, pharyngeal tumors*, pressure from without by cervical intrathoracic tumors, as *aneurysm*, or by displacement of the sternal end of the clavicle, and the presence of *foreign bodies* or *cicatricial strictures* of the gullet—all figure in the production of difficult deglutition. The history of the case, the age of the patient, the progressive emaciation (cancerous cachexia), and the obstinately increasing dysphagia will enable us to exclude the other affections named. In using the esophageal bougie for diagnostic purposes great care should be exercised, as an aneurysm may thus be ruptured or a deeply ulcerated

carcinoma perforated. The withdrawal of cancerous tissue upon the bulb will decide the case. The esophagoscope may be useful in certain cases. G. E. Pfahler¹ has shown that the disease can be diagnosticated by means of the roentgen rays, so that present-day diagnosis depends very largely upon this method. The exceptional occurrence of latent cases must be remembered. *Sarcoma* cannot be distinguished from carcinoma by the clinical symptoms. By means of the esophagoscope, however, a small piece of the tumor may be removed for examination.

The **prognosis** is hopeless, and the supervention of grave complications renders the chances of an early demise very probable.

Treatment.—This is essentially symptomatic and sustentative. If feeding by the mouth is difficult on account of the extreme stenosis, although permitting the passage of an esophageal tube, the later may be used for the passage of liquid nourishment. Rectal feeding may later become imperative. The local application of radium has been recommended. The mechanical treatment of the cancerous stricture by the passage of the graduated esophageal bougie is seldom of any avail. Soft, disintegrating, and ulcerating carcinoma should thus be treated, though with the absence of any force whatsoever. The performance of gastrostomy may prolong life in some cases in which there is formidable difficulty in passing a tube into the stomach.

RUPTURE OF THE ESOPHAGUS

The first recorded case of this rare condition occurred under the observation of Boerhaave in 1724 in the person of the Baron Wassemarr.

Pathology.—Softening together with a great friability of the esophageal walls may be found, this probably being the effect produced by the solvent action of the gastric juice upon the mucous membrane at a time when the local circulation is disturbed and the vitality of the tissues thus lessened.

The *postmortem* evidence of this accident consists of a longitudinal (as a rule) tear about 5 cm. (2 inches) in length, situated in the lower half of the esophagus. Food and air may be found to have escaped into the left pleural cavity, and unless death occur at an early date signs of purulent inflammation will probably be noticed. *Postmortem* digestion of the esophagus is more common (Osler). The perforation is often large, and is located in the posterior wall of the tube.

Etiology.—Softening of the walls of the gullet (*esophagomalacia*) is suggested by Zenker as a condition that always precedes spontaneous rupture, so called. The exciting cause is believed to be violent and persistent vomiting after a particularly heavy meal or during acute alcoholism.

Symptoms.—These come on *suddenly* or soon after a full meal, and commence with *nausea* and very *severe vomiting*, accompanied by *great pain* and rapid and extreme *collapse* of the whole body, due to the shock. A cutaneous emphysema of the neck and chest is manifested soon after the rupture.

The **diagnosis**, if made at all, must rest upon the clinical history. Death usually takes place in a few hours or days at the most.

Treatment.—Pain, if excruciating, should be dulled by the hypodermic administration of morphin.

¹ *Arch. Diag.*, January, 1909.

NEUROSES OF THE ESOPHAGUS

MUSCULAR SPASM

(Esophagismus)

Definition.—A spasmodic contraction of the muscular layer of the upper or lower portions of the esophagus.

Etiology.—It is almost always a secondary affection, met with not infrequently in hysteria, hydrophobia, and rarely in chorea and epilepsy. In this case the esophageal bougie could be passed only with a great deal of difficulty during the spasm. It may be observed in aged males, and especially in those suffering from hypochondriasis, though in many no evidence of a neurotic temperament can be elicited. It may be due to reflex causes, originating, for example, in the uterus; thus, in some cases, it occurs only during the pregnant state. Spasm may complicate all of the lesions of the esophagus, even organic stricture.

Symptoms.—The chief subjective characteristic is *dysphagia*. Although liquids can be swallowed, solids, as a rule, cannot. Poststernal *pain* is sometimes noticed, and choking signs are quite common. In the hysteric variety emotional disturbances are found among the prodromata. The general nutrition remains good.

Diagnosis.—The etiologic factors must be carefully weighed in connection with the symptoms and the valuable testimony gained by the use of the sound. The bougie on reaching the constriction is rather tightly gripped, though gentle pressure soon causes it to relax. After the subjective symptoms and spasm are over the sound passes without the slightest difficulty. The siphoned and vomited masses contain neither blood nor pus. An examination with the esophagoscope allows the diagnosis to be easily made. In some cases the dysphagia may be due to pharyngeal paresis. The *elderly hypochondriac* is, as before stated, liable to develop a similar condition, which must not be confounded with true cancerous stricture. The **prognosis** is good. Guisez speaks of severe spasms with lethal tendency.

The **treatment** is directed to the disease on which the condition is found to depend, and this must receive careful attention. The sound should be used as previously indicated under the discussion of Esophageal Stricture. Its passage has often been followed by speedy and permanent cures. A special electrode with which to apply electricity to overcome the spasm of the cardia has been employed.

PARALYSIS OF THE ESOPHAGUS¹

In extensive bulbar paralysis, when adjacent parts are involved, we may infer the existence of esophageal implication, though there be no objective evidence to adduce in confirmation. Doubtless the esophagus rarely shares in postdiphtheritic paralysis also. Dysphagia is the leading symptom. An invaluable peculiarity belonging to diphtheritic paralysis is the fact that solids are more readily swallowed than liquids.

DILATATION OF THE ESOPHAGUS

Pathology and Etiology.—Diffuse dilatation of the esophagus is usually secondary to organic stricture at or near the cardiac orifice. In accordance with the common law of compensation, the first effect of the stenosis is to en-

¹ For remarks on the treatment of this complaint the reader is referred to the section on Nervous Diseases.

gender hypertrophy of the muscular layer above it with a view of overcoming the resistance caused by the obstruction. The wall of the esophagus becomes thickened, and the tube is generally somewhat narrowed above the seat of the stenosis; but finally, as a result of degenerative changes, the muscular coat weakens, the esophagus dilates, and food accumulates above the stricture—a condition that, once begun, progresses. This condition also occurs without anatomic stenosis, and Plummer records 91 cases, and only 5 of the patients were of a neurotic type. Petersen reports 4 cases in which cardiospasm led to dilatation of the esophagus.

Congenital dilatation, in which the whole extent of the tube participates, has also been met with, though such a condition is rare indeed. It sometimes results from fatty degeneration of the muscular wall, and a predisposition to the complaint may be acquired as the result of injury or prior inflammation.

Symptoms.—The essential symptom is chronic *dysphagia*. When dilatation follows stenosis the patient often locates the point at which the food lodges in the esophagus. Most of the ingesta are regurgitated several hours after eating, and this process is often attended by more or less severe strangling. The *esophageal sound* comes upon the stricture, and is either gripped firmly or totally resisted; in the latter event the bulb can be moved about above this point with abnormal freedom. In the rare cases of spindle-shaped dilatation without stenosis the sound usually detects no obstacle on its way into the stomach. A *sac* is occasionally formed, however, as the result of localized bulging of the paralyzed wall, in which food may collect or the exploring sound may catch, thus leading to erroneous inferences. Dysphagia is present, though it presents peculiarities, in that the food may either pass down very slowly until it reaches the stomach, or it may lodge in the shallow pouch, as above described. In the latter event the food may be gulped up from time to time. If the sound can be easily introduced into the stomach, we may safely eliminate stricture as the cause of the dilatation. The roentgen ray is an extremely valuable diagnostic aid.

The **prognosis** is good as long as sufficient food can be gotten into the stomach for the support of life.

Treatment.—The chief object in the treatment is to keep the patient nourished. If sufficient food cannot be swallowed, a Symonds tube should be inserted and nourishment given through it; and when this mode of feeding is no longer feasible, the physician has to choose between gastrostomy and rectal feeding. There can be no doubt that by means of nutrient enemata nutrition may be fairly well maintained, but not indefinitely, as these cases would seem to demand. In the hands of a competent surgeon, on the other hand, gastrostomy is often fruitful of brilliant results. Galvanism has been recommended on high authority. Local lesions, when present, must be dealt with in accordance with the rules governing the treatment of the several causal conditions. The sac may be washed out daily with an antiseptic solution (*e. g.*, 3 per cent. boric acid).

ESOPHAGEAL DIVERTICULUM

(*Pharyngocoele*)

Definition.—A circumscribed sac in the wall of the esophagus.

Pathology and Etiology.—Two varieties are met with, which Zenker has termed *pressure* and *traction* diverticula; the latter are rare. Diverticula that occur at or near the inferior constrictor, and more particularly the larger

ones, are *congenital* in origin. When *acquired* they are the result of a localized lesion in the muscular coat, through which the mucous membrane bulges like a hernia. This is owing to repeated slight pressure occasioned by the passage of food. When once such a process is started, various factors tend to continually enlarge the pouch. Chief among these are the morsels of food that find lodgment and naturally tend to augment the size of the diverticulum by dragging it downward. The sac may finally attain a diameter of not less than 4 inches (10 cm.). Its situation is nearly always on the posterior wall at the pharyngo-esophageal junction, and its form is usually saccular or pear shaped. Most instances have been met with in males after middle life. The cause of the weakened area at which the diverticulum occurs is to be found sometimes in injury, but more frequently in an antecedent inflammation. Histologic changes are observed only in the mucous and submucous layers, these anatomic elements together forming the pouch.

Traction diverticula are produced by the fringe of tissues that often becomes adherent to the upper aspect of the esophagus, and from their mode of occurrence they will obviously be more or less funnel shaped. Their dimensions are small. They are more common in children than in adults, for the reason that in the former, more frequently than in the latter, do the bronchial glands suppurate, with subsequent cicatrization. This circumstance affords an explanation of the fact that traction diverticula are usually seated on the anterior wall of the esophagus near the bifurcation of the trachea.

Clinical History.—*Traction* diverticula do not, as a rule, give rise to clinical symptoms. Exceptionally, however, as the result of the mechanical irritation caused by bits of food that are retained in these funnels, ulceration may occur and be followed by perforation of their apices. In this manner the main bronchi are perforated (causing pneumonia and pulmonary gangrene), also the pleura (causing empyema), and, more rarely, the pericardium (causing suppurative pericarditis).

Pressure diverticula when small cannot be recognized owing to the absence of signs and symptoms. When they attain considerable size, however, they are often attended with severe symptoms. The earliest clinical manifestation is difficulty in swallowing; some of the food enters the sac, and, if allowed to remain, undergoes putrefactive decomposition, causing *fetor of the breath*. From time to time, and especially on attempting to swallow, the partly or wholly filled condition of the pouch excites *nausea* and *vomiting*, associated with prolonged *strangling*; this results in the ejection of a portion of the accumulated contents. These contain no hydrochloric acid. After such an attack the patient is unable, temporarily, to swallow food, and in consequence of the limited amount of food taken signs of inanition soon appear; this may finally become extreme, and is sometimes the immediate cause of death. The appearance of a *pear-shaped swelling* in the side of the neck has been observed. As the tumor enlarges it displaces the larynx and presses upon the enlarged vessels—more rarely upon the superior laryngeal nerve—giving rise to dyspnea and distressing fits of coughing.

Diagnosis.—A point in the differentiation of this affection is the enlargement of the sac after meals (not all the food passing into the stomach), and its disappearance after being emptied. Another discriminating sign is the effect of compression by the hand in causing the contents (“air and sodden food”) to flow back into the mouth. In those instances in which the tumor is absent we may demonstrate its existence by the use of the esophageal sound. If the sound passes into the sac, the descent will soon be arrested. If, however, the instrument fails to enter the mouth of the pouch, it readily glides into the stomach. An elbowed sound, bent at an obtuse angle near the tip, is useful

in such cases. It may be inserted in different directions, so as to avoid entrance into the sac. In doubtful cases the condition can always be recognized by the roentgen ray. Some writers advocate the methylene-blue test of Bökelmann. The esophagoscope should be used last in a routine examination, there being danger of a rupture of a possible aneurysm (Mayer).

Prognosis.—The outlook is unfavorable in the absence of operative treatment, though modern surgery gives promise of curing a certain proportion of cases. Wheeler has operated successfully in one instance at least. The physician may prolong life by directing attention to the nutrition of the patient, but he cannot hope to promote a cure.

Treatment.—If the patient cannot swallow an adequate amount of nourishment, he may be successfully fed through a tube, which he himself should be allowed to pass. When sufficient food cannot be introduced by this method, rectal feeding should be instituted. If excision of the diverticulum be deemed impracticable by the surgeon, then the establishment of a gastric fistula is worthy of extended trial in cases in which the above-mentioned modes of feeding have failed. It has been advised to wash the sac daily with sterile water or some mild disinfectant to prevent decomposition. Stetten collected statistics of 60 radically operated cases, which gave a mortality of only 16.6 per cent.

STRICTURE OF THE ESOPHAGUS

Etiology.—A stricture of the esophagus may be due either to: (a) Congenital narrowing (exceedingly rare); (b) squamous epithelioma, usually producing an annular constriction; (c) rarely to polypi protruding from the mucosa, which almost occlude the lumen of the tube; (d) rarely to specific inflammation, as syphilis and tuberculosis; (e) simple stricture generally results from the ingestion of corrosive fluids, which cause extensive sloughing of the mucosa, followed by cicatricial contraction; (f) rarely as a sequel of typhoid and peptic ulceration.

Clinical History.—The symptoms vary with the special cause and with the degree of stenosis. The first and most prominent indication of narrowing of the gullet is a very slowly increasing *dysphagia*. The patient for a long time complains of a *sense of pressure* at a certain substernal point on swallowing solid food, or, more rarely, an apparently healthy person will suddenly experience painful pressure in attempting to swallow a larger quantity of food than usual. By and by even fluids cause dysphagia, and the patient observes that the time required for the food to reach the stomach is lengthened. The impediment to the act of swallowing is not due alone to mechanical stenosis, but partly to the weakness of the muscular coat, sometimes owing to its partial destruction, and in exceptional cases partly to spasmodic contraction. When due to carcinoma, difficult deglutition is, as a rule, the only symptom complained of. When occasioned by corrosive fluids or traumatism, *pain* is prominent from the onset.

Above the seat of stricture the esophagus is often *dilated* and contains accumulations of the ingesta. The latter, together with considerable mucus, are regurgitated three or four hours after meals, and we may be certain that the materials thus ejected do not come from the stomach if they are alkaline in reaction. The leading clinical features are the gradually *increasing debility* and *emaciation*, finally reaching an extreme degree.

Diagnosis.—However characteristic the symptoms may be, the bougie should invariably be passed before pronouncing a positive diagnosis. By this

means we ascertain the degree and the seat of the stricture. To begin with, a medium-sized gum-elastic bougie (No. 16 English scale) should be employed, after warming it and lubricating with glycerin. Its use should be preceded by a cocain spray to prevent spasm. The patient should occupy a low seat, with his head supported by an assistant from in front of the operator. The head should be only slightly thrown backward. The forefinger of the left hand should then be passed back over the tongue until it touches the epiglottis, and the bougie inserted along it with the right hand, thus avoiding the error of passing it into the nasopharynx or the larynx. When the bougie reaches the cricoid cartilage it is sometimes gripped pretty firmly even in a healthy person—a fact that is always to be remembered. No force should be applied. The instrument may pass the constriction with a jerk, or it may not only be gripped, but distinctly arrested, when a smaller bougie should be tried. By moving the instrument upward gently we may detect sometimes several strictures lying one above another. To locate the obstacle, the distance from the teeth to the point of stricture is measured on the instrument, and the results compared with the normal measurements, which are as follows: from the teeth to the cricoid cartilage, 7 inches (17.7 cm.); to the left bronchus, 11 inches, (27.8 cm.); and to the opening into the diaphragm, 15 inches (37.9 cm.).

Auscultation of the esophagus has been practised, but the clinical indications afforded are of little practical value. The stethoscope is placed to the left of the spine, and the patient takes a mouthful of water, when, if the stricture be present, a splashing, cooing sound will be heard at the seat of the stricture instead of the normal esophageal bruit. The roentgen-ray examination after an opaque meal will show the location and degree of stenosis of the stricture, and in some cases the cause of the condition (*e.g.*, aneurysm). The rhythmic peristaltic contractions of the muscular fibers of the esophageal wall will be seen to stop at the site of the stricture.

Differential Diagnosis.—It is important for rational treatment to determine not only the existence of a stricture but also the underlying disease. First and foremost, we must exclude those affections that simulate simple and malignant stricture, in certain of which the introduction of the sound would be attended with grave dangers. *Compression of the esophagus* by enlarged or accessory thyroids, aortic aneurysms, vertebral abscess, enlarged lymphatic glands, and occasionally pericardial effusions, may produce dysphagia, and on passing the bougie resistance is offered at the seat of the external pressure. As a rule, the extent of the stenosis is moderate. If the narrowing be due to aneurysm—"(*a*) rhythmic movement is sometimes communicated to the free end of the sound introduced as far as the stenosis." Careful physical examination will often reveal the presence of an aneurysm or other pressing tumor, and should never be neglected. Passage of the sound in cases of aneurysm has caused rupture of the sac and death. (*b*) Spasm of the esophagus or paralysis (the latter rarely) may closely resemble true stenosis. These neurotic forms are almost exclusively met with in hysteric females; on the other hand, malignant strictures are found generally in males over forty years; while in simple stricture there is usually a definite history and certain etiologic factors.

To discriminate between simple and malignant stricture is not difficult, as a rule. When a clear history of gumma, of tuberculous disease, or of injury (from corrosive liquids) is obtainable, the presence of a simple stricture may be safely inferred after eliminating the affections previously mentioned. In the absence of etiologic data pointing to the simple form, cases occurring in the male after forty years of age may be looked upon as malignant.

Prognosis.—In forming a prognostic opinion the chief factor to be considered is the nature of the stricture. Practically, so long as the stenosis is dilatable, the prognosis is not unfavorable provided sufficient nourishment can be taken; moreover, not a few cases of simple stricture are curable. The majority, however, come to a fatal termination finally.

Treatment.—The chief object of the treatment is to gradually and methodically dilate the stricture. The flexible English bougie above mentioned is the the best for the purpose, commencing with one of good size; conical ivory bougies, having a flexible whalebone handle, may also be used, though, being quite hard, they are apt to inflict injuries unless used cautiously. It is sometimes necessary, on account of the tightness of the stricture, to begin with a catgut sound. The method of introducing these instrument has already been given. They should be used once daily, and often can be passed successfully by the patient himself. At intervals of three or four days trials of bougies of larger size should be made. I have seen truly remarkable results from this treatment when carried forward systematically in cases due to cicatricial contraction, the patients increasing in bodily weight and strength. In annular constrictions of a malignant type, however, it is productive of temporary benefit only.

The *diet* deserves most careful attention. When the stenosis is so pronounced as to prohibit sufficient food being swallowed, a Symonds tube should be passed into the stomach, and through it liquid food is introduced. Concentrated forms of nourishment, as raw eggs, meat-juice, and the various infants' foods, may be administered with milk.

When the passage of the bougie is no longer possible, relief may be secured in one of two ways: (1) rectal feeding; (2) gastrostomy, if the seat of the stricture be near the stomach, and esophagostomy if at the upper portion of the gullet. I have recently witnessed favorable results from gastrostomy in a case of simple stricture operated upon by Laplace. J. McCrae advises the wearing of a permanent tube, which may be fixed by cords through the mouth and fastened to the ear. It is important that the patient should thoroughly masticate the food before introducing it into the stomach. Before resorting to operative procedures, however, careful trial should be made of rectal feeding which will usually, however, prove inefficient.

VII. DISEASES OF THE STOMACH

METHODS OF DIAGNOSIS

The examination is begun by the patient's narration of his past and present troubles, family history, and any special peculiarities in health. It is all important to ascertain whether the patient has lost or gained in weight, and the condition of the bowels. The necessary knowledge is best acquired by asking a series of questions which, for sake of convenience, I have arranged under the following subheadings:

Pain, when present, may be located at the pit of the stomach (cardialgia) or in the gastric region (gastralgia). The pain may be severe, slight, or merely a discomfort and uneasiness. All important is it to know when and how (sudden or gradual) the pain appears, and what conditions excite or relieve such distress. Does the pain develop before meal-time and when the stomach is empty, and is appeased by the taking of food; or is it excited by taking food, and does it appear immediately after food, or one to four hours later? Is

the pain constant, and is it local or diffused? Does it radiate to the back or scapular regions?

Appetite.—The loss of appetite (anorexia), or a desire for unusual foods (parorexia), are frequently noted. When the appetite is increased, or the patient becomes hungry a short time after a meal, it is referred to as "bulimia."

One should determine further whether the appetite comes on when the patient begins to eat, or disappears at the sight of food, or after a few mouthfuls of food are taken. The taking of abnormally large amounts of food at meal-times only is termed "polyphagia." Where the appetite is not satiated, even after a full meal, we refer to such condition as "acoria."

Thirst.—In certain maladies the thirst is increased, while in a second class of conditions there is little or no desire for water or other liquids. Inquire whether thirst is allayed by taking water.

Taste.—Many gastro-intestinal conditions are accompanied with an unpleasant, sour, bitter, or sticky taste which may be experienced only on waking, or it may be more or less persistent.

Deglutition.—Does the patient swallow both solids and liquids naturally; also is he liable to cough while eating, and does such effort cause discomfort or pain?

Pyrosis.—This is a burning sensation in the epigastrium and sternal region. Note at what time, before or after food, it is experienced, its duration, and how it is influenced by various foods.

Regurgitation.—Note how long after taking food this annoying symptom is observed, and also whether the food tastes sour. Where the contents of the stomach are expectorated, it is referred to as regurgitation, but should it be again chewed and swallowed, it is termed "rumination."

Hiccup.—The time at which hiccup occurs, and whether or not it is accompanied with a burning sensation in the throat or by an unpleasant odor, are points of clinical value. Prolonged hiccup is of grave significance.

Nausea.—Is it occasional or frequent, and how influenced by food and by sleep?

Vomit.—Inquire carefully as to the frequency of the vomiting; how influenced by pain; when the stomach is empty, after soft food, solid food, or is it excited by certain odors? The quantity and consistency of the vomit, as well as whether it ever contains fresh blood (red), or blood that has lingered in the stomach for a time (coffee brown vomit)?

Such special symptoms as constipation, mental dulness, sleepy and giddy sensations, and a blurring of objects are not infrequently observed in gastric disorders.

EXAMINATION OF THE GASTRIC FUNCTIONS

Secretory Function.—While gastric secretion normally is continuous during the later stages of gastric digestion, the activity of the secretory function of the stomach diminishes, and to obtain accurate knowledge of any pathologic condition of the organ, examinations of the gastric contents must be made under conditions as nearly like the physiologic as possible. Reliable results cannot, therefore, be obtained from an examination of ordinary vomita, but the contents of the stomach must be procured at a definite period after a so-called test-meal (*vide infra*).

Numerous test-meals have been offered to the profession, but those that I have found most satisfactory are "the test-breakfast of Ewald and Boas" and "the test-dinner of Leube-Riegel." The former being simpler and easier of preparation than the latter, it is the oftenest used.

The *Ewald-Boas test-breakfast* consists of one or two rolls (50-70 gm.) and one cup of tea or water (300-400 c.c.). I constantly advise the use of

one roll and a glass of water. About an hour after this meal has been taken the contents of the stomach are to be withdrawn, and at such a time HCl should be the only acid present.

The *Leube-Riegel test-dinner* consists of a large plate of soup (300–400 c.c.), a large piece of beefsteak (150–200 gm.), and some potatoes (about 50 gm.) or a roll—practically, a large plate of soup, a piece of meat (preferably beefsteak), and a roll or bread. The examination is to be made about three and a half to four hours after the meal.

To obtain the contents of the stomach we should use Boas' bulb tube or similar apparatus. The tube is moistened with water and the end carried back to the pharynx; the patient is now asked to swallow, and the tube is gently pushed down the esophagus, these acts being repeated until the tube reaches the stomach. Care must be taken that the stomach contents are removed undiluted.

The method I have most frequently used is that of "expression," as follows: The patient is asked to take a deep inspiration, and then to contract his abdominal muscles as in the act of having a stool: in this way the contents are quickly expelled through the stomach-tube. A less disturbing method is by the use of the Einhorn tube or one of the many minor modifications of this tube. The tube is much smaller than the ordinary stomach-tube and the metallic end can be swallowed much as an ordinary capsule. When in the stomach the tube is so thin that it causes practically no discomfort in the mouth or pharynx of the patient and may be left in place for a long time, as in fractional studies. The gastric contents are withdrawn by aspiration with an ordinary glass syringe. Lunza warmly advocates examining the stomach contents every ten or fifteen minutes after a test-meal, leaving the stomach-tube in place for several hours, and using for the purpose a fine tube. Fishbaugh,¹ Best,² and others likewise advocate the fractional method of stomach examination. The stomach secretions should be first examined macroscopically to detect any residue from previous meals, such as meat and the like, and the quantity obtained should be 20 to 40 c.c. The gastric contents, which should be filtered if mucus be present, are to be promptly examined both chemically and microscopically.

Among qualitative tests the following are important:

To determine the *reaction*, ordinary litmus-paper is used; if acid, the blue turns red.

The presence of *free acids* is determined by Congo-red, a solution of which is turned blue by the addition of liquids containing free acids.

Free HCl.—Günzburg's Test.—Phloroglucin gr. xxx (2.0), vanillin gr. xv (1.0), absolute alcohol ʒj (30 c.c.). To 2 or 3 drops of this reagent add an equal number of the gastric filtrate in a porcelain dish, and slowly evaporate to dryness over a flame; if free HCl is present, a rose-red tint appears along the edges. Blowing at the edge will hasten the reaction. The great delicacy of this test is conclusively shown by its availability when HCl is present in the proportion of 1 to 20,000. There are no recognized interfering conditions.

Boas' Resorcin Test.—Resublimed resorcin 5 parts, white sugar 3 parts, and diluted alcohol 100 parts. The method of procedure is the same as in Günzburg's test, and a purple-red color appears. More caution is required in evaporating, but this method will also detect the presence of free HCl in the proportion of about 1 : 20,000.

Töpfer's Test.—To a few cubic centimeters of filtered (or unfiltered) stomach contents 1 to 4 drops of the reagent (dimethylamidoazobenzol in a

¹ *Jour. Amer. Med. Assoc.*, October 28, 1916, p. 1275.

² *Ibid.*, October 7, 1916, p. 1083.

0.5 per cent. alcoholic solution) are added; in the presence of free HCl a rose- or cherry-red color is produced. Combined HCl gives a negative result. The presence of acid salts, peptones, mucin, and starch (in the usual percentage) do not interfere with this reaction.

Lactic Acid.—Uffelmann's Test.—The reagent should always be freshly made, as follows: To 10 to 15 c.c. of a 2 per cent. aqueous solution of carbolic acid add 1 or 2 drops of neutral ferric chlorid, when an amethyst-blue color will appear. To 1 or 2 c.c. of the mixture add a few drops of the filtrate, and if lactic acid is present a canary-yellow color appears. Sources of error may be overcome by shaking 5 to 10 c.c. of the filtrate with double the quantity of ether, and, after allowing the ether to separate and pouring it off, adding more ether to the filtrate, again shaking, and repeating the washing. The ether is then evaporated almost to dryness in a water-bath. To the residue about 1 c.c. of water is added, and to this an equal quantity of the Uffelmann reagent from a pipet; and if a canary yellow now appears, positive proof of the presence of lactic acid is afforded. Bread contains lactic acid, and hence it is better to employ a thin gruel made by adding to a quart of water flavored with salt $\frac{1}{2}$ ounce of oatmeal-flour. Boas states that no lactic acid is present in the filtrate several hours after this test-meal, except in cases of carcinoma of the stomach. Lactic acid in the stomach contents also occurs with fermentation-stagnation from either obstruction or deficient motility.

A more reliable test for lactic acid than the foregoing is that of Boas, as follows: Digest the filtrate several times with ether to remove the fatty acids; add a few drops of phosphoric acid and boil. Transfer the mixture to a distillate flask; add H_2SO_4 and MgO_2 ; heat, and lactic acid will pass over. This can be conducted into a strongly alkaline solution of iodine and potassium iodide. The presence of lactic acid is then shown by the production of iodoform, which can be recognized by its odor and by the precipitate formed.

Fatty or Volatile Acids.—Heat to boiling a few cubic centimeters of the filtrate in a test-tube, over the mouth of which place a strip of moistened blue litmus paper; the presence of fatty acids will change the paper to red.

Acetic Acid.—In large quantities this acid is detected by its odor, and in smaller quantities its presence is determined by neutralizing with sodium carbonate the watery residue of the ethereal extract, and adding neutral ferric chlorid, when a blood-red color develops. Quantitative estimation of certain constituents is desirable.

Total Acidity.—To 10 c.c. of the filtrate add 1 or 2 drops of a 1 per cent. alcoholic solution of phenolphthalein, and decinormal solution of sodium hydrate is added slowly from a buret until the reddish color that appears fails to disappear on shaking. The number of cubic centimeters of the decinormal solution normally required ranges from 4 to 6; hence, if these be multiplied by 10, we have 40 to 60 as the percentage of acidity. Under pathologic conditions these numbers may be either higher or lower. This total represents both free and combined acids. If no organic acids be present, the above figures will represent the percentage of HCl. The latter is also reckoned thus: If it required 5 c.c. of the decinormal solution of sodium hydrate to be added to 10 c.c. of the filtrate to get the red color (alkalinity) with the phenolphthalein, we say the acidity is 50, and multiplied by $0.003,646 = 0.1823$ per cent. of hydrochloric acid. The normal range of percentage is from 0.1 to 0.22.

Estimation of Free HCl.—Mintz's method.—To 10 c.c. of the filtrate add a decinormal solution of sodium hydrate from a buret until no reaction is given with Günzburg's reagent. The number of cubic centimeters of the decinormal solution used, multiplied by 10 and then by $0.003,646$, gives the percentage of free hydrochloric acid.

Töpfer's Method.—To 10 c.c. of filtered gastric juice 1 or 2 drops of Töpfer's reagent are added, and then also a decinormal solution of soda, drop by drop, until the last trace of red has changed to yellow. To estimate the percentage of HCl, the number of cubic centimeters of soda solution required to neutralize the free HCl in 100 c.c. of stomach contents is multiplied by 0.00365. Example: To remove the red color 4 c.c. of soda solution are required; hence, $0.00365 \times 40 = 0.14$, the percentage of free HCl.

Estimation of Combined HCl.—The difference between the total acidity and the percentage of free hydrochloric acid represents approximately the percentage of combined hydrochloric acid.

Estimation of Lactic Acid.—If the volatile acids are present,* they should be removed by boiling. Take the total acidity of 10 c.c. of the filtrate; then to a second 10 c.c. add 25 to 30 c.c. of ether; shake well, allow the ether and filtrate to separate, remove the ether, and again add 25 to 30 c.c. of ether; shake, and repeat the process. Next obtain the acidity of the watery solution, and the difference between this and the total acidity, multiplied by 10×0.09 , will give approximately the amount of lactic acid.

In the *gastric digestion* of the *albuminoids* (proteolysis) the proteins are converted into peptone. The degree of hydration of albumins during the various steps of digestion are of little clinical value.

In a later stage of the process of albumin-digestion peptone is produced and its detection is easy. To a small quantity of the filtrate (the propeptone having been removed) add enough sodium or potassium hydrate to render the solution alkaline; then add a few drops of a 1 per cent. solution of cupric sulphate, and, if peptone be present, a rose-red color is presented.

The Test for Pepsin.—To a test-tube containing 15 c.c. of filtrate add a small piece of egg-albumen, and keep at a temperature of about 100° F. (37.7° C.); if present, the albumen disappears in from two to six hours. If hydrochloric acid is absent from the filtrate, add a few drops of the dilute acid. It should be pointed out that laboratory attempts to estimate the rate of albumin-digestion are unreliable.

Rennet Ferment.—To 10 c.c. of raw milk add 5 drops of the gastric filtrate, and keep it at a temperature of about 100° F. (37.7° C.); if rennet is present, coagulation into a single cake occurs in from a few minutes to an hour or more.

Rennet Zymogen (which is converted into *rennet ferment* in the presence of an acid).—To 5 c.c. of gastric filtrate add enough sodium carbonate or sodium hydrate to make it slightly alkaline; then add calcium chlorid (1 to 2 c.c. of a 2 per cent. solution); then mix with an equal quantity of milk, and, if zymogen is present, coagulation occurs as in the case of rennet ferment. Both rennet ferment and rennet zymogen may be assumed to be present when HCl has previously been found.

Starchy Derivatives.—To 10 c.c. of gastric filtrate add 1 or 2 drops of Lugol's solution; the presence of dextrin gives a blue reaction—erythro-dextrin purple, achroo-dextrin, grape-sugar, and maltose (intermediate substances)—showing a yellowish color. If there is a mixture of these starchy derivatives, as when the digestion of starches proceeds naturally, the first few drops of Lugol's solution may produce no color reaction, or it may be taken up by the dextrose or maltose, while the addition of more of Lugol's solution will give a purple (if erythro-dextrin be present) or a blue color, due to starch.

Indeed, if a minute quantity of the solution strikes a blue or purple tinge, conversion of starch into maltose has been abnormally tardy. I believe this is oftenest due to hyperacidity, though it may also more rarely

be due to a defective ptyalin supply.¹ For methods of detecting *occult blood*, see p. 777.

The Tests for the Motor Function.—More important than the secretory is the motor function of the stomach. There are several tests.

The oldest method is that of *Leube*. It consists in washing out the stomach from six to seven hours after a large meal, preferably consisting of beef soup (13 oz.), beefsteak ($6\frac{1}{2}$ oz.), bread ($1\frac{1}{2}$ oz.), and water ($6\frac{1}{2}$ oz.), or from two to two and a half hours after Ewald's test-breakfast. Normally, the stomach should be empty within these periods of time, so that if a residue remains it denotes a lack in the motor force. Boas recommends the giving of 400 c.c. of water to which 20 drops of chlorophyll (concentrated aqueous solution) have been added. Thirty minutes after the patient has drunk this the stomach-tube is passed. With normal motility about 50 to 60 c.c. are recovered. A simple test is to have the patient eat a few prunes with the meal taken the evening before the test-breakfast. Their recovery the next morning is indicative of hypomotility.

PHYSICAL OR EXTERNAL EXAMINATION

This implies the well-known physical signs—inspection, palpation, percussion, and auscultation, including succussion or splashing.

Inspection.—(a) *General*.—This may give an idea of the nature of the illness as well as its severity by noting whether the patient appears to belong to a neurotic group, the general health often being good, or whether the patient is emaciated, or has with the latter the cachexia of a malignant growth. In diseases of the stomach attention should be directed to the mouth, and especially to the teeth; these may be of causal importance in gastric ailments, and frequently prevent their cure.

(b) *Local Inspection*.—In patients with thin and relaxed abdominal walls the contour of the stomach can be plainly noted; especially is this the case in very large, dilated stomachs or in those that have been displaced. The examiner is greatly aided by inflating the stomach with air or gas. The former is to be preferred for the reason that the supply is easily regulated; he is enabled to watch the different steps of the distention, and after the examination is completed the air is allowed to escape through the tube. For this purpose an ordinary stomach-tube is most convenient, and its passage is to be effected in the same way as in removing the gastric contents. A double bulb-attachment is connected with the external end of the tube, by means of which air is readily forced into the stomach (*Runeberg's method*).

Frerichs' method is sometimes used. It consists in administering 3j (4.0) of tartaric acid, dissolved in half a glassful of water, and immediately afterward 3j (4.0) of sodium bicarbonate, dissolved in the same amount of water. Effervescence now occurs, with a progressive visible distention of the organ. There are many objections to this method.

The inflated stomach presents a circumscribed protuberance, usually in the epigastric and also in the umbilical region if the organ is dislocated or dilated. The air may find its way into the intestine, producing a visible change in the contour of the abdomen. Tumors and other abdominal enlargements may also be recognized, and an idea obtained as to which organ is involved, after making due allowances for displacement, as in gastroptosis and pyloric carcinoma. Exaggerated peristaltic waves may also be noticeable in the upper portion of the abdomen, usually when associated with the stomach,

¹ The tests for the estimation of the combined acids, of some of the fatty acids, and of many of the products of proteolysis are complicated and unnecessary in an ordinary clinical examination.

and in the lower portion if it is in the small intestine. Peristalsis is increased from various causes—inflation of the stomach, external tapping, neuroses, pyloric obstruction, and the like.

The value of the gastroscope in inspecting the interior of the stomach is, I think, questionable. Gastrodiaphany (illumination of the stomach) is sometimes useful in showing the fundus extending to a lower level (at the navel) than is indicated by percussion, and in indicating the presence of tumors in the anterior wall of this organ.

Palpation.—This elicits at times more trustworthy information than inspection. The patient should be in the recumbent position, the lower limbs partially flexed on the abdomen, and the head low. The examiner should stand at the right side of the patient and use the right hand, which should be warm. With the palmar surface down gentle pressure should be made with the fingers and the ulnar side of the hand. If the abdominal wall is tense, it is best to distract the attention of the patient from the examination by talking to him. In this manner we can corroborate inspection as to the size, shape, and position of the stomach, and can detect morbid growths as well as determine their consistency and movability.

Deep palpation, by increasing pressure with a slightly rotary movement, elicits the degree of sensitiveness, tenderness, or pain, whether circumscribed as in ulcer or diffuse as in generalized inflammatory states (enterocolitis, peritonitis). In deep-seated tumors palpation should also be made in the knee-elbow position, and if movable they may drop to the abdominal wall. Gurgling and succussion sounds of some diagnostic value may be elicited. In some instances relief from pain may be noted on pressure with the broad hand in neuroses. Variations in the degree of tension and of resistance are found and prove helpful.

Percussion.—The patient is placed in the recumbent position; the examiner uses his fingers and endeavors to discriminate the slightest differences in the note, and percusses lightly. If the stomach is empty or partially filled with gas, it gives a lower tympanitic sound than the colon. To ascertain the size and position of the stomach by percussion the process should begin at the symphysis pubis and follow the median line upward. The upper border of the stomach is at the ensiform cartilage, the lower about two fingerbreadths (3 cm.) above the umbilicus. If the upper margin is some distance below the ensiform, displacement of the organ is indicated; this depression may be occasioned by various diseases of the thorax. The stomach may be elevated by great distention of the gut or peritoneal sac.

It is well to trace the limits of resonance of the stomach and of any areas of dulness met with, so that their size and position may be graphically represented. The differences in the percussion-note over the stomach and colon may be greatly exaggerated by inflating the former. Runeberg's method is to be preferred. By employing light percussion the limits of the stomach can now be easily and accurately defined, unless the transverse colon be at the same time greatly distended with gas. In such instances Dehio's modification of Piorry's method is to be resorted to. It consists in giving about 1 liter (1 quart) of water in fractional doses while the patient is standing; one-quarter of the liter is swallowed and percussion practised, when a dull note will be obtained over the most dependent portion of the stomach. A second quantity of equal amount is given and a re-examination made, and so on, the object being to ascertain to what point the lower border sinks on the addition of more fluid. Boas holds that this method tests effectively the tone of the stomach, and that a *marked* descent of the lower border after each addition of water is indubitable evidence that there exists weakness or atony of its walls. If a

neoplasm originates posterior to the stomach or colon, inflation of the latter may cause the previous circumscribed dulness to disappear.

By striking the abdomen in the epigastric region splashing-sounds may be produced. This sign is of diagnostic value in dilatation of the stomach, though its absence does not contradict the presence of the dilatation. Again, if the splashing-sound is obtained in a fasting stomach, it may give a clue to some abnormal condition. The stomach may contain large quantities of fluid and no splashing-sound be obtained. Caution should be exercised lest the splashing-sound sometimes produced in the transverse colon be mistaken for that originating in the stomach; in the former the sound is usually associated with diarrhea, while in the latter constipation usually obtains. The outlines of the stomach can be most satisfactorily determined by auscultatory percussion.

Auscultation.—Various sounds are heard, none of which are pathognomonic of any diseased condition.

Succussion-sounds are produced by shaking the patient, and, if the stomach is dilated and contains fluid, a splashing sound may be audible some distance from the patient, and when heard after digestion has been completed they indicate some abnormal condition. Heard below the umbilical line, they usually indicate dilatation. In motor insufficiency (atony) of the stomach-walls splashing-sounds are audible after swallowing a few ounces of water. Partial obstruction of the cardiac orifice causes a delay of the “deglutition murmur” (a hissing sound followed in six or seven seconds by either gurgling, sprinkling, or splashing), as heard over the esophagus with the stethoscope while the patient is swallowing a liquid, “while in complete or almost complete closure of the cardia, this murmur is absent” (Ewald). The stomach may be roughly outlined by noting the change in sound that occurs when the stethoscope is placed over the stomach, as air is pumped in through the stomach-tube by a small bulb. The stethoscope is placed below the presumable lower border of the organ and is then moved about one inch toward the stomach after each squeeze of the bulb. As soon as the stomach is reached the sound of the air entering the viscus becomes clear and almost metallic as contrasted with the former less distinct dull tone heard over the abdomen elsewhere. By moving the stethoscope radially towards the stomach from all directions the various borders can be outlined with a fair degree of precision.

Roentgen-ray Examination.—By means of plates or the fluoroscope, much diagnostic information may be gained. It is to this method of examination that so much has been added to our knowledge of the physiology of the stomach and with a clear conception of the physiology has come greater ability to appreciate functional and organic changes. The roentgen ray is able to show the movements, size, shape, and position of the stomach. Variation in these factors may be caused by pathologic changes in the stomach, so that the diagnosis of ptosis, of atony, of ulcer, of cancer, or stenosis, may be made by this method, when the older methods fail. Functional disturbances may also be recognized by the study of the passage of the bismuth meal through the stomach. The motor functioning power is readily learned; from this certain secretory disturbances may be inferred.

MALPOSITION OF THE STOMACH

The stomach may occupy a truly vertical position in consequence of the persistence of the normal infantile condition or of improper clothing—*e. g.*,

long-continued pressure from corsets. Unless an angular condition of the duodenum, causing obstruction to the outflow of the gastric contents, followed by dilatation of the stomach, be engendered, the malposition is of little or no clinical significance. *Gastroptosis* is a downward displacement of the stomach (see *Gastro-enteroptosis*, p. 779).

DILATATION OF THE STOMACH

(*Gastrectasis; Gastric Atony*)

The condition is to be subdivided, clinically, into acute and chronic forms. The normal capacity of the stomach varies within rather wide limits, though the maximum normal capacity, according to Ewald, does not exceed 1600 c.c. (1.5 quarts); enlargements above this capacity may then be said to fall under the heading of dilatation.

Etiology and Pathology.—The chief factor in the production of chronic dilatation is **pyloric stenosis**. This is usually due (*a*) to carcinoma, cicatrix of an ulcer, fibroid overgrowth and spasm of the pylorus, or the contraction consequent on the action of corrosive poisons; (*b*) to the external compression arising from carcinoma of the liver, pancreas, or gall-bladder, the omental lymph-glands, and a displaced right kidney, or from large gall-stones; (*c*) to perigastric and duodenal adhesions—*e. g.*, with the gall-bladder, and congenital pyloric stenosis.

In all such instances increased force is necessary to propel the food from the stomach into the duodenum, thus leading gradually to a hypertrophy of the muscular fibers, particularly in the immediate vicinity of the pylorus. So long as this hypertrophied state of the muscular layer compensates for the obstructive lesion, pathologic dilatation cannot occur. Just as soon, however, as the muscles prove to be inadequate on account of secondary degenerative changes, accumulation of the food in the stomach ensues. This tendency for the contents of the stomach to accumulate is very much augmented by the increasing weakness of the muscle on the one hand and the progressing degree of stenosis on the other. Chronic gastric catarrh ensues in consequence of the mechanical effect of the undigested food. The degree of dilatation is enhanced by the generation of excessive quantities of gases under these abnormal conditions, as well as by the great weight of the accumulated gastric contents. When produced in this manner the stomach attains enormous dimensions. Dilatation is usually general, though there may be mere diverticula.

Dilatation may also occur *independently of pyloric stenosis*, although less commonly, and the condition is not so pronounced. In this variety there is atony of the muscular coats, due to various and dissimilar causes: (*a*) repeated overstrain of the muscular layer, due to overfilling of the organ with food and drink, met with in diabetics and in those who habitually drink large quantities of beer; (*b*) chronic gastric catarrh and sclerosis, due to old ulcers, frequently weaken the muscle; (*c*) fatty and other forms of degeneration or nutritional disturbances associated with certain constitutional diseases (particularly carcinoma, anemia, and tuberculosis); (*d*) congenital weakness of the muscular coat (myasthenia); (*e*) impaired innervation, leading to imperfect peristalsis and consequent dilatation; (*f*) omental hernias (Bamberger) that drag down the stomach; (*g*) perigastric and periduodenal adhesions without narrowing of the gut or pylorus (F. Billings); (*h*) *gastroptosis*.

Acute dilatation develops usually as the result of—(*a*) specific fevers, notably pneumonia; (*b*) operation, especially laparotomies; (*c*) the drinking of large

quantities of effervescing liquids; (d) shock; (e) dietetic errors; (f) trauma. The pathogenesis of the condition is in dispute. Three main theories have been advanced as a cause for the condition: (1) that it is due to an acute hypersecretion of gastric juice; (2) that it is the result of acute loss of tone in the gastric musculature; (3) that it develops as a result of obstruction of the duodenum by the mesentery of the small intestine where the duodenum passes under it.

Clinical History.—Since the diseases causing dilatation are numerous and diverse, the clinical history presents great variations. The symptoms of atony are sometimes overshadowed by those of the causal affections. The early stages when there is simply a certain degree of atony without much dilatation, are usually associated with varying indefinite gastric complaints. As the atony of the muscle wall progresses, dilatation occurs and with it a train of marked symptoms. Among these symptoms, *increased hunger and thirst* are frequently observed, partly due, most probably, to inanition. The thirst is also due, according to von Weinig, to the fact that the stomach does not readily absorb water, and the pyloric obstruction prevents the passage of water into the intestines. *Vomiting* occurs at intervals of several days, the matter ejected amounting to from 1 to 3 gallons (4–12 liters). Occasionally the vomiting occurs more or less regularly some hours after feeding. The clinical characters of the *vomit* are strikingly peculiar. The ejecta often contain remnants of previous meals, are, as a rule, excessively acid, emitting a sour odor, and on microscopic examination they show bacteria, sarcinae, and torulae in great numbers. The vomitus undergoes fermentative changes very rapidly, is ill-smelling, the odors being mainly due to sulphuretted and phosphuretted hydrogen. It consists of acetic, butyric, and lactic acids and partially decomposed food (HCl being usually absent), and on standing separates into three layers—an upper layer of brownish froth, a middle one of grayish-brown fluid, and a lower one composed of remnants of food. The acid contents of the stomach are not infrequently regurgitated, causing *pyrosis*. Eructations of foul gases are also common. A dragging pain is often present in the upper abdomen, most intense after eating.

Certain *general symptoms* almost invariably ensue. Progressive emaciation naturally follows, sometimes becoming extreme. A characteristic symptom is *muscular cramp* affecting the calves of the legs and sometimes spreading to the flexors of the arms and the abdominal muscles. Owing to the fact that but a small amount of liquid reaches the intestines, and also to the impaired absorption of the stomach, there are *constipation* and *scanty urine*, usually alkaline in reaction. The nervous phenomena of gastritis are in evidence and insomnia is often pronounced. *Loss of consciousness* has been met with. *Tetany* has also been observed. A striking instance is reported by J. T. Whitcomb, in which nearly all the muscles of the body appeared to be in a tetanic condition. Cardiac palpitation and arrhythmia are often present and are induced principally by the effects of the dilatation. Nocturnal dyspnea (asthma?) may develop.

Physical Signs.—*Inspection* may reveal a rounded prominence just above the umbilicus, patient in the supine posture, and just below the umbilicus when standing. In the epigastric region there is sometimes a noticeable depression. The outline of the stomach may be made distinct by the patient taking an effervescing draft, and may sometimes be readily seen. The outline of the greater curvature is at times visible, “passing obliquely from the tip of the tenth rib on the left side toward the pubes, and then curving upward to the right costal margin.” Sometimes peristalsis is visible through the abdominal walls, and rarely the peristaltic waves are seen passing from right to left. These movements may be excited mechanically by various

manipulations. *Palpation*.—The increased resistance of the walls of the stomach and their peculiar elasticity aid us in mapping out the contour of the stomach with more precision by palpation than by inspection alone. The movements of the organ can be plainly felt. A sign of considerable value is the loud splashing sound obtained by tapping the region of the stomach with the finger-tips of both hands alternately, or by shaking the body while the hand is placed over the epigastrium, though this should be distinguished from a similar sound produced in the colon. The patient may produce and maintain similar splashing sounds by voluntary efforts. *Percussion* furnishes subsidiary evidence as compared with palpation. The examiner should first percuss the empty, and then the filled stomach, if he would obtain reliable aid from this sign. When empty, an increased area of tympanitic resonance will be obtained, extending from above downward to a point several inches below the umbilicus. If now water amounting to 1 quart (1 liter) be introduced into the organ, and, in consequence, a line of dulness at or below the navel be noted where tympanitic resonance had been found, we have good evidence of the existence of dilatation. The posture of the patient should next be changed, when it will be found that the line of dulness has also altered. The stomach may be inflated by gas or air (*vide* Physical Examination) and its limits mapped out by *auscultatory percussion*. *Auscultation* reveals little that is of diagnostic value. The transmitted sounds heard over the stomach have a metallic ring. I have confirmed the observation by Franck and others, who claimed to have heard peculiar gurgling sounds produced by the heart's action and systolic in rhythm. Fluids swallowed by the patient may be heard dropping into the dilated stomach, and succussion sounds may be elicited by shaking his body. *Measurements* made by introducing a probang into the stomach until it reaches the greater curvature are valuable only when the degree of dilatation is considerable. In health the instrument passes about 60 cm. (24 inches), reaching a point more or less nearly on a level with the umbilicus, while in extreme dilatation it may be introduced 70 cm. (28 inches). The fluoroscopic examination of an atonic stomach shows, first, the bismuth dropping immediately to the bottom of the stomach, where it collects as more of the substance is swallowed until the normal cylindric form of the stomach becomes pear-shaped. In well-marked dilatation the roentgen examination shows a greatly enlarged, broadened stomach, the bottom of which is filled with the opaque substance which is expelled by insufficient and weak peristaltic waves, if they are present at all.

The **diagnosis** embraces, first and foremost, the recognition of the special causes. The unmistakable clinical manifestations are the characters of the vomitus and the peculiar manner of recurrence of the vomiting. The foregoing points, together with the physical signs, are adequate for a positive diagnosis.

Differential Diagnosis.—The condition is apt to be confounded with *ascites* or *overdistention* of the bowel, and in the female with *ovarian cyst*. In *dilatation of the intestines* the gastric symptoms of dilatation of the stomach are wanting; moreover, the physical signs are dissimilar. The splashing sounds on manipulation, the line of dulness below the umbilicus after filling the stomach, and other signs of gastric dilatation are absent in overdistention of the intestines. In addition, we may try the salol test, though this is now considered of little value (*vide* Chemical Examination). From dilatation of the stomach we may discriminate *ascites* by the history and by the characteristic gastric symptoms belonging to the former affection. In dilatation the abdomen is asymmetric, the projecting prominence being in the vicinity of or just below the umbilicus. In *ascites* the lower portion of the belly is chiefly distended, and

on assuming the recumbent posture the abdominal area becomes broadened and flattened. On palpation fluctuation may be elicited in the hypogastric and iliac regions. *Megalogastria*, or simple "big stomach," is distinguished by its absence of symptoms, and the fact that the food is passed into the intestines as quickly as in health. *Gastroptosis* may be distinguished by absence of decided motor insufficiency and by finding, on inflation, the lesser curvature lowered.

Acute Gastric Dilatation.—Acute dilatation of the stomach has a sudden onset. The *pulse* is small and rapid, but the temperature is subnormal. "The absence of a rise of temperature allows peritonitis to be excluded" (Neck). Cyanosis is a common symptom, and pain often a prominent one. The signs of shock are often the only symptoms present. Vomiting of large quantities of a clear watery fluid may occur, usually with relief of the symptoms. Examination will usually show marked tympanitic distention of the whole upper abdomen. If the stomach-tube is inserted large quantities of a watery, low acid (absent free acid) fluid may be expressed. The patient frequently passes into a condition of collapse that may prove speedily fatal. Acute dilatation may arise in the course of chronic gastrectasis. Some cases represent a mere episode in the course of the chronic disease (Veeder, Todd).

The **prognosis** in the *acute form* is uncertain, though the majority of cases recover; the condition may possibly merge into the chronic form.

Chronic dilatation offers a bad prognosis, most instances being utterly incurable. Obviously, it depends greatly upon the causal conditions. A resort to surgical interference sometimes gives promise of a more favorable subsequent course in cases of cicatricial stenosis. Cases of dilatation that are not secondary to pyloric obstruction, however, give a more favorable prognosis on the whole.

Treatment.—One of the chief aims of the physician should be to lessen the labor of the muscular coat and to prevent the continual necessity of passing the usual contents of the stomach into the intestines. This is to be accomplished by careful attention to the character and amount of food taken and by frequent cleansing of the stomach. It is necessary to thoroughly empty the organ by lavage, repeated daily. Perhaps the best way in which to thoroughly empty the stomach is by the use of the stomach-tube, as will be detailed under Chronic Gastritis. Recently this has been replaced by the siphon apparatus as a simpler and more convenient mechanism than the former, and one not so likely to be attended with harmful effects, though perhaps less efficacious. The long course of these conditions renders it desirable that the patient should, whenever possible, be taught to wash out his own stomach. On account of the fermentative and putrefactive changes going on in the ingesta it is necessary to use weak antiseptic solutions for this purpose, suitable ones being a 3 per cent. solution of boracic acid or a 1 per cent. solution of salicylic acid. Subsequently warm water alone may be employed. Lying on the right side for an hour after meals, so that the opening in the pylorus is on a lower level with the rest of the stomach, is worthy of trial. The *diet* should be composed chiefly of fluids, given in small quantities and at stated intervals. If the pyloric obstruction be not too far advanced, tender meats, eggs, and other easily digested albuminous articles of food may be allowed in moderate quantities. Since gastric digestion and absorption are very often markedly impaired, it is well to include those substances that are digested and assimilated after leaving the stomach, though they must be given in a fluid state. In no other manner can we bring such marked relief from gastric symptoms as by a suitable dietary, and in no other manner can the nutrition of the patient be so markedly improved. The weakened condition of the

muscle walls is due to overstrain and to degenerative processes; hence after having minimized the labor thrown upon it, we should attempt to overcome its parietic state by the employment of such agents as strychnin and electricity. Stockton, Reed, and others have obtained good results from direct electrization of the stomach by the use of special electrodes; it improves motility and lessens the size of the organ. Exercises to develop the muscles, abdominal massage, and suitable bandages are also useful. For the associated catarrhal state the remedies recommended under Chronic Gastric Catarrh may be employed.

The deficiency of intestinal fluid is to be met by rectal injections of a weak solution (gr. v to 3j—0.3–30.0) of sodium chlorid, not less than one pint of this solution being injected twice daily. In addition, nutrient enemata should be employed when, despite proper regulation of the dietary, loss of flesh and strength continue. For the anemia and debility tonics are indicated, particularly iron. Finally, surgical intervention often becomes necessary, and should not be too long delayed.

For *acute dilatation*, lavage of the stomach every hour or two if necessary, followed by complete rest and stimulation, with strychnin, pituitary preparations, eserin salicylate (dose, gr. $\frac{1}{30}$), and especially saline infusion, are the chief items of treatment. Place the patient upon the stomach with slight inclination to the right side so as to mechanically compress the dilated stomach and possibly unkink the duodenum (Morris).

INFLAMMATORY DISEASES OF THE STOMACH

ACUTE CATARRHAL GASTRITIS

(*Acute Gastric Catarrh*)

Definition.—An acute catarrhal inflammation of the mucous membrane of the stomach, attended with more or less severe local and constitutional symptoms.

Pathology.—The postmortem evidences of an acute inflammation of the gastric mucosa are distinctive only of the graver, fatal forms. Observations upon cases of gastric fistula, however, have shown that in milder grades the morbid appearances are similar to those characteristics of acute catarrhal inflammations of the mucous membranes normally exposed to view. Thus, at first there are small irregular patches of redness, dryness, and ecchymosis. Later, serum effused from the congested vessels, and mixed with an increased quantity of mucus, escaped leukocytes, and desquamated epithelium, is present. Hemorrhagic erosions may be seen; the mucous membrane is now thickly swollen, softened, and covered with a tenacious mucopus. Infiltration and swelling of the solitary lymph-follicles are frequent; these sometimes form minute abscesses that rupture and result in follicular ulcers. The gastric tubules may be filled with a granular debris of epithelial cells. The above-described changes are more pronounced near the pylorus.

Etiology.—The *predisposing causes* of acute gastric catarrh embrace those various impairments of the system in which the normal functional activity of the stomach is altered or diminished. These are seen as the result of (a) improper hygienic surroundings; (b) malnutrition; (c) the various anemias; (d) in gouty and rheumatic subjects; (e) in the tuberculous, cancerous, and malarial dyscrasias; (f) associated with chronic passive hyperemia of the stomach due to emphysema of the lungs, cirrhosis of the liver, and renal and cardiac

diseases; (g) in sickly and delicate children, in convalescents from acute diseases; and in enervated chronic invalids. (h) Persons having chronic gastric catarrh are predisposed to superadded attacks of the acute disorder.

The *excitants* are mainly (1) dietetic. These include the ingestion of much indigestible food; food or drink that is too hot or too cold (*thermal*); sour and highly seasoned articles; the too free use of condiments; and especially the eating of decomposed canned goods and tainted meats. In cases due to the latter the fermentative and putrefactive agents (acetic, lactic, and butyric acids, and the ptomains) are the immediate causes of the catarrhal inflammation and tend to produce the constitutional disturbances, sometimes typhoid or septic in nature, that give rise to the so-called "gastric fever." The term *crapulous gastritis* has been applied to those cases due to gluttonous meals. (2) Toxic gastritis. Excessive indulgence in spirituous liquors is a common cause. Certain drugs, as the salicylates, iodids, bromids, arsenic, and mercury. (For the intense form of toxic gastritis, *vide* p. 740.) (3) Acute infectious fevers, as measles, typhus fever, and scarlatina, provoke the disorder (*infectious gastritis*), as do also malarial fevers, especially when of the pernicious variety. (4) The influence of cold as an excitant of this disease has very probably been overestimated. (5) The *mycotic* origin of the condition cannot any longer be doubted. Among the micro-organisms incriminated are the anthrax bacillus, the favus fungus, the *Oidium albicans*, and the yeast fungus. (6) Animal parasites (*e. g.*, ascarides, tænia, oxyurides, etc.) may cause gastritis.

Clinical History.—The symptoms of the ordinary or milder variety of acute gastric catarrh are embraced in the description of the "subacute gastritis" or "acute dyspepsia" of some writers. Soon after eating there are uneasiness, fulness, pressure, distress, and, perhaps, a dull pain referred to the epigastrium. Thirst is common, also nausea, eructations of gas or liquid, and, less often, vomiting. The *vomit* consists of undigested food, considerable mucus, and fluid constituents that are sometimes bile-stained. The percentage of HCl in the stomach-contents is variable, although either absent or greatly diminished as a rule. The *tongue* is coated. The general condition of the patient remains unimpaired, and the average duration is less than twenty-four hours. In *severer cases* the symptoms before stated are intensified, and particularly the nausea and vomiting. Physical exploration discloses slight prominence of the epigastric area, with more or less tenderness on palpation. The *tongue* is dry and heavily coated, the breath unpleasant as a rule, the patient complaining of a flat or bitter taste in the mouth. *Constitutional symptoms* appear early, and the onset is often marked by rigor and a febrile reaction, the temperature rising to 102° or even 103° F. (38.8°–39.4° C.). *Herpes* may appear on the lips and skin—a fact that points to the infectious nature of this complaint. The *pulse* is usually accelerated, and there are indisposition to exertion, headache, dulness, and other nervous symptoms. An erythematous cutaneous eruption is often present, particularly in febrile cases in children. The marked general disturbance is due to the toxic effects of the products of fermentation and decomposition.

Complications.—Constipation is a comparatively frequent complication, and diarrhea a comparatively infrequent one. Either coincidentally or by direct extension the duodenum is similarly affected, and in some instances jaundice becomes an accompanying feature. The duration of this variety of the disease rarely exceeds four or five days.

The **diagnosis** of the lighter, afebrile forms of the disorder is not attended with the slightest difficulty. A logical diagnosis in cases in which well-marked local and general symptoms appear is not easy. The definite etiology, the vomiting (affording temporary relief), the pain or tenderness, the sudden rise

of temperature, and the equally sudden fall at the end of a few days, however, are almost unequivocal.

Differential Diagnosis.—The absence of prodromata, of rose spots, of the peculiar temperature-range, and of enlargement of the spleen serve to distinguish this complaint from *typhoid fever*. The instances of indeterminate etiology may present a clinical picture not to be differentiated from certain infectious diseases. Here a careful analysis of the local symptoms and signs will usually lead to a correct conclusion, despite the apparently complete identity of the general disturbances. Close observation of the behavior of any obscure case for two or three days will usually enable the physician to arrive at a correct diagnosis. In children headache and vomiting are symptoms often so well marked as to create a striking resemblance to *tuberculous meningitis* but the latter can be discriminated by the history and longer duration. In children acute gastritis with an erythematous rash is often mistaken for *scarlet fever*. The final elimination of the latter disease is usually easy, however, in consequence of the absence of angina, of the typical tongue, the hard and very rapid pulse, and the peculiar desquamation affecting the hair and the nails.

Prognosis.—Quite generally the prognosis is good. When, as sometimes happens, however, the disease is purely secondary, the prognosis must depend largely upon the primary affection. Many persons suffer from repeated attacks of gastric catarrh, each increasing the liability to subsequent attacks.

Treatment.—Our chief aim should be to remove the cause and then to give the stomach complete rest. Hence, whenever the disease is distinctly traceable to errors of diet, emetics of the blandest sort should be employed; large drafts of warm water usually suffice, but lavage is to be preferred in some cases. This should be followed by a purge made up as follows:

R. Hydrarg. chlor. mitis,	gr. j (0.065);
Sodii bicarbonatis,	gr. xx (1.300);
Sacchari lactis,	gr. xv (1.000).
M. et ft. cht. No. vj.	
Sig. One every hour as directed.	

The stomach must now have absolute rest for about twenty-four hours, when pancreatized milk or milk boiled with lime-water may be given at stated intervals. If nausea and continued vomiting prohibit the use of milk by the mouth, I resort to rectal alimentation early, and particularly in children. Certain symptoms, as *nausea*, *pain*, and *restlessness*, demand as early relief as possible, and can be most successfully met by the use of morphin in small doses hypodermically at intervals of twelve hours. When constant nausea is the symptom chiefly complained of, I have found creasote combined with bismuth or cocain in small doses to be highly serviceable. Convalescence is usually uninterrupted, and is soon complete. When protracted it is often on account of the too early return to solid articles of diet or the too early use of bitter tonics. The mineral acids should first be administered, well diluted, after the local symptoms have in a great measure subsided, and to these the bitter vegetable tonics are later to be gradually added. Locally, I employ sinapisms at the beginning of severe types of the affection, and follow these with warm linseed poultices lightly applied to the entire epigastric and hypochondriac regions.

TOXIC GASTRITIS

Pathology and Etiology.—This is an intense form of acute gastritis, produced by the ingestion of irritant and corrosive poisons, among the former

being such agents as phosphorus, antimony, and arsenic, and among the latter concentrated mineral acids and strong alkalies. When caused by the non-corrosive poisons, intense hyperemia and tumefaction, leading to desquamative changes in the glandular structure, ensue. When excited by corrosive substances necrosis of the mucous membrane may occur, leading even to an involvement of all the coats, and terminating in perforative peritonitis. Injurious retention substances, as in uremia, cholemia, and diabetes, may cause an autotoxic variety of gastritis. The lesions are either localized or general.

The **symptoms** vary somewhat with the nature of the special poison, though they are usually quite violent. *Incessant vomiting*, great pain in the epigastric region, and later, *diarrhea*, and excessive thirst, together with such symptoms as intense *burning pains* in the mouth and throat and dysphagia, are the most characteristic signs. The *vomit* contains mucus, sometimes blood, and, rarely, shreds of mucous membrane. The *physical examination* reveals a marked distention of the abdomen, which is also, as a rule, very painful on pressure over the epigastric region. The *general condition* of the patient soon becomes one of profound prostration; the skin surface is cold and clammy, and the pulse and respiration are hurried, terminating at times in fatal collapse within a few hours. Sometimes there is a febrile movement; the temperature may reach 104° F. (40° C.); the pulse ranges from 100 to 130; and if life be spared long enough toxic nephritis, with or without hematuria, develops. The nervous symptoms (convulsions, stupor, sometimes ending in coma) may be due in part to the renal lesions, though mainly to the diminished alkalinity of the blood. Symptoms of gastric ulcer or of esophageal stricture may be sequelæ.

The **diagnosis** rests upon the history of the ingestion of some poison, upon the character of the symptoms (referable not only to the stomach, but also to the mouth and pharynx), and upon the results of an inspection of the mouth, pharynx, and the vomitus. A chemical examination of the stomach-contents and urine may be necessary.

Prognosis.—This depends upon the nature of the poison and its dose. When free emesis occurs early the prognosis is thereby rendered more favorable, since both the local and constitutional effects are thereby mitigated. Among unfavorable symptoms may be mentioned signs of collapse or of peritonitis. Among sequelæ (due to scar-formation) are pyloric stenosis and hour-glass contractions.

Treatment.—To ascertain, in the first place, the special cause of the gastritis, and when this is found to administer the proper antidote to that poison, are measures of prime importance. The stomach should be cautiously washed out with warm water containing some demulcent substances and a small proportion of the appropriate antidote. Subsequently measures should be employed to combat the active local inflammation. Externally, leeches, followed by the ice-bag, have proved to be the best agents in my own hands; internally, opium, bismuth, and demulcents, with bits of ice, are most useful. Rectal alimentation should form the sole method of feeding so long as the signs of severe inflammation along the upper alimentary tract are present. The indications presented by the general conditions will vary with the general effects of the peculiar poison in each case.

DIPHThERITIC GASTRITIS

This form of gastritis is always a secondary condition, though it is not, as has often been stated, always caused by a direct extension of the diphtheritic process from the pharynx down through the esophagus to the stomach. It

arises more frequently in the course of some other acute infectious malady, as pneumonia, scarlet fever, or small-pox. Though it is regarded as a rare disease, the fact that it is unrecognizable during life renders it certain that the affection is sometimes overlooked. I have seen two instances associated with croupous inflammation of the intestines, both occurring in greatly debilitated children.

ACUTE SUPPURATIVE GASTRITIS

(*Phlegmonous Gastritis*)

Definition.—An acute suppurative inflammation of the submucosa.

Pathology and Etiology.—Phlegmonous gastritis is confessedly a rare, and almost invariably a secondary, disease. I have observed pathologic evidences of its presence, however, in two cases that came to autopsy, both patients having died of sepsis. It is excited by invasion with bacteria or fungi. The male sex is the more commonly affected. It may originate spontaneously or follow an injury; more commonly it is a symptom of a general septic process or a complication of an acute infectious malady. Two forms are described—namely, a *diffuse purulent infiltration* and a *circumscribed form* (*stomach abscess*). The morbid process begins in the submucous layer, and then spreads in various directions, soon involving all of the coats. The limited variety results in the formation of abscesses that may attain considerable size and rupture either into the peritoneal cavity or into the stomach.

Symptoms.—There may or may not be an initial rigor. Whether the attack is ushered in by a chill or not, the *temperature* rapidly rises to 103° or 104° F. (40° C.), and subsequently pursues an irregular course. The symptoms of the *typhoid state* supervene, and are usually associated with the symptoms of the primary affection. Hence the clinical picture is greatly diversified. For a variable period prior to the fatal issue the patient passes into coma. The *local symptoms* and *physical signs* are rarely diagnostic. There is a constantly increasing epigastric *pain*, which is not aggravated by movement; *emesis* also appears, the *vomit* often containing a notable quantity of pus-cells. Leukocytosis is generally found.

The **physical signs** reveal but little in most instances, and vary with the form of the complaint. Inspection shows in the *diffuse* form a considerably distended abdomen. On pressure the stomach is found to be quite tender. In the *limited variety* the gastric abscess sometimes gives rise to the physical signs of a tumor, and a localized prominence may be seen over the seat of the abscess; the tenderness to the pressing finger may be confined to the same area. Palpation has served to elicit fluctuation and to define the limits of the tumor, the latter sometimes attaining the size of a cocoanut; on percussion either dullness or a muffled tympanic resonance is elicited, varying according to the size of the mass.

Diagnosis.—The diffuse variety cannot, as a rule, be positively distinguished from certain other gastric affections. The detection of pus-cells is, however, of the utmost diagnostic value. Gastric abscess, on the other hand, is often recognizable, since the physician has not only the history to aid him, but also the physical signs, which may demonstrate the presence of a fluctuating tumor.

Course and Prognosis.—The majority of cases reach a fatal termination within one week, and those that do not terminate in death thus early pursue a subacute or even chronic course. They present such symptoms as local pain, chills, and fever, and death results, sooner or later, either from exhaustion or such complications as peritonitis and metastatic abscess with jaundice.

The **treatment** in the diffuse form is, at best, only palliative. In the circumscribed variety the aid of the surgeon should be invoked as soon as a probable diagnosis has been made.

CHRONIC CATARRHAL GASTRITIS

(*Chronic Catarrh of the Stomach; Chronic Catarrhal Dyspepsia*)

Definition.—A chronic catarrhal inflammation of the gastric mucous membrane, presenting various degrees of intensity and embracing the symptoms that are more or less characteristic of widely different clinical forms of gastric derangement.

Pathology.—The anatomic changes are most marked near the pylorus, where the mucous membrane often presents a distinctly wrinkled, mammillated appearance. The mucous membrane looks either red or gray (the latter hue being due to pigmentation), and is pretty generally covered by tenacious mucus, mingled with detached epithelium. Ewald describes the histologic changes thus: "The minute anatomy shows the picture of a parenchymatous and an interstitial inflammation. The gland-cells are in part eroded or show cloudy, granular swelling or atrophy. The distinction between the 'haupt' and 'beleg' cells cannot be recognized, and in many places, particularly in the pyloric region, the tubes have lost their regular form and show in many places an atypical branching like the fingers of a glove. Individual glands are cut off toward the fundus, but appear at the border of the submucosa as cysts, with a smooth membrane, partly filled with remnants of hyaline and refractile epithelium. An abundant small-celled infiltration presses apart the tubules, and is particularly marked toward the surface of the mucosa, and from the submucosa extensions of the connective tissue may be seen passing between the glands. The mucoid transformation of the cells of the tubules is a striking feature in the process and may extend to the very fundus of the glands." Hemorrhagic abrasions and superficial ulcers in the pyloric region may be found in cases due to cardiac disease or to portal engorgement. Long-standing cases also present sclerotic changes of the mucous membrane. Of these, two forms are distinguished. In the one variety the mucous membrane is smooth and atrophied; the glands are narrowed and shortened, while the gap thus formed is filled with connective tissue. There is a thinning of the stomach-wall, with enlargement of its cavity. The other form presents a hyperplasia of the mucosa, the glandular structure, and the submucous layer, sometimes resulting in enormous thickening of the stomach walls, with great diminution in the size of its cavity (*gastrophthisis*).

Etiology.—The causes of chronic gastritis act either as mechanical, chemical, thermic, or biologic irritants, and fall naturally into the following classes: (a) Errors of diet (referring more particularly to important articles of food), its variety, and preparation; excessive alimentation, the habit of eating at irregular intervals or with undue haste, and thus not allowing time for perfect mastication of the food. The too free use of ice-water, tea, and coffee during meals plays an important rôle in the causation of dyspepsia in America. (b) The immoderate use of alcohol, more particularly spirituous liquors, stands second in order of importance. Those persons who habitually indulge in alcoholic beverages to excess are prone to an irregular mode of life, which leads to digestive disturbances. Such patients are apt to suffer from the more active forms of the complaint, and, at intervals, from genuine acute gastritis. In the same category should be mentioned certain toxic irritants, as the overuse of tobacco and the prolonged use of tonics and purgatives. (c) Functional

derangements of the stomach sometimes merge into the disease under consideration. This is true of that form in which there is a deficiency in the gastric juice. Stockton holds that the majority of cases of chronic dyspepsia are of nervous origin. (d) Local mechanical influences (portal congestion) may offer resistance or obstruction to the outflow of venous blood from the stomach to the right heart. In this way chronic gastric catarrh is a secondary process in chronic affections of the liver, heart, and lungs. (e) Such constitutional conditions as gout, chronic rheumatism, chronic tuberculosis, Bright's disease, diabetes, anemia, chlorosis, chronic malaria, syphilis, and chronic forms of skin disease. Here gastric catarrh is due to obstruction of the hepatic and cardiopulmonary circulation. In gout, chronic Bright's disease, and syphilis, however, it is probably due largely to the action of chemico-vital irritants in the circulating medium. (f) Gastric carcinoma.

Clinical History.—The *local symptoms* vary greatly in severity, though never entirely absent, as in the case of purely functional disorders. Deficient secretion of the gastric juice is a potent factor in the production of the symptoms directly referable to the stomach. It is the function of hydrochloric acid, normally present in the gastric secretions, to destroy the ferment-producing spores; hence when, owing to lack of free HCl, the latter are not destroyed, deleterious products of fermentation are the result. The presence of an inordinate amount of mucus which is alkaline in reaction neutralizes in part the HCl; it may also more or less completely cover the ingesta, thus preventing the gastric secretions from reaching them and lengthening the period of digestion.

Among the *earlier symptoms* are anorexia (though at times the appetite is good or even keen); fulness and distress; burning sensations and dull pain in the epigastric region; eructations of gas, which may be either offensive or odorless, during and immediately after meals; regurgitation of fluid, either acid (heartburn), due to the presence of organic or hydrochloric acid. These symptoms are usually increased in intensity after meals. The *tongue* frequently appears broad and flabby, and almost constantly the edges and tip are somewhat reddened, while the papillæ are enlarged. Occasionally it is small, with enlarged and red papillæ, or it may look healthy. A bad or a persistently bitter taste and great thirst may be complained of. There may be a profuse secretion of saliva or the mouth may be dry. *Nausea* is common, and is most marked in the morning hours; it is frequent before or after meals, and often *vomiting* occurs either immediately after meals or a couple of hours later. The *vomit* will vary with the time of the occurrence of emesis. Usually it consists of food in the first stages of digestion, mixed with large quantities of mucus. In alcoholic catarrh morning vomiting occurs, and consists mostly of saliva and mucus. This class of sufferers may exhibit well-marked evidences of salivation. In Kelson's experience, aching throat is often associated with flatulent dyspepsia. The material expressed in chronic gastric catarrh is faintly acid in reaction, unless, as happens, the removal takes place several hours after eating, when it may be faintly alkaline or neutral. The acidity is not due to the presence of free HCl, but possibly in small measure to combined HCl, and partly and sometimes largely to acid salts (lactic, butyric) or resulting from the abnormal processes of fermentation. The absence of acid on the duodenal side of the pyloric sphincter relaxes it and permits food to pass out into the intestines with increased rapidity. This hypermotility does not depend upon excessive gastric peristalsis but upon the condition of the pylorus.

Microscopic examination sometimes reveals the presence of sarcinæ ventriculi, yeast fungi, and numerous bacteria. The relations of these low forms

of vegetable life to the pathologic processes going on in the stomach are not well understood. It is to be borne in mind that many of these bacteria are introduced with the food, and that certain of them contribute toward the production of gases, and of the organic acids of the stomach. Hydrochloric acid inhibits the development of bacteria.

A *chemical examination* of the contents of the stomach for purposes of diagnosis according to the methods laid down in the preliminary section (*vide* p. 727) should not be neglected. In simple chronic gastric catarrh the hydrochloric acid is found to be diminished, and lactic, butyric, and acetic acids are rarely present. In many cases of chronic catarrhal gastritis there is an abundance of mucus (*gastritis mucipara*—Boas); and in other cases there is present a normal amount of acid or even hyperacidity—the *gastritis acida* of Boas. In protracted forms free HCl is sometimes greatly diminished or entirely absent—*gastritis anacida*. According to Boas the difference between this and the atrophic form is but one of degree, all secretion being lost in the latter. In atrophic gastritis then there is little or no mucus in the gastric contents, and in established cases an absence of HCl and of the gastric ferments (*gastritis atrophicans*). Pilcher states that absence of HCl is often associated with the presence of occult blood in chronic gastritis, most commonly when the latter condition is secondary to disease of the gall-bladder, appendix or pancreas. Ewald has subdivided all cases into three varieties: (a) *Simple gastritis*, in which the fasting stomach contains only a small quantity of slimy fluid, while after the test-breakfast the HCl is diminished in quantity, and lactic acid and the fatty acids are usually present. (b) *Mucous gastritis*, in which class the acidity is always slight and the condition is distinguished from simple gastritis by the large amount of mucus present. (c) *Atrophy*. Here the fasting stomach is always empty, while after test-breakfast HCl, pepsin, and rennin are wholly wanting. Van Leersum¹ has described an exfoliating gastritis, in which scraps of mucosa are found in the stomach contents and wash water.

Physical Signs.—Sometimes there may be observed an undue distention of the stomach, the prominence being more marked toward the left. On making *firm pressure* over the epigastric region tenderness is often elicited. This is not present in the early stages, nor constantly later, since the degree of inflammatory action is subject to great oscillation. Diffuse tenderness in the absence of a new growth is of great diagnostic value. It is to be recollected, however, that resistance may be felt when the stomach is thickened in chronic interstitial gastritis. Dilatation of the organ may be indicated by splashing-sounds (*vide* Physical Signs, p. 735), but these are not suggestive of gastritis if detected at a time when the stomach should be empty.

On *percussion* we may note alterations in the size of the organ.

Among the general symptoms manifested the *nervous phenomena* are of first importance. The nervous derangements have been by many writers attributed solely to morbid sympathetic disturbances. We should, however, ascribe a share of the morbid influence to the absorption of toxic materials from the stomach and intestines. Headache is frequently complained of; it is generally frontal, though also occipital, and tends to appear before meals. The so-called sick headache more rarely occurs. Indisposition to mental or physical exertion, vertigo, depression of spirits, and well-marked hypochondriasis are common concomitants. Patients complain of wakefulness and disturbed dreams, though drowsy after meal-time. There is a sympathetic disturbance of the cardiac rhythm, and sometimes dyspnea, owing to the same cause. The urine is often highly colored, scanty, and occasionally it is of low specific gravity, rather copious in amount and pale in color.

¹ *Nederlandsch Tijdschrift voor Geneeskunde*, May 6, 1916.

Complications.—The intestines often become involved, and usually by direct extension. Implication of the duodenum may lead to jaundice and to obstinate constipation, though only moderate constipation is the rule in catarrh of the stomach. When the process extends to the large intestines diarrhea develops. Although diarrhea may be present at any time owing to the relaxed pylorus (from absence of free HCl) which permits (1) large quantities of poorly masticated food to pass into the intestine and irritate it mechanically and (2) excessive bacterial activity in the intestines from the bacteria, which under ordinary circumstances taken in with the food are destroyed by the free HCl of the stomach. The nutritive system is, in confirmed cases, seriously implicated in examples of combined intestinal and gastric catarrh, as shown by the anemia, emaciation, and general debility present. The gases generated in the stomach often find their way into the intestinal canal, giving rise to distention, and sometimes to colicky pain. Perhaps many reflex sympathetic disturbances are of intestinal origin. The gastric catarrh may extend upward to the oral cavity. Under such circumstances the tongue is large and heavily coated, with impressions of the teeth upon its edges. The abnormal condition of the secretions renders the breath foul and causes thirst. Certain skin eruptions, as eczema, lichen, and urticaria, are common. These disorders of the skin are probably due to a protein intoxication from the intestinal tract. I have frequently observed, however, that when present their improvement has been followed by an aggravation of the gastric symptoms, and *vice versa*. A sequel of the disease is dilatation of the stomach. The *course* of chronic gastric catarrh is long; the average duration being considerably more than one year. Its duration may be much abridged by early recognition and proper treatment. The symptoms at first remit, but later are persistent.

Diagnosis.—A positive diagnosis may be based on a clear etiology, the presence of persistent symptoms and signs of digestive disturbance, diminished (*usually*), normal, or even increased, amount of HCl (the atrophic form apart, *vide supra*), an abundance of mucus in the gastric contents, and deficient absorptive power with hypermotility. The finding of mucus in the wash-water of the fasting stomach is truly diagnostic (Riegel). The points of difference between the more serious affections of the stomach (carcinoma, ulcer, and dilatation) and chronic gastric catarrh will be detailed when the former diseases are considered. As I have said, Ewald makes three leading forms of the complaint, based on the results obtained from an analysis of the stomach-contents, but transitional types are constantly met with.

Prognosis.—Chronic catarrh of the stomach may be said not to manifest an innate lethal tendency. It, however, aggravates the symptoms of existing forms of acute and serious forms of chronic diseases, especially other organic affections of the stomach. The prognosis depends considerably upon the stage that has been reached when first met with, since the condition is amenable to treatment only when not too far advanced. The prognosis is rendered somewhat more grave by the presence of certain complications, particularly intestinal involvement. I have seen one case that proved fatal in consequence of stricture of the pylorus.

Treatment.—It must never be forgotten as far as possible to search for and remove the causal affections in every case. When associated with grave forms of cardiac, hepatic, or renal disease these must receive careful attention primarily.

The masticating apparatus must be looked after by the physician, who must also instruct his patient in the art of eating slowly, so that insalivation of the food is thoroughly effected. Too often the quantity of aliment consumed is beyond the need of the bodily functions, and the method of preparing

the same faulty. All food eaten should be fresh and pure. Such patients should eat oftener than in health, taking four or five meals in the twenty-four hours. The physician must with untiring diligence attend to every dietetic, sanitary, and therapeutic detail. The major portion of the treatment has relation to—

(1) *The Diet.*—In the matter of arranging the dietary in separate cases the general condition and peculiarities of the individual must be taken into account. The wise physician will be guided to some extent by the dictates of his patient's experience, and will not fail to avail himself of any information obtainable upon this head. The teachings of physiology direct that animal food should be allowed with a view to stimulating the secretion of HCl when found to be deficient in the gastric contents. We must, however, select the special articles of diet according to the severity and nature of the morbid process. In *severe cases* an exclusive milk diet for a period of two to four weeks often gives the best results. The daily amount requisite to meet the caloric needs of the individual is about 1500 c.c. Of this, 120 to 200 c.c. are to be taken *slowly* every two hours during the day. The beginning amount, however, must occasionally be smaller—to be gradually increased. A pinch of salt or from 15 to 30 c.c. of lime-water may be added to each feeding, or the milk may be diluted with Vichy. The milk should not be taken iced, but warmed or at the temperature of the room. Boiled milk is objectionable. The stools are to be watched for curds, and when the digestive capacity is exceeded the amount of the nutrient should be lessened and other articles cautiously added.

When *whole* milk cannot be digested on account of an actual loathing for it, skimmed or partly skimmed milk or buttermilk should be substituted. If the latter cannot be utilized in proper amount, animal broths, together with some of the artificial foods, may be added. As tolerance for a liberal amount of milk becomes established the appetite is no longer satisfied, and then I begin to add the light solids in a gradual manner; for example, white meat of chicken or game (except tame ducks and turkey), stale or twice-baked bread, milk or dry-toast or zwieback, soft-boiled eggs, oysters, fish, and, later, Hamburg steaks, stewed sweetbread, and the like. For dessert, junket or custards, sweetened with saccharin, are well borne as a rule. Subsequently, farinaceous articles, if thoroughly cooked (except oatmeal), and certain plain vegetables, may be allowed, but their effects must be minutely observed. The former are to be eschewed in cases in which acid-fermentation or flatulency is a prominent feature. Among the latter, rice, spinach, lettuce, and macaroni (stewed in milk) are to be selected. Peas and beans, if green and succulent, may be tried, but if overripe are to be discarded. The only form of fat permissible is good butter. Stewed fruits, graham bread, and soft, green vegetables are often well borne and tend to overcome constipation. Pig's- and calf's-foot jelly may be allowed.

In light cases and in those of moderate severity, particularly if the cause of the complaint is removable, the dietary need not be rigid at the start. Indeed, to minimize the saccharine articles and starches and to avoid the coarser vegetables, hot bread, pastries, and the like, is all that is required. In the case of confirmed dyspeptics the following articles are to be scrupulously avoided: very fat meats, fat fish-foods, condiments, certain fruits (strawberries, bananas), hot bread, saccharine articles of diet and farinacea, potatoes, and coarser vegetables. Fermentable foods, as milk, eggs, and rare meats, should be avoided in selected cases.

The best drink during mealtime is simple hot water, to which a little milk may be added, or a single coffee-cup of weak tea. Occasionally cocoa is allowable, but ordinary chocolate, coffee, and strong tea are harmful. Too

much liquid should not be taken during a meal, since it dilutes the gastric secretion to a deleterious extent, and cold drinks are to be interdicted during the same period. Alcohol, and particularly concentrated spirituous liquors, exert an irritating effect, and hence should be forbidden. In cases in which there is no gastric fermentation certain wines may be allowed (Oporto, Malaga, imported Hungarian Tokay).

(2) *Hygienic measures* are of signal value in this disease. Of these the most important are forms of fresh-air exercise, as bicycling, walking, boating, and horseback-riding. Open-air exercise may be supplemented by suitable indoor apparatus. Physical exercise must be carefully supervised, so as to avoid the deleterious effects of overexertion. I am convinced of the superior advantage of travel, including a sea-voage, and an appropriate change of air—for example, to the seaside or mountains—particularly for the large class of self-centered and low-spirited dyspeptic patients. A cold sponge-bath, followed by brisk friction of the skin, is to be advised. An abdominal bandage, made of woolen or silk material and constantly worn, tends to increase the patient's comfort.

(3) *Medicinal Treatment.*—Saline laxatives, as sodium phosphate, Rochelle salts or Carlsbad salts, taken fasting in hot water, are advantageous, since they serve to regulate the bowels, to deplete the engorged gastro-intestinal vessels, as well as to rinse the stomach. Hunyadi Janos or Carlsbad water may be substituted. Their efficacy is much enhanced when the alkaline carbonates are administered simultaneously. Patients may be advised to seek suitable watering-places, but the course should not be for too long a period. The use internally of antiseptics, combined with alteratives and mild astringents, is often beneficial. I can speak most positively in favor of the following pill:

R. Argenti nitratis,	gr. iv . (0.25);
Ext. hyoscyami,	gr. viij (0.5);
Bismuthi subnit.,	gr. xxxij (2.100).
M. et ft. cap. No. xvj.	
Sig. One a half hour before meals.	

The stomach should be prepared for the above capsule by washing with one or more pints of a 2 per cent. solution of borax in water. Hemmeter recommends silver nitrate, in the form of lavage (1 : 2000), or in the form of solution 0.3 to 120 of peppermint-water; of this one tablespoonful three times daily on an empty stomach.

In the *fermentative* form of chronic gastric catarrh the hyperacidity is, in reality, often dependent upon the lack of free HCl; hence this agent should be supplied. It is best administered immediately after meals, the dose being not less than 10 minims (0.6), well diluted, and this may be repeated in the course of ten or fifteen minutes in obstinate cases; it may be combined advantageously with pepsin (gr. v to x—0.3–0.6) in those forms of gastritis in which both the free HCl and digestive ferments are either much diminished (mucous variety), or absent (atrophic variety). This remedy is rarely indicated in simple chronic gastritis. Pancreatin is better associated with sodium bicarbonate in the form of a tablet containing each gr. ij (0.13). Of these two or three may be administered fifteen to thirty minutes after meal-time. Care is to be taken to use only the best articles of pepsin and pancreatin. This class of cases represents an aggravated or advanced form of the disease (atrophic stage), and demands prolonged and varied treatment. At the end of the digestive process it is well to irrigate the stomach (lavage) if evidences of dilatation be present. The stomach may also be cleansed and prepared for the reception of the next meal in a very agreeable manner by

having the patient sip a 2 per cent. solution of borax in warm water or a 2 per cent. solution of sodium chlorid half an hour before meals; indeed, the continued use of simple hot water for the same purpose has, in my hands, often given excellent results. With it must, of course, be combined the saline laxatives and the restricted diet. Not less than 1 pint of water, hot as it can be taken by the patient, should be sipped at each sitting. Boas considers magnesium salicylate (gr. xv to xxx—1.0–2.0, t. i. d.) the best antifermentative remedy.

To assist the appetites of these patients and to stimulate the secretory function a few drops (not more than 5) of the tincture of *nux vomica* may be given fifteen minutes before meals, with gr. ii to iij (0.13–0.19) of sodium bicarbonate. These indications are also fulfilled by lavage once daily or twice daily (if the patient be feeble). If hyperacidity, due to the organic acids, tends to persist, we may combine bismuth subnitrate with magnesia and a few grains of charcoal, this being administered when the stomach is empty. We may also check fermentation by the exhibition of salicylic acid (gr. v—0.3) thrice daily or creasote (gr. $\frac{1}{2}$ —0.03) thrice daily. Germain Sée has recently found strontium bromid (3ss to 3j—2.0–4.0) to be of great value in cases in which gaseous fermentation with hyperacidity is combined with permanent tenderness. Happy results often follow a course at some spa if the patient be under the charge of a competent physician during his sojourn. The robust or plethoric should go to Carlsbad, Ems, and Kissingen abroad, and to Saratoga at home, using more especially the Hawthorne water. The anemic should go to Franzenbad and to the iron springs at Bedford, Pennsylvania. A course of the alkaline mineral waters may be successfully taken at home in many instances, though patients are much more apt to obey the physician's injunctions as to diet, exercise, and the like when at a spa than when at home. These waters do not simply act as purgatives, but also as antacids. It has been experimentally shown that sodium chlorid, sodium carbonate, as well as carbon dioxid, promote the secretion of the gastric juice. In the more chronic cases belonging to this class or those that have resisted other forms of treatment intestinal complications are usually found. Here the alkaline waters are to be alternated with calomel in small doses, prescribed thus:

R.	Hydrarg. chloridi mitis,	gr. ij (0.13);
	Sodii bicarb.,	3j (4.00);
	Sacchari lactis,	3ss (2.00).
M. et ft. chart. No. xij.		
Sig. One four times daily.		

I have been in the habit of continuing the use of these powders for one week, then returning to the alkaline waters for two weeks.

In the *mucous* variety of gastric catarrh additional indications for treatment are presented. The chief aim should be to limit, as far as possible, the production of mucus and to cleanse thoroughly the stomach prior to each meal, thus preparing the organ for the reception and better digestion of food. Here, again, at least one pint of hot water, containing the substances before mentioned, should be sipped half an hour before each meal. This mode of cleansing the stomach is usually successful; if unsuccessful, however, it should be supplemented by lavage once daily, employing two or more pints of warm water. The siphon is also quite useful in cases of this sort in which stricture of the pylorus is suspected and when the food is retained in the stomach much longer than the normal period of digestion; a condition which is enhanced by the mucus collecting upon the food and thus preventing it from being acted upon by the gastric juice. For the same reason absorption is greatly retarded. The therapy of this form of chronic gastritis requires the more potent astringents

for the purpose of arresting hypersecretion of mucus. The best way to use these agents is topically. The stomach may be washed (at bed-time or early in the morning) with a 2 per cent. solution of alum or a 1 per cent. solution of tannic acid; antiseptic solutions are employed in like manner, a 2 per cent. solution of salicylic acid being especially efficacious. If lavage cannot be practiced, such astringents as cerium oxalate and silver nitrate, with small doses of opium (*vide supra*), should be tried. For use internally, one of the best remedies is atropin sulphate.

Certain symptoms belonging to all varieties of the affection may demand relief. These must be met in accordance with general principles. Vomiting, which is at times a distressing symptom, is best allayed by small doses of resorcin or creasote in combination with cerium oxalate.

As soon as the morbid irritability of the stomach has been reduced mild forms of bitter tonics, with a view to imparting vigor to the digestive organs, may be cautiously employed. Their too early use is very apt to aggravate existing symptoms, or even to reproduce such as have already disappeared. Iron is often indicated during convalescence.

PEPTIC ULCER

(*Simple or Round Ulcer of the Stomach; Duodenal Ulcer*)

Definition.—An ulcer presenting sharp borders, with a tendency to extend in depth, generally without collateral inflammation, giving rise, usually, to one or more characteristic symptoms, as pain, vomiting, and hematemesis. Peptic ulcers may be single, but are often multiple. Peptic ulcers occur in the parts of the gastro-intestinal tract which may be reached by the gastric juice, hence occur in the stomach, duodenum and at times in the jejunum after a gastro-enterostomy.

Pathology.—The gross anatomic characteristics and peculiarities may be briefly considered *seriatim*. (a) In *shape* it is usually round or oval. Frequently there are several ulcers, and these may unite to form larger ones having irregular borders. They are at first superficial, though their floor (when seen at autopsy) is below the mucous membrane. Thus, the ulcer has for its base frequently the muscular or serous coats, but sometimes the ulcerative process extends through the walls of the stomach ("perforating ulcer"), in which case adhesions form between the stomach and the adjacent viscera, one or other of the latter organs occupying the base of the ulcer. The walls usually slope inward, giving rise to the characteristic funnel shape. The edges may, however, be sharp and abrupt. The floor of the ulcer is quite generally clean. A recent ulcer presents clean-cut edges that are not the seat of collateral inflammatory edema, though an old ulcer often presents thickened margins. (b) The *size* is quite variable. The majority of the ulcers are not larger than a dime; others may measure as much as 10 cm. (4 inches) in their greatest diameter. The edges are almost invariably formed from the coalescence of two or more smaller ones. (c) The *position* is most frequently when in the stomach near the pylorus on the posterior wall, and particularly in the vicinity of the lesser curvature.¹ This is the point of greatest irritation from

¹ Of 793 cases collected by Welch from hospital statistics, 288 were on the lesser curvature, 235 on the posterior wall, 95 at the pylorus, 69 on the anterior wall, 50 at the cardia, 29 at the fundus, 27 on the greater curvature. MacNevin and Herrick noted the location of the lesion in 97 fatal cases, as follows: lesser curve 47, posterior wall 30, anterior wall 17, and greater curve 3.

the moving mass of gastric contents which the disturbed muscular mechanism ejects before they have become reduced to a liquid (Barker). Fortunately they rarely occupy the anterior surface. Ulcers of the duodenum are much more frequent than gastric ulcers as shown by the statistics from the Mayo clinic. They are usually located close to the distal side of the pylorus and practically always above the orifice of the common duct. In 2500 patients operated upon up to July 1, 1915 for peptic ulcer, 27 per cent. were in the stomach and 73 per cent. were duodenal.

The deeper ulcers heal by cicatrization. The resulting scar is pale and stellate, and there is puckering of the surrounding mucous membrane. If the ulcer has not extended deeper than the mucous membrane, granulation-tissue develops from the edges and base; this tissue slowly contracts, uniting the margins without a distinct scar. On the other hand, if the ulcer be large and involve the muscular and serous coats, stricture of the pylorus, followed by dilatation, may result. The stomach may present an hour-glass shape, due to the contraction of a girdle ulcer in the central part of the organ. Nearly all peptic ulcers would perforate the coats were it not for the development of a localized peritonitis with the establishment of protective adhesions. The ulcers being usually situated on the posterior wall, the surface of the pancreas forms the point of attachment most frequently, though the stomach may also become adherent to the left lobe of the liver, the spleen, omentum, diaphragm, or the transverse colon. The organs with which the stomach becomes agglutinated may be penetrated by the ulcerative process, resulting in suppurative inflammation (*abscess*); or, guided by the limiting adhesions, fistulous connections of the stomach with the transverse colon, the pleura, the pericardium, lungs, gall-bladder, and the duodenum may be established. Of these, gastrocolic fistulæ are the most common. The ulcer has perforated the left ventricle. Penetration of the ulcer through the posterior gastric wall opens the lesser peritoneal cavity, in which case the base remains limited, producing a condition known as subphrenic pyopneumothorax. When the anterior surface of the stomach, which has no anatomic relations with other organs favorable for the establishment of protective adhesions is perforated, general infectious peritonitis rapidly supervenes. Intense hyperemia or the erosion of small vessels gives rise to small or moderate hemorrhages. If the ulcer penetrate one of the larger vessels, then fatal hematemesis is the usual result. The development of a "protective thrombosis" may prevent this accident. In several instances small aneurysms have been found at the bases of the ulcers (Douglas, Powell, Welch).

Frequency and Etiology.—The prevalence of gastric ulcer in the various countries is shown by the statistics of C. P. Howard; he analyzed the records of 161,599 cases treated in American hospitals, and found 930 instances in which gastric ulcer was present (0.57 per cent.); Bromwell, of Edinburgh, in 43,357 cases, found 2.02 per cent. to suffer from gastric ulcer. The percentage for London is 1.24 per cent. lower than that given for Edinburgh; Breslau 0.66 per cent.; Berlin 1.33 per cent. Concerning its pathogenesis, there are two points that are generally accepted: (*a*) that the ulcer is due to a self-digestion of a circumscribed portion of the stomach; (*b*) that the resistance of the part digested has been previously reduced or even lost. Diminished or lost resistance may be due to a lessening of the supply of alkaline arterial blood, which prevents the stomach from being digested in health; also, to *embolism* and *thrombosis* of the nutrient artery of the part, the infarct thus produced being annihilated by the gastric secretions (Virchow). W. E. and E. L. Burge ascribe the digestive action of gastric juice to a decrease of the oxidative processes of the cells of the part. Bassler thinks the lack of

gastric mucus, which protects the glandular elements in hyperchlorhydria, is a factor. Stockton holds that the disease is of nervous origin. Traumatic injuries have been suggested. Says Lichty,¹ the theory most accepted is probably lowered vitality, localized traumatism, and increased or changed secretions as the chain of events, which leads to the formation and continuation of an ulcer. It is probable that microbial invasion has not received sufficient attention in the past as an etiologic factor. The gastric juice, while bactericidal does not afford universal protection. Turck claims that round ulcer of the stomach and duodenum can be produced in dogs by feeding the colon bacillus, and Rosenow has found that intravenous injection of streptococci of the proper grade of virulence may be followed by ulcer of the stomach and duodenum. Bolton has produced a gastrototoxic serum by making an emulsion of certain organs, which, when injected into animals constantly produced a peptic ulcer. Peptic ulcers occur frequently after severe burns, particularly in the duodenum, or may follow injection of toxic substances as diphtheria toxin or by injury of the gastric mucous membrane, as by chemicals.

Predisposing Causes.—Hyperacidity of the gastric juice is doubtless most influential—a condition almost universally present in this disease; although the ulcers may not result primarily from the presence of an excess of acid, it is quite probable that further extension of the ulcerative process may be due to this factor. Lane holds that gastric ulcer is produced by an endogenous toxin resulting from intestinal stasis, and that it is a predisposing condition, in some cases at least, would seem to be certain. Peter assumes the cause of simple ulcer to be gastritis. It rarely follows cutaneous burns and also wounds of the bladder. The affection is often secondary in chlorosis, anemia, and amenorrhea. Surgical experience at the Mayo and Moynihan clinics indicate a preponderance of the cases in the male sex. It is most common between seventeen and thirty-five years; it is rare in young children, though Gorgart saw an instance in a child thirty hours after birth, and less rare in those past middle life. Cackovic states that the age was under ten years in 2.32 per cent. of 172 operative cases. The relation of males affected to females is in the ratio of 4 to 1. It is more frequent in the poor than in the rich; occupation has also a noticeable influence, and I have personally seen instances in weavers. It is also prone to attack servants, cooks, and needlewomen among females, and shoemakers, tailors, saddlers, and carpenters among males. Exner has discovered that gastric ulcers are frequent in tabetics.

Clinical History.—In *typical cases* of gastric ulcer the clinical symptoms are almost positively diagnostic. The earliest manifestations commonly point to chronic or subacute gastric catarrh, these being followed, soon or late, by those that are characteristic, as *pain*, *vomiting*, and *hematemesis*. Of these, pain is most constantly present, and presents certain peculiarities that demand rather elaborate mention. It is commonly dull, at times burning, and is associated usually with great oppression. The character of pain that is most diagnostic is an *intense gnawing, burning or boring* in the epigastrium, more or less *periodic* and *strictly localized* in a circumscribed area. These paroxysms may either come on almost immediately after eating, or from one to four hours later, depending on the site of the ulcer, and disappear quite promptly when the stomach is emptied. Hamburger, following the experimental lead of Cannon and Carlson, who showed that hunger pains are due to contractions of the stomach, has cleverly demonstrated that the pain of gastric ulcer is due to hyperperistalsis, increased gastric tonus, gastric muscle spasm and increased intragastric tension. Sharp, intense, lancinating pains, that are caused by

¹ "Some Clinical Aspects of Gastric Hemorrhage," *Amer. Jour. Med. Sci.*, November, 1914, p. 680.

local or general peritonitis, may appear suddenly. The pain in round gastric ulcer is greatly modified by numerous conditions. The *effect of taking food* has been already referred to, and it should be added that indigestible, imperfectly masticated, and highly spiced food, sweet and hot substances, cause the paroxysms to be more intense than do less irritating articles of diet. *Rest* diminishes the pain by preventing traction on the ulcer. *Certain postures* may aggravate it, and, while not a trustworthy guide, we may often determine the situation of the ulcer by the effect of posture after taking solid food. The severity of the pain is often increased by bodily fatigue or even moderate exercise and emotional influences. The situation of the pain, when strictly localized, is of the utmost importance in diagnosis. I have found it almost invariably from one to two inches below the ensiform cartilage, yet it has rarely been observed in the umbilical and hypochondriac regions. It is absent in one-half of all cases. There is a pain-point in the dorsal region (often at a level with the tenth to the twelfth thoracic vertebra) on the left side. Says Moullin: One special symptom that indicates the spread of ulceration is persistent cutaneous hyperesthesia in Head's epigastric triangle and at the dorsal pain-point.

Vomiting, next to pain, is the most frequent symptom, but unless the vomitus contains macroscopic blood, which is present in less than 50 per cent. of all the cases, or occult blood (*vide* p. 777), it has little diagnostic importance. Nausea and eructations of acid or food often precede or accompany the emesis. Vomiting usually occurs about two hours after eating, often at the height of the paroxysm of pain, which the vomiting relieves as a rule. The *vomitus* and *gastric contents*, as first shown by Riegel, commonly contains an increased proportion of HCl (hyperacidity) in 90 per cent. of the more acute forms, though many cases of ulcer are found without secretory disturbances. The total acidity is abnormally high. The withdrawn test-meal usually contains blood, either macroscopic or occult. The acidity is reduced with the age of the patient and chronicity. Kemp confirms Rubow's assertion that the amount of residue is large and extremely acid.

Hematemesis is a symptom of unequaled clinical significance, and on it alone frequently rests a positive diagnosis. When the hemorrhage is considerable, pure blood, more or less clotted, may be ejected, this being highly characteristic of gastric ulcer. Frequently, however, the blood oozes gradually into the stomach and mingles with the gastric juice, and in consequence the oxyhemoglobin of the blood is converted into hematin, the vomitus presenting the appearance of coffee-grounds. On *microscopic examination* large and small granules of blood-pigment are seen, but the red cells are incapable of recognition.¹ Vomiting of blood may occur at intervals of a few hours or on each successive day. The *amount* also varies within the widest limits according to the size of the vessel eroded. Some of the effused blood passes through the pylorus, escaping with the feces and giving to the latter a tarry, black appearance. In duodenal ulcer the blood is usually evacuated with the stools except that which was absorbed from the alimentary tract. Steele claims that gastric ulcers do not bleed as often as might be expected, and that in dubious cases the stools must be examined for several weeks for occult bleeding before chronic ulcer could be excluded. *Intermittent* occult hemorrhages, however, generally occur, pointing strongly toward ulcer. Either as the result of a single copious hemorrhage or of repeated smaller bleedings a *pronounced anemia* is produced. The profound shock may result from profuse hemorrhage. As a rule, however, the evidences of anemia are only moderately well marked, and to assume

¹ The blood, however, can be identified by the guaiacum and other chemical tests and through its spectroscopic appearance.

that the anemia is due solely to the hemorrhages would be an error. A slight rise of temperature is often observed under these circumstances; this is the so-called *anemic fever*. The pain and the most unpleasant local symptoms have been frequently observed to disappear after its cessation. Both cardiospasm and pylorospasm, as shown by radioscopy, are not infrequent accompaniments, but the latter does not occur when the ulcers are at a distance from the pylorus. In duodenal ulcers there is usually a hypermotility. The appetite may be good, but the patient is disinclined to eat, owing to the pain resulting therefrom. Not infrequently convalescence sets in immediately.

Physical signs are few and slight. On *palpation* tenderness is found, though not in all cases. The spot of localized agonizing pain before alluded to is often excessively tender on pressure—a valuable sign. The true gastralgic attacks are at times relieved by making firm pressure with the broad hand over the epigastrium. Near the pyloric end of the stomach palpable tumors may be felt, due to the thickened floor of the ulcer. When these indurated masses become adherent to adjacent organs—the pancreas, for example—epigastric tumors of considerable size may be felt, suggesting the presence of carcinoma. *General symptoms* often do not appear until late in the disease. Anemia is usually noted first, to be followed by debility and emaciation; the degree of the general disturbances is in direct proportion to the severity and duration of the coexisting catarrh, hemorrhages, pain, and vomiting. The cachexia may be pronounced, and the face assumes a gaunt appearance.

Other Clinical Forms.—These have been subdivided into numerous types, some of which merge into one another and cannot be separated clinically. The following atypical forms should be distinguished: (a) Latent ulcers, whose existence is not suspected during life, but which are revealed, should they come to autopsy, as open ulcers or cicatrices. (b) An explosive form, in which the ulcer may or may not give rise to gastric disturbances prior to the occurrence of perforative peritonitis. This type must not be confounded with *acute peptic ulcer*, which is a medical condition. (c) A recurrent form, described by Welch thus: “In this the symptoms of gastric ulcer disappear, and then follow intervals, often of considerable duration, in which there is apparent cure, but the symptoms return, especially after some indiscretion in the mode of living. This intermittent course may continue for many years. In these cases it is probable either that fresh ulcers form or that the cicatrix of an old ulcer becomes ulcerated.”

Complications and Sequelæ.—Perforation of the ulcer (most common when it is situated in the anterior wall) leads to peritonitis, which almost always ends fatally. Rarely a localized peritonitis is the result, owing to rapidly formed limiting adhesions or perforation into the lesser peritoneal cavity. The symptoms of this complication will be given in their proper place (see also *Pain*, p. 752). Hemorrhage may prove a serious complicating accident, being in not rare instances an immediate cause of death. Severe hemorrhage may also cause a diminution of free HCl, with an amelioration of the symptoms. Parotitis, due to oral starvation and multiple neuritis, have been noted.

The cicatrization of an ulcer may lead to *hour-glass stomach*, which presents features as follows: “(1) In washing out the stomach part of the fluid is lost. (2) If the stomach is washed clean, a sudden reappearance of stomach-contents may take place. (3) ‘Paradoxical dilatation’ when the stomach has apparently been emptied, a splashing sound may be elicited by palpation of the pyloric segment. (4) After distending the stomach a change in the position of the distention tumor may be seen in some cases. (5) Gushing, bubbling, or sizzling sounds are heard on dilatation with carbon dioxid at a point distinct from the

pylorus. (6) In some cases, when both parts are dilated, two tumors with a notch or sulcus between are apparent to sight or touch" (Moynihan).

Diagnosis.—The typical cases in which the characteristic symptoms above mentioned are conspicuous are easy of diagnosis. Hemorrhages occurring with gastralgic attacks are almost pathognomonic. A considerable proportion, however, offer formidable difficulties. In the absence of hemorrhage we may infer the altogether probable existence of ulcer if there be a history of the more important etiologic factors; if there be pains at a definite time, hyperacidity, localized tenderness, a dorsal pain-point; and, particularly, if the latter symptoms be aggravated by the taking of food. The Einhorn string-test and that for occult blood in the stomach contents and feces are helpful aids, while the long course and liability to remission are also strongly confirmatory. Roentgen-ray examination of the stomach and duodenum is an extremely valuable aid in arriving at a diagnosis, but it should not be forgotten that the absence of typical roentgenologic findings does not, by any means, preclude the possibility of ulcer being present. The most typical and positive finding is the shadow of the ulcer. Failing this, other suggestive findings include increased gastric peristalsis, pylorospasm or spasm of the muscle in the area corresponding to the location of the ulcer, the so-called duodenal cap, early hypermotility, particularly in duodenal ulcer, and so on. Old chronic ulcers may produce deformity of the stomach-wall by cicatricial contraction.

Differential Diagnosis.—This disease may be mistaken for *gastralgia*, *chronic gastritis*, *the passage of gall-stones*, *cirrhosis of the liver*, and *carcinoma of the stomach*. The differentiation of the latter complaint will be given later. (a) In certain cases of cirrhosis of the liver hematemesis is met with, but here there is absence of all the other characteristic symptoms of ulcer, and the presence of a group of symptoms and physical signs pointing to disease of the liver. (b) Hepatic colic simulates ulcer of the stomach without hemorrhage. The sudden onset, the longer duration of the attack of pain, its sudden complete cessation, the presence of jaundice and certain physical signs presented by the liver, often suffice to distinguish this affection from gastric ulcer. The urine may contain pepsin in ulcer, and the administration of orthoform (Hemmeter) will relieve the gastric pain but not that of cholelithiasis. (c) Chronic gastric catarrh with hematemesis resembles ulcer of the stomach in many particulars. The great diminution in the proportionate amount of hydrochloric acid found in chronic gastric catarrh and the increased amount in gastric ulcer help materially in discriminating these two diseases. When associated with one another my observation teaches that there is an excess of HCl present; hence a proportionately diminished amount of HCl probably argues against the presence of ulcer. The vomiting in ulcer is combined with severe paroxysms of pain; not so in chronic gastritis, and the vomit in the former contains larger quantities of blood than in the latter disease. (d) Doubtless ulcer of the stomach has often been mistaken for neurotic gastralgia and the discrimination cannot always be accomplished to a certainty.

GASTRIC ULCER

History unimportant.

Most frequent from fifteen to thirty-five years of age.

The paroxysms of pain usually come on at a definite period after eating.

Eating rarely relieves pain.

Position of patient may relieve pain.

GASTRALGIA

History of neurasthenia, neuralgia, and hysteria the rule.

Most frequent before or near the menopause (in the female).

Paroxysms more frequent when stomach is empty and show less periodicity.

Eating usually brings relief.

No decided relief.

GASTRIC ULCER

Tenderness on pressure over a certain limited area in the epigastrium.

Pressure usually aggravates, and only occasionally relieves patient during paroxysm of pain—not during the intervals between seizures.

In the intervals gastric disturbances, more or less severe, are present.

Hematemesis present in nearly one-half of the cases.

General health often much impaired, particularly late in the affection.

Physical signs of a mass may be present.

Dilatation may coexist in the late stage.

Hyperacidity of gastric juice usually present.

Improvement follows rest and regulation of diet.

GASTRALGIA

Tender spot absent. General hyperesthesia of the skin of epigastrium often present.

Pressure almost always relieves the pain.

In the intervals between attacks no gastric disturbances present, as a rule.

Hematemesis absent.

General health less affected than in ulcer.

Signs of tumor always absent.

Dilatation never present.

Hyperacidity present only in certain forms (*supra*).

Regulation of diet has no effect.

The **prognosis** is obviously uncertain. The average mortality is about 15 per cent. Such grave complications as free bleedings and peritonitis have been discussed in the Clinical History. Among serious thoracic complications, pneumonia, tuberculosis, and left-sided perforative empyema are the most frequent. The more recent the case the better the prospect of recovery. The possibility that the resulting scar may cause gastralgia, and the probability that a cicatrix surrounding the whole or any part of the pylorus may cause obstruction, followed by ectasy, must be remembered. Carcinoma often develops in the floor of an old ulcer (*vide* p. 759). Innately the disease is an exceedingly chronic one, often lasting several, and sometimes ten or fifteen, years. Acute ulcers are commoner, however, than usually thought. More-over chronic duodenal ulcers show a marked tendency to severe exacerbation of symptoms with long intervals of quiescence, following proper treatment.

The **treatment** of simple peptic ulcer embraces three leading objects: (1) Of paramount importance is *absolute rest for the stomach*. This is to be accomplished by maintaining the recumbent posture in bed, on the one hand, and by rectal feeding, wholly or partly, on the other. This mode of alimentation will be discussed presently. Perfect rest ensures more rapid cicatrization than any other single agent. The process of repair is very slow under the most favorable circumstances; hence the patient should be informed at the outset that from six to eight weeks, at least, must be spent in bed. (2) *The careful regulation of the diet*. It is not possible for the stomach, when the seat of ulcer, to digest the normal amount of nitrogenous food without being injuriously affected thereby. Those articles of diet should be employed that are digested and assimilated chiefly in the intestinal tract. But, though the patient is fed by the mouth, this should be supplemented by rectal feeding almost from the beginning. By pursuing this combined method and giving per rectum but a limited amount of albuminous food the vital forces can be more effectually supported. Failure to cure cases of gastric ulcer is often due to the fact that the patient's general strength early becomes exhausted. Frequently the stomach is so irritable as to render it exceedingly difficult to introduce into it even a fractional part of the amount of food necessary to support life properly; in such cases "a period of absolute abstention from food by the stomach should be inaugurated" (Lambert). Nothing but water and pieces of ice should be allowed. Exclusive rectal feeding during the first week is a method quite commonly adopted. The following dietary will be found useful: At 7 A. M. give 100 c.c. (3ij) of Leube's beef-solution; at 11 A. M., 200 c.c. (3vj)

of pancreatized milk-gruel;¹ at 3 P. M., 200 c.c. (3vj) of peptonized milk or skimmed milk or buttermilk; at 7 P. M., 200 c.c. (3vj) of pancreatized milk-gruel; in addition, the following by rectal injection: at 8 A. M., 6 ounces of pancreatized milk-gruel, and, if necessary to overcome rectal irritability, 5 to 10 drops of tincture of opium, this to be repeated at 2 and 8 P. M. If, on the other hand, the stomach rejects the above-mentioned food, then the feeding must be, for a time, exclusively rectal; this is quite practicable if the proper choice be made of nutrient preparations. In addition to the substances before mentioned we may employ from 4 to 6 ounces (150-200 c.c.) of Leube's beef-solution, or the same amount of defibrinated blood or pancreatized milk with brandy.

Lenhartz treated 295 cases of gastric ulcer with a more nourishing diet than that allowed by von Leube, with a mortality of 2.3 per cent. Harris² has simplified the Lenhartz diet so that it can be carried out with greater ease and accuracy: The nurse prepares enough of a mixture in the proportion of 1 egg and 1½ ounces of cream to 4 ounces of milk and gives it every hour from 7 A. M. to 7 P. M., in gradually increasing quantities, beginning with ½ ounce the first day and increasing ½ ounce each day. It requires six days to get up to 3 ounces at each feeding, and the quantity is kept at 3 ounces for four days. From the seventh to the tenth day a soft cooked egg and 2 tablespoonfuls of strained oatmeal may be given with the feeding at 7 A. M. and 7 P. M., and at 1 P. M. 2 tablespoonfuls of scraped beef lightly broiled and 2 tablespoonfuls of thoroughly cooked rice with butter. After ten days until the fifteenth day, 3 ounces of the egg, milk and cream mixture are given at 9 and 11 A. M. and 3 and 5 P. M.; and 2 ounces of strained oatmeal with cream and sugar, and 1 or 2 thin slices of dry toast and 2 soft eggs for breakfast at 7 A. M. and supper at 7 P. M.; and chopped or minced chicken or scraped beef, dry toast, rice and ice cream or gelatin at 1 P. M. Butter is allowed after ten days. Beginning with the fifteenth day and for two months, the patient should have small meals three times a day with an egg and goblet of milk between meals and at bedtime.

This diet may be commenced forty-eight hours after a hemorrhage.

Da Costa reported recently a number of instances that were cured by a diet of ice cream. Senator advises the use of gelatin as food in gastric ulcer. Owing to the abnormally free secretion of HCl in this disease, the proteins should be limited in the dietary; while carbohydrates are indicated, physiologic investigations have shown that the latter (also fats) diminish the secretion of the normal acid. It has been recommended to employ lavage when the stomach is exceedingly irritable, but the use of the stomach-tube is liable to damage the ulcer even in the most careful hands. The good effects from washing out the stomach for uncontrollable vomiting and pain have, however, been frequently witnessed. It may often be accomplished by the use of 1 pint (½ liter) of warm water containing a few grains of sodium bicarbonate, sipped slowly when the stomach is empty. Speedy emptying of the stomach is facilitated by the patient lying on his right side as much as possible while food is in his stomach (Cornwall). If at the expiration of two months the condition of the patient indicates that the reparative process is far advanced, then well-boiled rice, stale bread, and potatoes may be allowed; and later eggs, oysters, fish, and sago, while an ordinary solid diet should not be resumed for at least six months. When pain follows the use of the solid foods, they should be discontinued. Sippy employs an extremely bland, largely carbohydrate diet

¹ The milk-gruel is prepared with wheaten flour or arrowroot, mixed with an equal quantity of milk.

² *Southern Med. Jour.*, November, 1916, p. 960.

together with large doses of alkalis, in order to keep the stomach contents alkaline or as nearly so as possible. Smithies believes that the neutralization of the acid is simply attacking the result, not the cause, of the ulcer and is therefore partially counterindicated. Basing his mode of treatment largely on the theory that, as Rosenow and Bolton have pointed out, ulcers may be bacterial or toxic in origin, he advocates complete eradication of all foci of infection, plus rest of the stomach.

(3) The *medicinal treatment*, which is altogether subsidiary to the dietetic, has reference to two ends: (a) Promotion of the healing process. We cannot be certain that any known remedial agents can accomplish this object, yet it is our duty to attempt it. Of the efficacy of alkaline remedies we are thoroughly convinced; in neutralizing the hyperacidity of the gastric secretions they fulfil an important indication, since the excess of HCl must have an unfavorable effect upon the ulcer. Of these, sodium bicarbonate (in full doses) or the alkaline purgative mineral waters, as Carlsbad, Kissingen, Hunyadi Janos, are most useful. The Carlsbad salts are beneficial, and may be prepared artificially as follows: sodium sulphate, 50 parts; sodium bicarbonate, 6 parts; sodium chlorid, 3 parts—of which a teaspoonful may be taken in hot water, fasting, in the morning. The alkaline waters must not be allowed while the stomach is at perfect rest. The preparations of bismuth may be given in combination with antiseptics, which latter are especially to be recommended. Fleiner's method of giving 10 gm. of bismuth in 200 gm. of warm water on an empty stomach, then allowing the patient to drink several swallows of water, and afterward placing him in the horizontal position with the hips elevated for about an hour, has yielded gratifying results. About 200 gm. of bismuth administered in the above manner usually suffice to effect a cure (Savelieff). Cohnheim recommends 1 teaspoonful of bismuth stirred up in a glassful of water before breakfast, the patient lying on his right side for half an hour afterward. For the chronic gastric catarrh which may be associated with ulcer, silver nitrate is efficient, and may be combined with small doses of opium or hyoscyamus. Cohnheim advises silver nitrate in $\frac{1}{2}$ -grain doses in a wine-glassful of water from a quarter- to a half-hour before food. The previous general condition of the patient is frequently unfavorable to the successful healing of the ulcers, and to combat the anemia and chlorosis that are often present we may employ iron and arsenic. Small doses of Fowler's solution of arsenic are generally well borne by the stomach; the former may also be given hypodermically. When organic cardiac diseases are concomitants they should receive careful attention, and also any other associated conditions.

(b) The relief of symptoms. The extract of opium, combined with silver nitrate, often relieves the pain, as does also belladonna. Mild counter-irritation is also of service. The application of the ice-bag sometimes alleviates the pain, but Hemmeter advises orthoform. For the gastralgic attacks morphin may be required. For *vomiting*, bismuth, creasote, silver nitrate, and opium are useful; chipped ice, with a small amount of brandy thrown over it, is also of value. When obstinate, the following remedies may be tried separately: cerium oxalate, potassium bromid, tincture of iodine, cocain, chloral, and hydrocyanic acid.

For the *hematemesis*, rest, rectal feeding, the application of a broad, flat ice-bag, will usually suffice. For exhaustive hemorrhages infusion into the veins or into the subcutaneous tissue of normal salt solution is an important measure. For stopping a hemorrhage, lavage followed by bismuth is highly recommended. Notebaum recommends tincture of iodine in small doses at short intervals. Gelatin, in solution, may be employed per oram, and glucose solution, by the Murphy method, per rectum. Operative

intervention in gastric ulcer is demanded: 1. In recurring hematemesis, W. L. Rodman advises operation between attacks—always after the third bleeding. 2. In perforation, so soon as the diagnosis is clearly established. In the cases of perforation which have been operated upon within the first twelve hours during the past three years, 83.78 per cent. have been saved (Tinker). 3. Most of the cases not cured by medical treatment are savable by timely surgical intervention, but in simple ulcer of the stomach operation is not advised, "the medical treatment of which should be more careful and more prolonged than was formerly deemed necessary" (Robson¹). 4. If gastrectasis due to pyloric obstruction or if adhesions form and persist, operation is indicated. The treatment of callous ulcer is purely surgical.

CARCINOMA OF THE STOMACH

Pathology.—Next to the uterus, the stomach is the most favored seat of carcinoma. In a total of over 30,000 cases studied by Welch, 21.4 per cent. showed involvement of this organ. With reference to the parts of the organ attacked, Welch analyzed 1200 cases with the following results: pyloric region, 791; lesser curvature, 148; cardia, 104; posterior wall, 68; greater curvature, 34; anterior wall, 30; fundus, 19. The forms of gastric carcinoma noted are columnar epithelial (including colloid) and the glandular carcinomata (embracing encephaloid and scirrhus). The epitheliomata grow from the lining epithelium, while the encephaloid and scirrhus are new growths from the glandular epithelium. The last two forms are, therefore, similar in structure, but differ in the rapidity of their growth; the encephaloid cancers are soft, and readily break down on their surface, forming large ulcers that have a clean floor, while the scirrhus cancers are hard and firm. Columnar epitheliomata are frequent, and are situated at the pyloric end of the stomach. They are often the seat of colloid degeneration. Squamous epitheliomata occur at the cardiac end. Secondary new growths in adjacent organs occur, the scirrhus, however, manifesting the least tendency to metastasis. Perforation of the stomach-walls occurs in 3.3 per cent. (Brinton). Welch collected 37 cases of secondary gastric carcinoma; 17 were secondary to mammary carcinoma. Atrophic gastritis ensues.

Etiology.—The factors bearing upon the etiology of gastric carcinoma may all be regarded as **predisposing causes**. Of these *age* is the most potent. Of 2038 cases examined by Welch with reference to this point, 75 per cent. occurred between the fortieth and seventieth years, 24.5 per cent. between forty and fifty years, 30.4 per cent. between fifty and sixty years, and 2.8 per cent. before the thirtieth year. The maximum liability lies between the forty-fifth and sixtieth years (Lebert). In 1069 cases collected by Osler and McCrae,² 2.5 per cent. developed before thirty years of age. Smithies found a percentage of 2.2. under thirty years of age among a group of 721 consecutive cases examined by a uniform method. There are records of 6 cases before the tenth year. Collingsworth reports the case of a child at ten days and death at twenty-ninth day; and Widerhofer 1 at sixteen days. I find records of 13 cases between ten and twenty years. *Heredity* stands next to age as a causal factor, though it is far less influential. Welch analyzed 1744 cases, and found that a family history of carcinoma was present in about 14 per cent. *Sex* has little if any influence. The colored *race* enjoys comparative immunity.

¹ *Brit. Med. Jour.*, November 17, 1906.

² *New York Med. Jour.*, April 21, 1900, p. 581.

Lerche claims that "hot fluids" are an important predisposing factor. Gastric carcinoma may follow a pre-existing chronic catarrh. More commonly, however, *chronic ulcer* precedes as the important statistics from the Mayo clinic show. The statistics of Klaus (126 cases) give more than 26 per cent. that grow from either ulcers or cicatrices, while Friedenwald holds that this change does not take place in more than 23 per cent. According to Wilson and McDowell, in only 42.6 per cent. of 309 cases of gastric cancer was the evidence of previous ulcer formation doubtful. The disease is rare in the tropics.

Clinical History.—Prior to the development of gastric carcinoma the symptoms of catarrhal dyspepsia may be present for a variable period of time. The onset, however, is oftener abrupt. Again, it may be insidious, and be marked by the evidences of failing general health and strength than by distinct local subjective symptoms. Osler and McCrae¹ have reported cases of latent carcinoma of the stomach. A *progressive decline of the appetite* is generally observed, though occasionally it remains unimpaired. A sense of oppression, rarely true cardialgia, and eructations (*pyrosis*) come on soon after eating. In many cases but little *pain* is complained of, while in a lesser number pain is a prominent symptom throughout the entire course. Its character is very often described as lancinating, less often as burning or gnawing. The pain is often referred to the shoulders and the back or loins. *Vomiting* is infrequent, except in the more advanced stages of the disease, when it is almost constantly present to a greater or less degree. During the early stages it is due to the catarrhal irritation, later to obstruction. When the latter is at the cardiac orifice, the vomiting occurs at once after eating; when at the pylorus, it appears several hours after meals. The *vomit* has few, if any, of the physical characteristics noted in simple ulcer of the stomach. Free hematemesis is very rare; when, however, the surface of the new growth ulcerates, there is almost invariably an occasional slow oozing of blood into the stomach. It is here acted upon by the altered gastric juice, and the black hematin resulting from the transformation of the red hemoglobin gives rise to the well-known "coffee-ground" vomit of carcinoma of the stomach.² The chocolate-colored appearance of the vomitus is not found alone in carcinoma of the stomach. Small hemorrhages are more common in ulcerated carcinoma than in gastric ulcer.

The *chemical examination* of the aspirated stomach contents is of prime diagnostic importance, showing as it does the almost constant absence of free HCl after the *test-meal* (see p. 727). The presence of free HCl, supposing the examinations to be properly made (by the use of the color-test) and sufficiently often repeated, speaks almost positively against carcinoma. In not one of 154 artificial digestive experiments was albumin digested in this disease. Cases do occur, however, in which free HCl is present, as when carcinoma of the stomach is secondary to all ulcer. Moreover, in the incipient stage of gastric carcinoma a small percentage of HCl is occasionally found. Free HCl is also absent in carcinoma of the esophagus, duodenum, extensive amyloid disease, advanced cases of renal disease, and the febrile state.

The leading view as to the cause of the absence of HCl is that the inflammatory degeneration of the mucous membrane, commencing as a catarrhal inflammation and advancing to interstitial change and atrophy (*Rosenheim's view*), diminishes and finally arrests hydrochloric acid secretion. Moore³

¹ *Phila. Med. Jour.*, February 3, 1900.

² *Teichmann's test* for hematin crystals may be employed as follows: Place a drop of the "coffee-ground" material upon the slide and add a few crystals of sodium chlorid. Then introduce a few drops of acetic acid beneath the cover-glass and warm.

³ *The Lancet*, 1905, i, 1120.

believes that the non-production of HCl is due to the relative diminution of H ions and an increase in the OH ions and alkalinity of the blood. *Lactic acid* in excess occurs in the stomach contents after a test-meal in carcinoma. Sick¹ concludes that the most important factor for lactic acid fermentation is the soluble albuminoids produced by the carcinoma (autolysis). The *microscopic appearances* of the vomitus and wash-water are in some ways identical with those observed in gastric ulcer, and if they be examined speedily, red blood-corpuscles may rarely be seen. The constant finding of *occult blood* with the guaiac or benzidin test has great significance. Invisible hemorrhage in the stool is a fairly constant finding. The microscope, also, very seldom reveals pieces and bits of cancer-tissue, and Kaufmann and Hemmeter emphasize the frequency of long bacilli, the latter observer finding the Boas-Oppler bacillus in 94 per cent. of cases. The presence of this organism, which is culturally identical with the *Bacillus bulgaricus*, explains the development of lactic acid in the gastric contents (Galt and Iles). Riegel states that sarcinæ are infrequent. Both the proteolytic and amolytic power of the stomach are greatly diminished. The presence of pus in the gastric contents is confirmatory of carcinoma. The motility of the stomach is defective at an early stage—an important diagnostic feature. Says W. J. Mayo,² remnants of food twelve hours after a test-meal of half-cooked rice and raisins are important for diagnosis.

Physical Examination.—*Inspection* may reveal an irregular tumor in patients much emaciated. When dilatation exists, the outlines of the organ may be seen. On *palpation* the new growth, in a majority of cases, may be felt through the abdominal walls, though often not clearly, as a hard, nodular, and sometimes movable mass. Though this generally appears in the epigastrium, it must be recollected that it depends upon the part involved; also that a tumor united with the wall of the stomach, particularly if situated at the pylorus, sags downward, even to a point below the umbilicus. Less frequently it is discovered in such unlooked-for situations as the right or left hypochondriac region. Varying degrees of fulness of the stomach will alter the position of the tumor. When situated at the cardia it is beyond reach; when attached to the lesser curvature of the stomach or the posterior wall, it is rarely to be felt unless of large size. The new growth cannot be definitely made out when it assumes the form of a diffuse infiltration, though it offers increased resistance and exhibits tenderness on pressure. Usually the patient lies in the dorsal position during the examination, with the limbs drawn up, breathing regularly, while the mouth is kept open. The detection of a tumor when in an unfavorable situation may be facilitated by shifting the patient's position from the dorsal to the lateral, the standing, or the knee-elbow position respectively; at the same time one or two tumblers of some carbonated water should be given with a view to distending the stomach and carrying the tumor downward. Pulsations are frequently communicated from the aorta to the palpating hand through the tumor. If the growth is situated at the lesser curvature, a deep inspiration will often cause it to fall lower and become accessible to palpation. *Percussion* over the growth causes a muffled tympanitic resonance; superficial percussion, however, may give dulness.

The presence of *metastatic new growths* in the liver and enlargements of the supraclavicular or inguinal lymph-glands are of value in the diagnosis. In one instance that I saw in the Philadelphia Hospital a nodule the size of a walnut protruded from the umbilicus, leading to the suspicion of gastric carcinoma. Subsequently a nodulated pyloric neoplasm could be readily held

¹ *Deutsch. Archiv. f. klin. Med.*, Berlin, 1906, lxxxvi, Nos. 4 and 5.

² *Jour. Amer. Med. Assoc.*, June 28, 1913.

in the grasp. Boas contends that enlargement of the supraclavicular glands is not observed in the early stages.

General Symptoms.—Quite early in the disease such evidences of general nutritional disturbance as loss of flesh and anemia may be observed, and, obviously, cases attended with constant anorexia and vomiting will earliest manifest the wasting process. Almost from the beginning the face gradually assumes the cachectic appearance which, in the advanced stages, becomes so characteristic of gastric carcinoma. Anemia (*secondary*) soon becomes a prominent feature. There is a waxy pallor of countenance, and the peculiar cardiac murmurs of anemia appear. The blood frequently presents peculiarities that bear a resemblance to those seen in pernicious anemia, and at times such bloods are indistinguishable from those of true pernicious anemia. I have observed leukocytosis late during the course of this malady. A differential study of the leukocytes is of no value, and the presence or *absence of digestive leukocytosis* is too uncertain to be of diagnostic importance. Nucleated red cells (normoblasts) are not uncommon, and myelocytes are occasional findings. If the monocytes show ameboid nuclei, the case is almost certainly one of malignant disease (Gruner). The anemia of cancer is accompanied by loss of flesh, while in pernicious anemia the superficial fat is preserved. The causes of the profound anemia met with in this affection are not quite plain, since frequently it becomes pronounced before the nutritional disturbances (shown by a loss of flesh) have become marked. The fact that metastatic carcinoma has been found to be abundant in the marrow of the bones is significant in this connection, as pointing to the probable interference, in some instances, with the blood-producing function of the bone-marrow. In advanced cases moderate *edema* of the ankles and of the backs of the hands is frequently observed, and is probably dependent upon excessive anemia. The *temperature* at first shows no abnormalities, as a rule, though after the cachexia has become decided it is often subnormal. Sudden elevations of temperature (103° to 104° F.— 39.4° – 40° C.), preceded by rigors and followed by profuse sweating, are rarely observed. Giordano found that it was evident in 60 per cent. of 100 cases of cancer. The mind almost invariably remains clear to the last, though delirium may be a late-appearing symptom.

Complications.—*Intestinal symptoms* are frequently observed, and *constipation* in particular is quite common. It is apt to alternate with *diarrhea* toward the close of the disease, or diarrhea may in the later stages become a persistent and obstinate symptom. Some of the complicating conditions have reference to the *secondary* new growths. When, as frequently happens, the liver is implicated, *jaundice* is rather common, being associated with signs of hepatic enlargement. Indeed, so prominent may be the symptoms and physical signs referable to secondary carcinoma of the liver as entirely to mask the more or less hidden forms of carcinoma of the stomach. The mesenteric and retroperitoneal lymph-glands or the lungs may be the seat of secondary carcinoma, which, however, rarely gives rise to characteristic symptoms. Occasionally the new growths spread to the peritoneum (and excite exudation) or to the rectum. Perforation may rarely occur, and we then have the pronounced and rapidly supervening symptoms of diffuse peritonitis. *Fistulous communications* between the stomach and the transverse colon or the small intestine—the latter rarely—may also occur. *Nervous symptoms* may be regarded as complicating conditions, and sometimes hasten the fatal termination; the patient becomes somnolent or, rarely, even comatose; the breathing is difficult and the respiration deep and labored. This mode of termination I noted in one case. Traces of *albumin*, and in the later stages tube-casts,

may be present in the urine. Indicanuria is a rather common symptom, while acetonuria is seldom seen. Diacetic acid is present in rare instances.

Latent Forms.—The disease may be latent, most often in feeble persons and in the aged, and accidentally discovered on physical examination. In some cases the cachexia furnishes ground for suspicion.

General Course and Duration.—The course of gastric carcinoma is invariably toward a fatal issue, death usually taking place before the expiration of two years. The average duration of the disease is about one year. When it occurs in emaciated persons it pursues a slower course than when occurring in fleshy individuals. Cases develop only slowly in old ulcer cases. The younger the individual the more rapid the course of the disease. The symptoms are far less intense in the cases in which food stagnation is absent.

Diagnosis.—A positive diagnosis of gastric carcinoma is easily made when a tumor is demonstrable. The history, the presence of characteristic symptoms, such as pain, ectasy, coffee-ground vomit, deficient motor power (*early*), the constant absence of free hydrochloric acid, especially the almost constant presence of lactic acid after the Boas test-meal (unfortunately not an early feature) and a constant positive blood reaction in the stools, all occurring in persons beyond middle life, together with the existence of progressive cachexia, are sufficient to warrant a diagnosis in the absence of a palpable new growth. A putrid smelling tube and putrid eructations have diagnostic importance, and Hemmeter states that the early diagnosis of carcinoma of the stomach is possible in a certain number of cases from histologic examination of small fragments of gastric mucosa, if a direct invasion of the gland-substance by epithelial cells is observed. Carcinoma of the stomach in the late stages is usually diagnosed with ease. It is the early diagnosis, when operative procedures may cure the conditions, that is of primary importance. The case should be most carefully studied. The onset of gastric symptoms in a person over forty previously free from gastric symptoms, the history of an ulcer, evidences of impairment of motility, repeated finding of occult blood in the stool or other corroborative laboratory tests are extremely suspicious symptoms. Exploratory laparotomy may be advised if improvement does not follow medical treatment in suspicious cases within a few weeks at most. Moullin has emphasized the diagnostic value of direct inspection through an incision. Wolff and Junghans¹ first pointed out a special method for the estimation of the soluble albumin in the gastric extract and claimed it to be of value in the diagnosis of gastric carcinoma. Smithies, and Friedenwald and Kieffer² confirm this view, although it is only of significance when taken in connection with other signs. Kelling's method,³ or the hemolytic serum test, was applied by Rosenbaum⁴ in 70 patients, including 26 of carcinoma; he obtained favorable results. The Abderhalden dialysis method of serodiagnosis, while not infallible, is probably useful.⁵ The meiostagmin reaction (Ascoli) has been found to be reliable by certain observers. The glycyltryptophan test is valuable for diagnosis (Weinstein). Goodman's⁶ modification of the Salomon test, which shows the percentage of phosphates (over 10 mg. per 100 c.c.) in the wash-water, is corroborative in ulcerative cases. Falk and Salomon's salicylate method is of material aid.⁷ Salomon and Saxl⁸

have found a reaction of neutral sulphur in the urine very constant in carcinomatous patients. Smithies¹ found in 1175 cases this test less constant than the glycytryptophan reaction. A positive skin reaction is strong presumptive evidence of carcinoma (Lisser and Bloomfield).² B. K. Brown found the stools uniformly Gram-positive in a series of cases. An expert roentgen-ray examination is an important aid in the diagnosis. The roentgen study may show distinct alterations in the normal stomach outlines or there may be merely changes in the rhythmic peristaltic waves to suggest pathologic changes in the stomach-wall.

When malignant degeneration of an ulcer sets in, pain increases in intensity and may radiate to the thorax and back, anorexia develops, hyperacidity often gives way to achlorhydria, and hematemesis may occur early and recur at frequent intervals.

Differential Diagnosis.—A gastric carcinoma presenting a discernible mass is liable to be mistaken for a *cicatrized ulcer*, for *carcinoma of the pancreas*, of the *transverse colon*, *duodenum*, *omentum*, and the *left lobe of the liver*, as well as for *aneurysm of the abdominal aorta*. The *aneurysmal tumor*, however, is smooth, and is not nodular, like the cancerous growth, moreover, it gives rise to an expansile impulse. In aneurysm the characteristic cachexia is wanting. In *pancreatic carcinoma* the tumor is fixed (*vide infra*, p. 892). *Carcinoma of the transverse colon and omentum* will be excluded by the presence in malignant disease of the stomach of a chocolate-colored appearance of the vomitus, deficient motility of the organ, the permanent absence of HCl, and persistent presence of lactic acid in the gastric contents. For the recognition of hidden gastric carcinoma with grave anemia the reader is referred to p. 444.

Chronic ulcer may in cicatrizing give rise to a small tumor, followed by pyloric stenosis and secondary dilatation—an exact counterpart of the course of gastric carcinoma. Great reliance should be placed on the age of the patient, the presence of HCl in the gastric secretions, the points of pain (dorsal epigastric and localized tenderness with hematemesis, and the longer duration of ulcer. Ulcer with tumor-like thickening may show an excess of lactic acid, due to associated motor insufficiency, rendering a differential diagnosis exceedingly difficult. Hypertrophic stenosis of the pylorus is also simulated (*vide p. 765*).

Simple gastric ulcer and chronic gastritis are often confounded with carcinoma of the stomach without palpable tumor (*vide parallel differential tables below*, modified slightly from DaCosta):

CHRONIC GASTRITIS	GASTRIC ULCER	GASTRIC CARCINOMA
Not confined to any age. More common in middle-aged or elderly people.	May occur in middle-aged persons, but is most frequent in young adults, especially women.	Most common in elderly people; rarely occurs in persons under thirty years of age.
Pain at the epigastrium somewhat augmented by food; soreness is also present. Both are constant, although comparatively slight.	Pain at the epigastrium much augmented by food; subsides when this is digested; paroxysms of pain, not lancinating; strictly localized soreness to touch in epigastrium; sometimes a painful spot over lower dorsal vertebrae. Intermissions in the pain are frequent.	Pain frequently of a radiating kind, often paroxysmal, not infrequently severe and lancinating, but not of necessity associated with soreness. Little or not at all affected by food. Pain rarely remits; never intermits for any considerable time.
Symptoms of indigestion marked.	Symptoms of indigestion sometimes very slight.	Symptoms of indigestion marked. Anorexia; extreme acidity of stomach.

¹ *Centralbl. f. die Grenzgeb. der med. und Chir.*, Jena, August 30, 1911.

² *Bull. Johns Hopkins Hospital*, December, 1912.

CHRONIC GASTRITIS

Sometimes vomiting.

No hemorrhage, or but trifling hemorrhage; at most blood-streaks in vomited matter.

Bowels constipated.

No fever.

Not so.

Not much emaciation; no cachectic appearance.

Disease may be relieved or cured; is often of very long duration.

No tumor.

Contents of stomach almost always contain free hydrochloric acid.

No lactic or fatty acids after the rigid Boas test-meal.

Slight motor disturbance.

No dropsy.

GASTRIC ULCER

Vomiting may be present or absent.

Abundant hemorrhage from the stomach common. Stools may contain blood (tarry).

Bowels usually constipated; intermittent occult blood in stools.

No fever.

Acids taken increase pain.

Frequently extreme pallor and debility, especially if preceded by anemia.

Duration uncertain; may get well, may run on rapidly to perforation; or may last for years.

Rarely a tumor.

Hydrochloric acid in excess in contents of stomach.

No lactic or fatty acids after the rigid Boas test-meal.

Motor function fair.

No dropsy.

GASTRIC CARCINOMA

Vomiting a very frequent symptom.

Hemorrhage not very abundant, but frequently occasioning coffee-ground-looking vomit.

Bowels obstinately constipated. Occult blood in feces continuously.

Attacks of slight fever occur; temperature often subnormal.

Not so.

Progressive loss of flesh, and cachexia; enlarged lymphatic glands.

Average duration one year; may be shorter, but seldom longer.

Generally a tumor.

No hydrochloric acid in contents of stomach.

Lactic acid present after Boas test-meal.

Early marked disturbance.

Edema of ankles common.

Treatment.—The diet should be adapted to the peculiarities of the individual case. Physiology indicates that meat and meat-extracts stimulate the secretion of HCl, hence they deserve a careful trial in the earlier stages. If these fail of their physiologic effect, however, then articles of food that are digested and assimilated in the intestines should be employed. After well-marked evidences of pyloric obstruction appear we may add to the comfort of the patient by limiting the diet to liquids, and by predigesting them if they are not otherwise well borne. Should the stomach reject all food, rectal alimentation should be promptly instituted. The more troublesome symptoms—pain, vomiting, hematemesis—are to be met on general principles. The claims that have been advanced in favor of arsenic and other preparations as possessing power to control the progress of gastric carcinoma await confirmation. If dilatation coexists, it is to be managed in accordance with the recommendations found under Dilatation of the Stomach (p. 737). Gastric carcinoma is usually primary and for some length of time it is a local disease. Early surgical intervention, therefore, offers promise of relief and even cure. After operation, the use of radium may be tried for its prophylactic influence.

Hypertrophic Stenosis of the Pylorus.—By this term is meant pyloric obstruction due to hypertrophy, principally of the circular layer of the muscularis, with hyperplasia leading to secondary dilatation of the stomach. This may be (a) congenital; (b) acquired (*e. g.*, tuberculosis). The *etiology* is unknown, although spasm of the pylorus has been suggested. The *symptoms* are those of dilatation of the stomach and a pyloric tumor may be palpable. The resemblance to ulcer with tumor-like thickening and to *ulcus carcinomatosum* may be striking (*vide* also p. 764). The symptoms of the congenital form, according to Binnie, are: 1. Explosive, expulsive vomiting with resultant emaciation. 2. Visible gastric peristalsis. 3. Persistent constipation. 4. Oliguria. 5. Tumor, not always palpable. Roentgenology is valuable for diagnosis in doubtful cases. Medical treatment—massage, electricity, lavage,

and antispasmodics internally—should be tried; this failing, pyloric stretching or other form of operation is indicated. A. Bernheim¹ lauds the use of thiosinamin, administered subcutaneously, at intervals of from three to four weeks.

Benign Cirrhosis of Stomach.—This is a rare condition and difficult of diagnosis. Sheldon states that it may be suspected in patients presenting symptoms of benign stenosis of the pylorus with contracted stomach. The symptoms pointing to it are long-standing disease, absence of hematemesis, contraction of the stomach, absence of tumor on palpation, absence of glandular or hepatic involvement, and general improvement and relief of the stomach symptoms for a period of time when rectal feeding is resorted to. The treatment is necessarily surgical.

Congenital atresia proves rapidly fatal, while the adult form may run a long course. Exceptionally other forms of gastric tumor occur—*lipomata*, *sarcomata* (a total of 56 cases—von Graff), *fibromata*, and *cysts*.

HEMATEMESIS

Hematemesis is a symptom, hence it is hardly to be properly classed among gastric affections.

Etiology.—Among the causes of hematemesis are—1. Traumatic injury to the stomach. 2. Diseases of its coats (carcinoma, ulcer, miliary aneurysms, acute congestion). 3. A mechanical impediment to the portal circulation. 4. Vicarious menstruation. 5. The hemorrhagic dyscrasias, more particularly Banti's disease. 6. Esophageal varices in the course of cirrhosis of the liver may rupture, bleed into the stomach with subsequent vomiting of the blood. 7. A disease of some neighboring organ, such as carcinoma of the pancreas, may perforate the gastric coats and open its vessels.

Symptoms and Diagnosis.—If the fact that it is always a symptom, and not a disease, be recollected, the importance of recognizing its causal condition in each instance will be greatly facilitated. The manner of its occurrence and the characteristics presented by the blood often give a clue to its nature and origin. Thus, we have seen that the clinical signs in hematemesis due to carcinoma and ulcer of the stomach vary greatly, being almost peculiar to each. This fact must, however, be weighed with the history and symptoms of the case in which it may occur; in this manner, and in this manner only, can errors be avoided. A process of exclusion is the best way to reach a decision. If a careful inquiry determines the absence of morbid lesions of the stomach, such as carcinoma, ulcer, or chronic gastritis, then the other organs of the abdomen, and more particularly the liver, must be examined. If this and the heart be found to be healthy, attention should then be turned toward the state of the blood, as in the specific fevers.

Differential Diagnosis.—It is to be recollected that the source of the blood may be other than the stomach. Rarely, an abdominal aneurysm bursts into the stomach; occasionally, too, a thoracic aneurysm opens into the esophagus, whence the blood speedily finds its way into the stomach. A careful consideration of the history and of the attending symptoms, together with a thorough physical examination, will, after excluding the various conditions causing true gastric hemorrhage, lead to a correct interpretation of the phenomena. Blood coming from the *throat*, *tonsils*, *mouth*, or the *respiratory organs*, including the nose, is sometimes swallowed, and afterward ejected by vomiting. To discriminate from this condition it is only necessary to make an examina-

¹ *Interstate Med. Jour.*, 1914, xxi, No. 9.

tion of the lungs and elicit most carefully the history. It must also be recollected that *hysterical females* and *malingerers* have been known to swallow the blood of animals and other dark fluids, and vomit them subsequently. The vomitus may resemble dark blood in appearance when stained by bile or iron or after a free indulgence in wine. The points of contrast between hematemesis and *hemoptysis* are correlatively considered below:

HEMATEMESIS

The history points to gastric, splenic, hepatic, or cardiac disease, or anemia. A feeling of uneasiness, and sometimes of nausea or faintness, precedes the hemorrhage.

The blood is ejected by vomiting; violent vomiting may excite cough.

The blood is either clotted or fluid and dark; it may be mingled with remnants of food, and is acid at times in reaction.

HEMOPTYSIS

History of cough and other symptoms points to pulmonary or cardiac disease. A feeling of weight and uneasiness in the chest, a saline taste, and a tickling in the throat precede the hemorrhage.

The blood is raised by coughing or clearing of the throat, though, if it be swallowed, vomiting may follow.

The blood is bright-red, frothy, in small coagula, sometimes mixed with mucus, and alkaline in reaction.

Prognosis.—Hematemesis, except it be due to rupture of an aneurysm, rarely presents a hopeless prognosis. In cases of splenic enlargement, hepatic cirrhosis, or gastric ulcer, it may prove fatal.

The **treatment** has been detailed in the discussion of Gastric Ulcer.

NEUROSES OF THE STOMACH

NERVOUS DYSPEPSIA

(*Neurasthenia Gastrica*)

Definition.—A functional disorder of the stomach, usually characterized by regularly (and sometimes irregularly) recurring attacks of gastric disturbance followed by almost complete freedom from symptoms. Sensory disturbances of the stomach are constantly present, and with these either motor or secretory disturbances or both may be associated.

Etiology.—The majority of cases occur in highly emotional and hysterical persons, under such exciting conditions as great anxiety, violent passion, dissipation, social excesses, mental overexertion in business life, grievances, and any startling news. The condition is most commonly met with in healthy-looking, ruddy-cheeked adults. It is more common in females. Persons living amid luxurious surroundings suffer most. Gastric neuroses may be of reflex origin, arising from derangement of the nervous system. Deaver¹ states that they may be manifestations of disease in the liver, gall-bladder, bile-ducts, or appendix, which will demand surgical interference.

The **symptoms** follow immediately upon the action of the exciting cause and are largely under the influence of the emotions. In the ordinary form the gastric secretions are often normal, and the stomach is found empty after a test-meal within the physiologic time limit. There is anorexia, which occasionally alternates with a voracious appetite. After meals the patient complains of distress and oppression in the epigastrium; eructations, and an occasional regurgitation of the acid liquid or solid contents of the stomach, with heartburn, will also be noted. Vomiting is not rare, and occurs independently both of the time of eating and of the character of the food. *Gastric*

¹ *Amer. Jour. Med. Sci.*, February, 1909.

peristalsis is sometimes so well marked as to be readily felt and even visible through the stomach-wall. Kussmaul has called special attention to this symptom (*vide peristaltic unrest*, p. 772). The increased peristaltic waves excite cooing, gurgling sounds that are a source of annoyance.

The *physical examination* sometimes reveals abdominal distention and hyperesthesia of the surface, but no localized tenderness, pressure with the broad hand usually affording relief from pain. *Nervous phenomena* always exist, and their correct interpretation is of the utmost importance in the diagnosis. Neurasthenic and hysteric manifestations are commonly associated. The mental condition is unstable and illy regulated, and this fact furnishes a satisfactory explanation of the operation of the etiologic factors. The general health is in many instances not noticeably impaired; but in those subject to frequent vomiting and complete anorexia, the general nutrition suffers considerably.

Complications.—The bowels are often constipated, distended with gas, and may be the seat of an abnormal peristalsis. The *course* of nervous dyspepsia is chronic, and it may terminate in catarrh of the stomach.

Nervous dyspepsia with hypochondriasis forms a group of cases in which the hypochondriasis may sustain a causal relation; it may, however, be secondary to the gastric disturbances. It is apt to be marked after the gastric symptoms have lasted a long time. The symptoms other than the nervous are similar to those described above.

The **diagnosis** is based on the following points: (a) The etiologic factors. Here it is important to ascertain the particular causative influence that produces the gastric symptoms, taking also into consideration any well-recognized predisposing causes. (b) The course of the complaint and the absence of some of the physical signs and symptoms that would point positively to anatomic lesions of the stomach. When there is a catarrhal process, the symptoms become more pronounced immediately after taking food than in neurasthenia gastrica. The influence of the ingestion of indigestible substances upon sympathetic dyspepsia is often to relieve, or is of neutral effect, whereas in catarrhal indigestion it decidedly aggravates the condition. The dull pain after eating and the tenderness on pressure are more marked in the catarrhal variety, and the stomach contains large amounts of mucus. The symptoms of the latter do not intermit, as in nervous dyspepsia, but are more constant. The analysis of the stomach contents obtained after a test-breakfast shows digestion to be normal as to time and chemism, although rarely any secretory abnormality may be present. The motor function may be either reduced or increased, but, as a rule, it is normal.

Prognosis.—If there be an absence of an inherited predisposition, and if the cause is removable, complete recovery may be prognosticated. In a neurotic constitution, however, the tendency to recurrence is very strong. The most unpromising cases are those in which the cause is irremovable, though as to life the prognosis is favorable.

Treatment.—Every causal factor must be recognized and mitigated or removed. The dietary should be generous and composed of highly nutritious articles of food, and to convince the patient that his stomach is capable of digesting a full meal is the physician's first duty. So soon as the patient realizes the truth in reference to his digestive capacity his sufferings are largely at an end. The nervous system demands especial attention, and the internal treatment of the stomach is merely placebo. Nerve tonics combined with nerve stimulants are serviceable.

A change of air from the city to the country, the mountains, or the sea-coast is usually followed by improvement. In some manner the patient must

be extricated from the old surroundings under the influence of which the disease was started and has continued. Sea air has seemed to me to be more serviceable than mountain air in these cases, though I believe it to be an axiom in climatic therapeutics that the latter confers more lasting benefits than the former. These patients are often averse to taking exercise, but this sanitary measure should be insisted upon. Cold sponging of the surface, followed by friction to the skin, should be practised daily for its effect upon the nervous system. Occasional lavage, hot and cold douches, electricity (intra- and extragastric), and gastric massage may all be tried. In highly neurotic and hysteric females the S. Weir Mitchell treatment is often attended with good results. The hypochondriac form is often intractable. Strychnin, however, if perseveringly used, and if coupled with a change of air, often proves beneficial. One of the most obstinate examples of this nature that I have seen occurred in a retired merchant living in Philadelphia. This man was finally cured in consequence of his own suggestion, resulting in his removal to the country and engaging in farming.

SPECIAL FORMS OF GASTRIC NEUROSES CHARACTERIZED BY MARKED AND PECULIAR ANOMALIES OF SENSATION, MOTILITY, AND SECRETION.

NEUROSES OF SECRETION

HYPERCHLORHYDRIA

(Hyperacidity)

Definition.—An augmentation of the secretory function of the stomach during the digestive period, resulting in excess of HCl.

Etiology.—Hyperacidity is common during digestion, and is usually due to the causative influences mentioned under Nervous Dyspepsia (grief, great anxiety, mental overtaxation). The disease is common among the professional classes (male sex) and in the young. Highly seasoned foods and alcoholic intoxicants may occasion the condition. Lichty emphasizes organic disease of the gall-bladder and ducts as a cause, while chronic appendicitis or some other chronic inflammatory intra-abdominal lesion is a well-recognized cause.

Symptoms.—Hyperchlorhydria may be *continuous*, though more often it is *discontinuous* and lasts from a few hours to several days. After the periodic form has lasted a long time it may gradually become a permanent condition. The patient first complains of *uneasiness* in the epigastrium one or two hours after meals. Later, this amounts to *pain*, and follows every meal after a like interval. The duration of the pain is from one to three hours. Acid eructations are frequently noted. The increase of hydrochloric acid interferes with the digestion of starches, and thus tends to increase the pain. On the other hand, however, a diet composed of albuminoids often affords relief, and the salts of the alkalies also ease the pain. Associated *nervous symptoms* (headache, dizziness) are often observed, though the bodily nutrition is usually well maintained. *Palpation* of the epigastrium may show a diffused tenderness. Evidences of moderate gastrectasis may be detectable. The amylolytic power of the stomach is uninfluenced as a rule.

Diagnosis.—Though the diagnosis of hyperacidity is made probable by the above symptoms it is rendered certain only by a repeated analysis of the

gastric contents. The findings, according to Einhorn, are: (1) On examination of the stomach in the fasting condition the organ contains only a few cubic centimeters of juice; (2) one hour after Ewald's test-breakfast the hyperacidity is increased, owing to the great amount of free HCl present and there is an associated hypersecretion. To make a decisive diagnosis the examination should be made every ten minutes by means of the duodenal tube, as the height of the acidity may be reached before or long after the theoretic height of digestion.¹ Thus Rehfuß has shown that there may be three types of secretory curves normally, viz.: the isosecretory, the hypersecretory, and the hyposecretory, depending on the rapidity of acid secretion, height of acidity, and continuation of acid crest to the end of the limit of digestion.

Gastric ulcer must be eliminated. In this disease hyperacidity occurs, but the pain is aggravated immediately after eating, and is not relieved by albuminous food nor by large doses of alkalies, as in hyperchlorhydria of nervous genesis. In ulcer, moreover, the pain often leads to vomiting, and severe, painful attacks frequently occur at night.

Gastrosuccorhea (*Reichmann*); **Gastroxynsis** (*Rossbach*).—In this affection there is an increase of hydrochloric acid, either constantly or intermittently, when no food is present. An *epigastric gnawing pain* and nausea appear in the full bloom of health. The *nausea* soon results in the *vomiting* of enormous quantities of gastric contents. The *appetite* is lost, but the thirst is excessive, and the amount of drink taken and of liquid vomited are proportional. During the night or in the early morning hours the patient commonly vomits large amounts of a clear or bile-tinted liquid containing hydrochloric acid and the gastric ferments in excess. This may be followed by persistent vomiting, attended with much retching. After a lapse of a few hours the ejection of a large quantity of highly acid liquid may be repeated. The *pain* often becomes intense, headache is common, and a tendency to collapse is usually marked. The attacks last, as a rule, about two or three days, when they quite abruptly give place to apparent good health. *Recurrence* at the end of periods ranging from a few months to a year or more are common. A physiologic form has been advanced.

The *diagnosis* is made upon the presence of the cause (a violent psychic shock), the clinical symptoms and course, as well as upon the results of oft-repeated analyses of the vomitus. Gastric ulcer and certain organic spinal and cerebral nervous affections, in which there is excessive gastric secretion, must be excluded before diagnosis can be made.

Gastrosuccorhea Continua Chronica.—Reichmann first described a condition characterized by a *constant hypersecretion of gastric juice* either in the absence or presence of food. (Hawk and Rehfuß have shown that normally there may be present in the fasting stomach from 30–120 c.c. of gastric contents, usually containing bile and trypsin, regurgitated from the duodenum; the free and total acidity varying from 20 to 40 per cent. and 26 to 50 per cent. respectively). The *symptoms* are much the same as those in *hyperacidity*, but tend to become continuous, so that the vomiting finally becomes a daily occurrence. In the fasting state a highly acid secretion that contains no food-particles flows through the stomach-tube. Albuminoids are rapidly and starches slowly digested. The disease is quite rare, and must not be confounded with the organic diseases to which continuous gastric succorhea may be secondary and upon which it is dependent. Schreiber, Boas, and others believe that this is almost always a symptom of gastric atony or gastric ulcer.

Larval Superacidity.—This variety arises early in the period of digestion; the amount of gastric contents after the test-meal is large, and consists mainly

¹ See papers of Hawk, Rehfuß, and their co-workers.

of a watery secretion with low specific gravity and with a normal acidity. Leube has described a neurosis with constant **subacidity of the secretion**.

Gastromyorrhea.—The fasting stomach often contains small quantities of mucus (5 c.c.), but when above 25 c.c. Cuttner considers it pathologic and terms the condition *gastromyorrhea*. It seems to be largely of nervous origin. There are two forms of the disease, the intermittent and the continuous. In the first, the attacks develop suddenly with severe headache, pain, and vomiting, and after a period varying from one to five days the attack suddenly ceases (Friedenwald). The other type is usually discovered in examination for chronic catarrh. The *treatment* is symptomatic, although lavage is of service in the acute form. The neurotic tendency must be combated during the intervals.

Achylia Gastrica (*Einhorn*).—The suspension of the gastric secretions may result either from gastric atrophy (common) or from a nervous derangement of secretion. The condition has been mistaken for carcinoma of the stomach. Lactic acid, however, is not present in excess. Eosinophil cells generally occur in the gastric juice. Skray found in cases of simple achylia that hydrochloric acid appeared in the stomach contents after meat was added to the test-breakfast, while in carcinoma it remained absent. Functional achylia of the stomach and pancreas may occur together (Orloff). Achylia gastrica may cause chronic lenteric diarrhea (A. A. Jones).

The **prognosis** in the foregoing affections is not bad as to life, and not infrequently a cure, even, can be effected.

Treatment.—The dietetic treatment differs according to different observers. Einhorn advises three large and two small meals, composed principally of nitrogenous articles, daily. Physiology, however, teaches that when milk, bread, fats, and starchy substances are taken, the amount of HCl secreted is small, hence the proper causal treatment is to limit the amount of proteins. Acids, tobacco, and spirits—substances that excite the glands of the stomach—must be excluded. The medicinal treatment should, in addition to meeting the general neurotic condition, consist of full doses of sodium bicarbonate or sodium citrate. In some cases more active alkalies than sodium bicarbonate may be needful—*e. g.*, magnesium and sodium salicylate, aluminum silicate (3ss-j ad aqua ʒiij a. c.), either separately or in combination. Belladonna reduces acidity and may be combined with the alkalies. Lavage daily, before the chief meal, is beneficial and may be combined with a salt-free diet. Lemoine advises hydrotherapy and rest to strengthen the nervous system.

NEUROSES OF MOTILITY

INCREASED PERISTALSIS OF THE STOMACH

(a) **Belching and Eructations.**—These may be of *nervous origin* and are met with generally in *hysterical* subjects, and less frequently in *neurasthenics*. The air is swallowed, and then expelled with more or less noise, owing to an increased contractility of the stomach. The gas is *odorless*, and differs in this point from the gases of fermentative dyspepsia. Epigastric distress and distention often arise, and certain nervous phenomena, as anxiety or palpitation, may coexist. In hysterical subjects the belching may be from the esophagus alone.

(b) **Pyrosis** means regurgitation of the acid contents of the stomach.

(c) **Rumination** (*Merycism*).—A rare affection in which the food is regurgitated into the mouth, the cud chewed, and again swallowed after the fashion of ruminants.

(d) **Nervous Vomiting.**—This is a *reflex neurosis* that may affect persons of any age, though most frequently it is seen in adult females with an hysterical

tendency. Without previous nausea, and independently of the character of the food taken, the contents of the stomach are readily expelled or, more correctly speaking, regurgitated into the mouth, and then expectorated. Though this usually takes place after meals, it may occur without reference to meal-time—a feature that indicates its nervous origin. The *attacks* of vomiting are separated by longer or shorter intervals of excellent health. Periodic vomiting may also occur independently of hysteria or other nervous affections, as pointed out by Leube. The *course* is rarely unfavorable.

(e) **Peristaltic Unrest** (Kussmaul).—It has been observed in compensatory hypertrophy of the stomach wall following pyloric stricture. In a case of gastric carcinoma in my own care the supermotility of the stomach caused an almost immediate expulsion of the gastric contents, and even of the rigid test-meal at certain times. True *gastrospasm* shows no peristalsis and may be circumscribed.

(f) **Cardiospasm**.—By this term is meant a painful cramp of the cardia. Two forms are distinguished: (a) acute cramp; (b) chronic cramp (exceedingly rare). Among causes are neurasthenia, hysteria, and local irritation (thermal, mechanical). Bassler found, postmortem, firm adhesions of the pleura, particularly at the base, in association. Chronic spasm may lead to complete atresia of the cardia, and is a distressing affection. In acute cardiospasm the attacks may recur.

(g) **Pylorospasm**.—Cramp of the ring-musculature of the pylorus may be *primary* or *secondary*. The latter is due to intense local irritation (hypersecretion, gastric ulcer, excess of organic acids). The painful spasm in the pyloric region induces stagnation of the ingesta, followed by atony of the stomach and consequent dilatation. *Gastrospasm* may simulate ulcer or ring carcinoma when confined to the pylorus.

Treatment.—To the regimenal management the attention of the physician should be primarily directed. The medicinal treatment is to be aimed at the causal nervous affection. The valerianates and the bromids often do good service. For the cramp of the cardia and pylorus belladonna is especially efficient; these failing, stretching of the cardia, either by means of a bougie or an inflatable bag, is indicated. If internal treatment fails in functional motor insufficiency, operative intervention may be indicated.

DIMINISHED PERISTALSIS OF THE STOMACH

(a) **Pyloric Relaxation or Incompetency**.—This is a neurosis that allows the partially digested gastric contents to pass the portals of the stomach prematurely. It likewise permits the regurgitation of the intestinal contents into the stomach. Its recognition is possible upon inflating the stomach, when gas may be seen to pass into the intestines, and also upon the regurgitation of intestinal contents into the stomach. It is frequently found when there is a hypo-acidity of the gastric contents.

(b) **Insufficiency of the Cardia**.—This condition leads to eructations and regurgitations, and when these are of aggravated form they impair the general nutrition. Ordinarily no ill-effects follow.

(c) **Atonic Dyspepsia**.—This may occur either as a neurosis or secondary to chronic gastritis and reflexly in chronic appendicitis, carcinoma, and tuberculosis of the intestines. It implies *hypomotility*. The *chyme* is retained in the stomach beyond the natural time-limit. There is an *epigastric oppression* with a distention of the organ during digestion that tends to become permanent. There are eructations of gas, an impaired appetite, and often constipation. The stomach is found empty in the morning, and six or seven hours after Leube's test-meal it contains some chyme.

Treatment.—The diet is to be regulated as in chronic gastritis with dilatation. It is rarely necessary to restrict the solids to any marked extent, but the quantity of fluids should be lessened. The patient must be taught to eat slowly and masticate thoroughly. His hygienic standard of living must be high, and he must not be allowed to overuse his mental faculties. Exercise in the open air and cold baths, properly regulated, are potent for good. Of medicines, strychnin stands first, and I have found the following formula of great service:

R. Tr. nuc. vomicæ, fʒiiss (10.0);
 Inf. gentian. q. s. ad fʒiv (120.0).—M.
 Sig. ʒij (8.0) three times daily.

Electricity is indicated, and intragastric faradization has given excellent results. The constipation is to be overcome by an appropriate dietary (green vegetables, graham bread, an abundance of fruit). There is an advantage in assuming the right lateral position, which hastens evacuation. Lavage deserves a prudent trial.

NEUROSES OF SENSATION

CARDIALGIA

(*Gastralgia; Gastrodynia*)

Definition.—Severe paroxysmal pain in the epigastrium in the absence of gastric lesions. There are two other forms of this disease that are clinically identical with nervous gastralgia, the one occurring in ulcer and carcinoma of the stomach, and the other in certain chronic nervous diseases, forming the so-called gastric crises.

Etiology.—The subjects are often hereditarily predisposed to neuroses of other types. Such conditions as anemia, exhaustion from repeated hemorrhages, and syphilis exert a *predisposing* influence. The female sex is more liable than the male, and in the former it appears to be dependent upon disturbances of the menstrual function or quite frequently upon hysteric conditions. It is sometimes excited by reflex irritation, by deep grief, worry, and great anxiety. Hypochondriasis and hyperacidity are also among its frequent causes.

Symptoms.—These are *sudden in their onset* as a rule, and quite characteristic. Occasionally the attack is preceded by anorexia, or it may begin with a sense of oppression and distention in the epigastrium, lasting for a few minutes. In any event, the onset of the attack proper is marked by *agonizing pains* in the epigastrium, that dart through to the back, and at times also pass around the lower ribs. The seizure lasts from a few minutes to an hour or two, and terminates with *eructations of gas*, or, less frequently, with vomiting. From the nature of the causative factors it is obvious that the gastralgic seizures are in nowise dependent upon the character of the food taken; hence the fact that they occur more frequently when the stomach is empty need occasion no surprise. Firm pressure over the epigastrium relieves the pain. *Nervous phenomena*, varying with the etiology of individual cases, are constant attendants, but cannot be detailed here. A distinct clinical variety is found associated with that form of nervous dyspepsia in which an excess of HCl is secreted (*vide* Hyperacidity); this occurs at varying intervals. Many functional nervous disturbances are thus subject to the law of periodicity. I believe that a very small percentage of cases are caused by malaria, since I have met with two such cases in a malarial district, both of which yielded readily to quinin.

The disease took on a desultory, periodic character, and was associated with other malarial symptoms.

Diagnosis.—The history, the absence of any local causes, the violent, spasmodic attacks of pain, that cease abruptly, and their occurrence at irregular intervals, will enable the clinician to render a positive diagnosis in most instances. The gastric crises that occur in locomotor ataxia closely resemble gastralgia and must be excluded. Gastralgia may be simulated by cholelithiasis (*q. v.*). To discriminate this condition from *gastric ulcer* is difficult, but stress has been laid upon the differential points in the description of the latter disease (*vide p. 756*).

Prognosis.—This depends entirely upon the causal condition. The disease itself has no intrinsic fatal tendency.

Treatment.—This is to be subdivided into: (*a*) the treatment of the attack; (*b*) the management of the intervals between the seizures. The pain is, as a rule, sufficiently intense to demand morphin, which is best administered hypodermically in combination with atropin. This should not, however, be given if an idiosyncrasy exist. In mild attacks the constant or the faradic current often affords prompt relief. Under these circumstances counterirritation, together with the internal use of Hoffman's anodyne or chloroform in small doses, may relieve the pain.

(*b*) *The Management of the Intervals.*—Here the physician's efforts should be directed to the detection of the causes and their removal by appropriate means. In hysteric females I have obtained good results from the prolonged use of valerianates, combining with them iron and arsenic, thus:

R.	Ferri arsenatis,	gr. ij	(0.13);
	Zinci valeratis,	gr. xvijj	(1.20);

A change of air is often highly serviceable, and should be advised whenever financial considerations permit. These patients are constantly in a more or less exhausted, anemic, and run-down condition, and a tonic plan of treatment is always indicated to overcome the primary cause. In the intervals between the attacks digestion, as before stated, proceeds normally, and the stomach, therefore, requires no treatment. Constipation, if present, is a condition demanding relief not, however, by the use of purgatives, but by such means as massage, a suitable diet, enemata, or laxative suppositories. The physician must carefully regulate the sanitary particulars of the patient's daily life.

HYPERESTHESIA OF THE STOMACH

This is met with in functional and organic diseases, as well as in chronic gastric catarrh and other affections of the stomach. Again, it may occur as a *neurosis*, most frequently in chlorotic girls and women. There is an increased gastric sensibility, so that the mildest irritant produces *painful sensations* that may be either gnawing or burning in character. A feeling of fulness and nausea are among the common features of the complaint. Food and certain articles that are not easily digestible may afford relief, and, oppositely, fasting or restriction of diet may aggravate the condition. The complaint, however, is often aggravated during digestion, particularly after excessive indulgence in certain kinds of food (crabs, lobsters, oysters, strawberries). Cutaneous symptoms, as erythema and urticaria, may appear. *Hypochond-*

driasis, neurasthenia, and hysteria are often associated. The above symptoms are dependent upon an individual idiosyncrasy.

Treatment.—At first a restriction of the diet to soft and liquid articles should be tried, and later a cautious return to solid food is to be made. Of medicaments, the bromids, given for a period of two or three months, have given the best results in my own hands. For the chlorotic type iron in the form of Blaud's pill, in ascending doses, is the best treatment.

ANOREXIA

This consists merely in a loss of appetite, and occurs in many organic gastric disorders. It may also be a primary gastric *neurosis*, the latter being often associated with gastric hyperesthesia. Anorexia sometimes leads to a repugnance to food and a degree of abstinence that may induce grave nutritional disturbance. Among exciting causes mental shock of any sort ranks first. The recognition of anorexia as a neurosis of the stomach is difficult after the general nutrition has become seriously impaired. Chronic dyspepsia, phthisis, and other diseases associated with emaciation and debility must be excluded before the diagnosis is established.

HYPEROREXIA

(*Excessive Appetite*)

This may either be symptomatic of other affections (*e. g.*, diabetes mellitus); may be a gastric neurosis; or it may be the result of hypersecretion, as in gastric ulcer. It may also be paroxysmal (*bulimia*). The patient complains of burning sensations in the epigastric region and of an insatiable hunger. The symptoms of neurasthenia and hysteria are often in association. The local and general symptoms are relieved by food. It may also accompany affections of the brain, exophthalmos, and migraine. In *bulimia* the abnormal sensation of hunger may come on at any hour, even immediately after abundant food has been taken. When the morbid sensation of hunger develops more gradually and some time after meals it is spoken of as *polyphagia*.

Pica is the term applied to the craving for substances not used as food (slate-pencils, dirt, chalk).

Malacia represents the desire for highly spiced dishes (mustard, salads, pickles, fruits).

The above conditions are met with in neurasthenia, chronic gastric affections, and chlorosis.

VIII. DISEASES OF THE INTESTINES

METHODS OF DIAGNOSIS

Examination of the Feces.—Although the results are in some cases unsatisfactory, an examination of the feces should not be neglected, especially in the more serious affections of the intestine. This embraces: (*a*) a macroscopic; (*b*) a microscopic; (*c*) a chemical, and (*d*) a bacteriologic examination.

(*a*) The *macroscopic* appearances often suffice. A thorough inspection of the stools furnishes valuable points in regard to the presence or absence of coarse parasites, fragments of tumor, foreign bodies, concretions, blood, bile, fat, pus, mucus, undigested meat, and the like.

The shape, color, and consistence of the stools must be noted, and it is

to be remembered that in these particulars, as well as regards their frequency, they exhibit a considerable range of normal variations, according to individual peculiarities, the character of food taken, and so on. It is to be recollected that normal stools contain fat in varying amounts, for the reason that only a limited quantity can be emulsified and taken up from the intestine. The naked eye may, at times, detect its presence from the "peculiar silvery appearance" of the feces. Fat in the stools (*steatorrhea*) is often pathologic, and the separate affections in which it is met with will be considered hereafter. The dejecta present a shining, tallowy appearance, either throughout or in circumscribed spots. Again, the fat may occur in the form of oil floating on the surface of liquid stools. Mucus is also visible, either as slimy or jelly-like masses, or as shreds and granules (sago-grains). Diarrheal stools should be examined macroscopically with great care for gross admixtures (flakes of casein, bits of meat, etc.). Constipational dejections often assume a rounded form (*sheep's dung*) on account of their delay in the large bowel. They may attain to the size of an orange, and may be, though rarely, enveloped in mucus or blood streaked. Their color is dark. On the other hand, the stools may be colorless in cases in which the bile-ducts are occluded; these usually contain a large proportion of fat, though not invariably. The effect of certain drugs upon the color of the stools is to be borne in mind. When blood is intimately mingled with the feces they have a reddish, dark- or blackish-brown (tarry) color, according to the quantity and the time allowed for decomposition in the intestine. Blood, either clotted or fluid, may also be passed in a pure state. Its source is usually the lower bowel, though when peristalsis is augmented, it may come from the small intestine, as in typhoid fever. Pus may occasionally be recognized macroscopically. From a diagnostic point of view it is most important to examine for biliary concretions in doubtful abdominal colic. "For the detection of small concretions the stools should be passed through a sieve" (Ewald).

(b) *Microscopic Examination*.—Diarrheal stools can be examined as discharged, but to solid and mushy dejections normal salt solution or distilled water should be added and all hard masses thoroughly broken up. Different portions of the stools are to be selected for microscopic examination. *Microscopically* we are enabled to detect the eggs of parasites, pus, blood, protozoa, mucus in the form of shining, vitreous, homogeneous, or whitish masses; and in the interior of the latter certain pathogenic bacteria, various crystals, and intestinal epithelium may be seen. Remnants of vegetable food may simulate mucous islets, but the former strike a blue color on the application of Lugol's solution. Microscopically, diarrheal stools show undigested muscle-fibers, fat-crystals, vegetable cells, starchy granules, and innumerable bacteria. Von Leersum¹ advocates the sedimentation process until the sediment finally contains most of the meat-fiber, and that the nuclei be then stained and examined to estimate the degree of pancreatic digestion. Undissolved starch in even moderate quantity points to catarrhal enteritis of the small intestine. On microscopic examination of the dejections in constipation we find "a copious detritus of brown or black color, usually numerous colorless or slightly tinged triple phosphates (phosphate of ammonium and magnesium crystallizing in the form of a coffin-lid), or, more sparse, crystals of neutral phosphate of lime." Seldom do we meet with the rhomboid plates of cholesterin, which are recognized in that they are colored from a reddish-brown to violet by dilute sulphuric acid (1 : 5), and become blue or green on the further addition of a solution of iodine. Needle-shaped crystals of fat, single and also in the forms of tufts, are frequently met in obstruction of the biliary ducts. Bile-pigment

¹ *Münch. med. Woch.*, February 6, 1912.

cannot be detected. Remnants of food are sparsely present in normal feces. Epithelium from the mucous membrane, pus-cells, and blood-corpuscles, unless they come from the passage of the fecal mass through the anus (in which case they are simply adherent to the external surface of the scybala and are but little changed), are greatly altered; they are fatty, degenerated, shrunken, and hardly recognizable. Rhomboid crystals of hematin may be at times observed. The microscopic examination for animal parasites will be referred to in appropriate sections of this work.

(c) *Chemical Examination.*—The presence of bile-pigment is easily detected by the Gmelin reaction. The stools must, if needful, be rendered fluid by the addition of water, then filtered, and the filtrate allowed to dry. At the margin of the drop the characteristic green color will appear. Urobilin strikes a red color. The stools in diarrhea may contain ferments capable of digesting albuminoids. The fatty acids are distinguished from fatty soaps by the solubility of the former in ether.

For the detection of occult blood, to an ethereal extract of 2 to 5 c.c. of liquid feces or solid stool reduced by water, 2 c.c. of a 10 per cent. solution of guaiac in glacial acetic acid is added, followed by 2 c.c. of hydrogen dioxid, the mixture is thoroughly shaken, and in the presence of blood turns blue. A dilution of blood, 1 in 250,000, is recognized by the Adler technic, in which to boiled feces add 1 c.c. glacial acetic acid in which a small amount of benzidin has been dissolved, alcohol, and an equal volume of hydrogen dioxid; if positive, a dirty green or deep blue develops. Boas' phenolphthalein test may also be employed.¹ In bleeding from the stomach and intestines, from the mouth, pharynx, rectum, or vagina, the ingestion of meat, watermelon, or medicinal iron must always be excluded. The indol-reaction may be increased, pointing to increased intestinal putrefaction.

(d) A *bacterial examination* of the intestinal contents, and particularly of any mucus or mucopus that may be discharged, may decide the diagnosis of certain intestinal disorders (tuberculosis, amebic dysentery). For the method of carrying on these investigations the reader is referred to special works on diagnosis and bacteriology.

(e) The roentgen rays have been shown to be of great diagnostic value in many intestinal conditions.

Physical or External Examination.—*Inspection.*—This should be made with the patient in the dorsal position and with proper illumination. Localized prominences are to be noted (sometimes simulated by localized contractions of the abdominal muscles). The influence of respiration on these circumscribed bulgings is also to be observed. In the absence of unusual distention of the abdominal walls it is of great value to inflate the large intestine with air *per rectum*, and to note the progressive distention of the intestinal coils as a means of detecting obstructing lesions in the bowel; the position and mobility of a tumor should also be noted. It is often of marked aid to inspect the mucosa of the rectum by the use of approved specula. The volume of the abdomen may be diminished or even "scaphoid." Abnormal peristalsis may rarely be noted (important if associated with distention).

Palpation.—This is of first importance. The patient should occupy the dorsal decubitus, with the head raised, the thighs drawn up, and the mouth open, so as to relax the abdominal muscles. Something may be gained in this direction by distracting the patient's attention. I have found that placing the patient in the lateral decubitus, with the thighs flexed on the abdomen, to be the most satisfactory way of determining the degree of mobility of certain tumors. The examiner should not fail to remember the knee-elbow position

¹ *Amer. Jour. Gastro-enterology*, September, 1911, p. 48.

in cases in which it is desired to palpate the parts occupying the bottom of the pelvic cavity and all deep-seated, movable growths. In certain cases relaxation of the abdominal muscles is only obtainable by anesthetizing the patient, and I do not hesitate to do this in cases in which the diagnosis is important. In palpating the abdomen for abnormal conditions we must keep in mind steadily the relations of the different parts of the intestines, and also that the latter may vary considerably in position—a fact particularly true of the transverse colon (*vide* Enteroptosis). In this connection Ewald's statement "that abnormally situated organs or neoplasms of parts other than the intestines will, under the pressure of the intestines filled with air or water, return to the position that the organ normally occupies," should be emphasized. New growths of the pancreas, of the spinal column, or of the pelvis, and retroperitoneal tumors will remain fixed. Palpation may detect pathologic peristalsis, and increased resistance if the coats are thickened. Tenderness, localized or diffuse, as well as peritoneal friction, is noted. The rectum may be palpated if the symptoms point to disease of that organ.

The palpation of pathologic conditions of the intestines will be considered in connection with the separate intestinal affections.

Percussion detects a fluid effusion either in the general peritoneal cavity, the position varying with the patient's posture, or in circumscribed localities; the latter must not be confounded with areas of dullness that are occasioned by splenic and hepatic enlargements, solid new growths, or abscesses. Air in the peritoneal cavity (*meteorismus peritonei*) generally gives a pure tympanitic note, though if the tension be very strong, a non-tympanitic tone may be elicited. These sounds are general, even extending up to the fifth or fourth rib, and hence they cover the regions of the spleen and liver. The best results when the abdomen is not tense are obtained after inflation of the large intestine with air. The pitch of the tympanitic note becomes elevated with increase in the tension of the gut; it falls with relaxation of the bowel. Hence the large cannot always be told from the small intestine by percussion.

Auscultation.—Noises are often audible either at a distance or by means of a stethoscope applied to the abdomen. They are sometimes occasioned by the natural peristaltic movements or by certain voluntary or involuntary spasms of the abdominal muscle. I have repeatedly confirmed the observation of Ewald, who frequently found in those suffering with chronic intestinal indigestion a swashing or splashing noise, sounding as though air and water were being forced through a narrow space in the ileocecal region. These sounds may rarely be found in healthy persons. Similar noises sometimes have their seat in the descending colon, particularly if the bowel is unnaturally dilated by air or fluid. They are often audible prior to an evacuation in cases of colitis. Noises may also originate in the transverse colon, and to discriminate these it is necessary to empty the stomach if we would avoid confusion with identical gastric sounds. Direct auscultation of the intestines renders audible the peristaltic movements, and the absence of the latter indicates paralysis of the intestine, which may be local or general. Friction-sounds may be audible when inflammatory exudates are present. When obstruction of the large intestine is suspected, auscultation should be practised while air is being forced into the rectum, inasmuch as the degree of permeability can be thus determined. Metallic tinkling and amphoric noises may be audible, particularly on making auscultatory percussion, but these are without real diagnostic value.

GASTRO-ENTEROPTOSIS

(*Visceroptosis; Splanchnoptosis; Glénard's Disease*)

Definition.—The descent of the viscera—*e. g.*, stomach, intestines, liver, spleen, and kidneys—from their normal positions. Gastro-enteroptosis is not a morbid entity, but a condition or symptom-complex dependent upon a variety of causative factors.

Etiology.—The fact that dropping of the stomach and kidneys is often linked with ptosis of the right kidney, and less commonly with that of the liver and spleen by common etiologic influences, must be recollected. Among recognized causes are: (a) Age and sex. Meinert, of Dresden, found among girls of fourteen years gastroptosis in 80 per cent., and among the women who presented themselves at his private clinic in 90 per cent. According to my observation, gastroptosis is not as frequent among American girls and women as among the Germans. "Dislocation occurs in about 5 per cent. of the male population of Dresden." In a series of 898 patients with digestive symptoms examined roentgenographically by Levy and Kantor the incidence of gastroptosis was 64.4 per cent. They found that the condition was only slightly more frequent in women than in men, the proportion being about 6 to 5. It was found to occur more often in individuals under forty years of age than in those forty or over, and this relationship held for both sexes. (b) Improper clothing, particularly tight lacing. (c) Dislocation of the right kidney. This operates potently, and prolapse of other abdominal organs, as the liver and intestines, is often associated, and may constitute the chief point of departure. (d) Repeated pregnancies and recurrent ascites, inducing a relaxed state of the abdominal wall. (e) Muscular strain and local injury, by diminishing the tonicity of the gastrohepatic omentum. (f) Abnormalities of the chest formation (kyphosis); gastrectasis; great meteorism and enlargement of the abdominal organs, especially of the spleen and liver. Certain chronic diseases may be active, *e. g.*, chlorosis, tuberculosis. (g) Congenital fragility of the supporting ligaments. (h) Kaiser mentions a disproportion between an unusually large abdominal cavity and unusually small abdominal viscera.

Symptoms.—The cases should be classified, so far as possible, according to their etiology, although this is not always practicable. The cases due to repeated pregnancies and recurring ascites form an easily recognizable class. They may manifest an extreme degree of ptosis of both stomach and intestines, but, as a rule, the descent is moderate, the greater curvature of the stomach being found about a handbreadth below the transverse umbilical line. In many of these cases symptoms fail to appear, and the condition may be discovered in the course of a routine physical examination. The diagnosis rests upon the history, together with the physical signs after inflation of the stomach with air.

The cases that follow either an acute or chronic illness, with wasting, are easily distinguishable, and manifest disturbance of digestion coupled with the symptoms of neurasthenia. Among the nervous manifestations, throbbing in the abdomen, dragging pains, and cardiac palpitation, as well as debility and lack of energy, are observed. Cases of gastro-enteroptosis attended with ptosis of the liver are commonly caused by tight lacing, which tilts the organ forward and downward, a condition often confused with enlargement of the liver. A floating spleen is sometimes noted, and the organ may be found in the pelvic region. It has been confounded with ovarian and fibroid tumors.

Both gastric secretion and motility are apt to be diminished in gastro-enteroptosis, the latter being due to stasis occasioned by pyloric spasm and kinking of the duodenum. Steele and Francine, from a study of 70 cases,

found that diminution of free hydrochloric acid was the rule. Says Sandrock: "It would seem conclusive from my figures that in ptotic stomachs there is a general tendency toward diminished acidity, which, however, is influenced by the degree of atony present." *Constipation*, due to defective peristalsis, and *colicky pains*, due to spasm of the intestinal muscles, are important features. *Diarrhea* is sometimes present. Chief among the intestinal symptoms, however, is excessive flatulence, and "there is membranous enteritis at times, the latter probably being due to the flexures that produce an arrest of fecal masses, and this, in turn, causing inflammation" (Boas). In the majority of these cases both stomach and intestines are abnormally low, and the symptoms of nephroptosis are often associated (*vide* p. 911).

The **physical signs** after inflation of the stomach permit the accurate demonstration of gastropptosis. The epigastrium is hollowed, while the lower quadrants of the abdomen are prominent. The percussion-note now indicates the position of the organ. It is to be borne in mind that the cardiac end remains fixed at the twelfth dorsal vertebra, while the pylorus moves downward and to the left; this will explain why the epigastrium is free of gastric tympany. Dilatation of the pyloric end is present in varying degree in most cases. Much more rarely general dilatation is found with gastropptosis. *Succussion splashing sounds* may be heard if atony, with retained gastric contents, obtains. Roentgenologic studies have shown that it is not so much a question of how low the stomach extends into the abdomen, but that it is more a question of the relation of the fundus to the position of the pylorus. Thus, if the stomach is low but the pylorus is so situated that the stomach can empty normally, ptosis or, at least, pathologic ptosis cannot be said to truly exist.

The colon may show accessory loopings and tortuosities as the result of an unusually long mesentery. The transverse colon and cecum are most often seen to deviate from their normal course, with kinking at the hepatic and splenic flexures, as well as "at the pylorus, where the duodenum passes into the jejunum and where the ileum enters the cecum" (Osler). Inflation of the colon with gas or water may enable one by careful percussion to detect this condition with reasonable certainty. Radiography may give accurate information as to the position of the colon after it has been filled with an emulsion in which barium sulphate or bismuth is contained. Lying immediately above the symphysis pubis, the colon is sometimes elongated and tortuous, "**S** or **M** shaped."

Diagnosis.—It is necessary to differentiate gastrectasis from gastropptosis; this is easily accomplished by the method of inflation, since it makes plain the course and position of the lesser curvature and of the pylorus. It must be recollected that more or less dilatation of the stomach may be consequential to gastropptosis. Colo-ptosis may be determined by inflation with air or gas, and roentgenography is of the greatest diagnostic value in this condition (Fig. 52). Movable tenth rib is common, but not a distinctive sign, since it is just as frequent in nervous gastric disturbances in general. Again, after the injection of water (f3 viiss-ixss—200-300 c.c.) a splashing sound is audible; this is double the amount of water required in the normal condition. The pancreas, except the segment which is firmly bound to the root of the mesentery, may undergo descensus, and may be felt as a constricted cord. It must not be forgotten that many stomachs that are ptosed according to roentgenologic or physical findings are functionally efficient. Moreover, there is no standard upon which to determine whether a moderate degree of ptosis of the stomach or colon exists. Modern ideas seem to hold that variations of great degree may exist which are in no sense pathologic. Apparently normal individuals with normal functional power of the gastro-intestinal tract may show changes in position of the stomach and intestines which a few years ago

would have been considered distinctly abnormal, but which nowadays are held to be normal for that individual.

The **prognosis** as to cure is encouraging in the milder cases at least, while in a minority of the severer ones amelioration only is attainable without operative intervention.

Fig. 52.—Roentgenogram of enteroptosis (Pfahler).

Treatment.—Prophylaxis.—There is often to be noted a characteristic body form (see Nephroptosis, p. 911), with slight displacement of the abdominal viscera. In such, attention to diet, recumbency after meals on the right side, carefully chosen physical exercises to strengthen the diaphragm and abdominal walls in the young, as well as efforts to increase the bodily weight

and strength, should be carried out. A condition of subnutrition and deficiency of body weight is often operative as a cause, and such patients should be restored to normal tone and weight by suitable measures. Following acute disease patients should not be permitted to resume active occupation until health is fully regained, especially if any tendency to gastropnoxis is shown. An abdominal binder is useful after delivery, and afterappings for recurring ascites.

Success in the treatment lies in the direction of meeting the special etiology of individual cases. Unfortunately, in many cases, splanchnoptosis is caused mainly by a congenital weakness of the supporting ligaments, to which certain of the other causative factors may be superadded. The medical treatment aims at meeting symptomatic indications, such as flatulence and fermentation, as well as overcoming atonicity of the gastro-intestinal tract. Regular bowel movements are to be secured by the use of mineral oils; dose, f3j on retiring, to be renewed on the following morning if required. To improve the tonicity of the abdominal walls, massage, gymnastics, and athletic exercises, as well as hydrotherapy, are useful.

A careful dietary is to be advised in cases in which the digestion is more or less impaired. Tender meats, milk, stale bread, green vegetables, and stewed fruits, as well as small amounts of carbohydrates and fats, may be allowed. It is often necessary to increase the body weight; this may be accomplished by adding raw eggs and milk between meals, associated with rest. The Weir Mitchell rest treatment is indicated in cases manifesting marked neurasthenic symptoms, combined with emaciation. Iron and arsenic are the remedies of choice if anemia be present.

Many cases are relieved by the support of a properly adjusted belt and pad. McCloskey advises for the support of the viscera a strip of zinc oxid adhesive plaster across the lower abdomen, to each end of which is attached a bandage long enough to reach around the body above the iliac crest.¹ My own preference is for a belt which should not extend higher than the umbilicus above, and it should be adjusted while in the recumbent posture, the patient being taught to draw the abdominal viscera upward at each step during its application, so as to furnish a support to the fallen organ. The aim should be to keep the belt fitting quite snugly below but loosely above, and, to prevent its riding up, perineal straps should be provided. A thin pad should be placed across the lower segment of the belt. The great majority of the cases can be successfully treated in this manner, although both time and patience are required. Operations for the relief of ptosis have been extensively advocated and have run in great waves of popularity, which have so ebbed in the present time that only for extreme, marked symptom-producing ptoses are operations performed. Numberless kidneys have been sewn into position, stomachs stitched up, colons removed, but without sufficiently good results to warrant a continuation of the practice.

INTESTINAL CATARRH

(*Catarrhal Enteritis; Muco-enteritis*)

Definition.—A catarrhal inflammation of the mucous membrane of the whole or of any anatomic division of the intestinal tract. It may be either acute or chronic, primary or secondary. The chronic variety occurs less frequently than its counterpart, chronic gastritis, particularly in adult life.

Pathology.—The morbid lesions of the acute variety do not differ essen-

¹ For details, see *Jour. Amer. Med. Assoc.*, October 28, 1911.

tially from those met with in catarrhal inflammation of any other mucous membrane. The first stage is characterized by swelling and dryness of the mucosa; this is soon followed by a copious exudation of mucus, and more rarely of pus, which bathes the membrane more or less completely. After an abundant secretion is poured out the membrane appears rather pale, though the tips of the valvulae conniventes in the small intestine may appear reddened. The solitary and agminated glands, as well as Peyer's patches, may stand out prominently, owing to their corrugated condition (*follicular enteritis*). The apices of the solitary glands often undergo a necrotic change, thus forming follicular ulcers. The remainder of the mucosa may also be the seat of rather extensive areas of superficial erosion, though this must not be confounded with postmortem softening of the epithelium. In some cases the desquamation of epithelium is more pronounced than the abnormal mucous secretion. In chronic intestinal catarrh the mucosa presents a slaty hue, with a more or less dark pigmentation of the villi and follicles; it is in most instances thickened, owing to an increase in its connective-tissue elements. In a smaller number of cases it is thinned, particularly in the intestinal catarrh of children, on account of atrophic changes affecting chiefly the glandular and muscular layers. Roughening of the inner surface of the bowel, due to projecting glands, is frequent in those forms of chronic intestinal catarrh that are attended with thickening of the coats. Polypoid cysts may develop in long-standing cases.

Etiology.—The **primary** form is produced by (a) local irritants, either mechanical or toxemic, that find their way into the intestinal canal. The chief source of these excitants is an unsuitable dietary, and especially is this the case in children. It is readily seen from this fact why the stomach and the intestines are often simultaneously involved in a catarrhal process. (b) Overeating may be productive of the disease, though this often excites diarrhea by merely increasing intestinal peristalsis. (c) Idiosyncrasy has a positive influence, the ingestion of certain substances not difficult of digestion being invariably followed by this affection in individuals thus predisposed. (d) Toxic substances, whether in the form of tainted food-stuffs (spoiled meats, ice cream, beer) or inorganic poisons (mineral acids, caustic alkalies, mercury, arsenic) or irritating cathartics, often produce intestinal catarrh. (e) Impure water, or water to which individuals are unaccustomed. (f) Atmospheric changes, particularly a prolonged high or a sudden fall of temperature, the latter being especially apt to cause it in children. (g) An excess or a lack of biliary secretion. Two functions of the bile (its antiseptic properties and its power to stimulate peristalsis) must not be forgotten: the one explains how a paucity of this secretion favors the abnormal processes of fermentation that are capable of exciting catarrh, and the other makes plain the possibility of a bilious diarrhea being due to an excessive hepatic secretion. It is not clear, however, that the latter condition is attended with an actual catarrhal process. The same is true of diarrhea due to fright, excitement, or other nervous influence. (h) Bacteria are, doubtless, among the *excitants*—e. g., the normal colon bacillus, under conditions favorable to its growth and development. The small intestinal *diplococci* probably operate to produce catarrh, particularly fermentative dyspepsia (Schmidt and Strasburger).

Secondary or complicating forms are caused: (a) By direct extension from adjacent organs (ulcers, gastritis, peritonitis, hernia, and invagination); (b) by general infectious processes (septicemia, pyemia, typhoid fever, dysentery, cholera, tuberculosis, pneumonia).

The **chronic forms** are met with (a) in certain cachectic states (carcinoma, chronic malaria, chronic Bright's disease, Addison's disease, and profound anemia); (b) in connection with disturbances of the circulation, particularly

such as produce stasis in the terminal branches of the portal system of vessels: among the chief diseases that tend to prevent the return of venous blood from the intestines are chronic heart affections, diseases of the liver (especially cirrhosis), and emphysema; (c) severe cases of chronic diarrhea may be due to intestinal parasites.

Among predisposing causes is the *age*, children being particularly liable to the disease. Unfavorable hygienic surroundings, especially when a high temperature prevails, and epidemic and endemic conditions also strongly predispose to the affection.

Clinical History.—From a clinical standpoint we recognize acute and chronic forms of enteritis; also special varieties (*vide infra*).

The **simple acute form** of general catarrh of the intestines (muco-enteritis) has for its two most characteristic symptoms slight *gripping* or *colicky pains* in the abdomen (sometimes absent), that are followed soon by *diarrheal stools*. The *discharges* consist, at first, of feculent masses, and later of a watery, highly irritating fluid. Diarrhea is due partly to increased peristalsis and partly to the abnormal irritability of the intestinal mucous membrane. Active peristalsis of the intestines may (*vide ante*) be of purely nervous origin (*e. g.*, in neurasthenia), and produce a diarrhea that is to be distinguished from that due to catarrh, although an exceedingly difficult task in some cases. Again, steatorrhea may be present in cases in which the pancreatic secretion is absent. The causes that produce the catarrh also produce the undue peristaltic movements. If it be true, as physiology teaches, that the stools, owing to the absorption of the watery portions of the food, are normally formed in the large intestines, then catarrh of the small intestines alone does not excite diarrhea, though both large and small are involved in the majority of the cases. On the other hand, in *acute colitis diarrhea* is *conspicuous*, and forms the most important clinical symptom. The vigorous peristalsis also accounts for the gurgling and rumbling sounds (*borborygmi*) that are often felt and heard by the patient himself. These peculiar noises, if pronounced, point to isolated catarrh of the small intestine. The *stools* vary in number from two to ten or more, being increased in frequency after taking food; gases are also formed, causing tympanites. The thin or mushy stools either present a bright yellow or a yellowish-brown color and emit offensive odors. Occasionally they are greenish in color from the presence of considerable quantities of bile-pigment or from bacterial action. In advanced cases of considerable severity there is painful tenesmus; the stools are often small and contain mucus and blood, becoming dysenteric in character, especially in colonic catarrh. Nausea, impairment of appetite, and great thirst are commonly present.

A *microscopic examination* reveals large masses of epithelium and mucus, as well as countless micro-organisms and isolated leukocytes, crystals of calcium phosphate, oxalates, remnants of food (starch-granules, fat, and muscular fibers). Flakes of yellowish-brown mucus, of epithelium, and grayish-white masses of fat may often be seen *macroscopically*. The stools give an alkaline reaction as a rule.

The *physical examination* reveals on *inspection* slight tympanitic distention as a rule. The tongue is dry and furred. *Palpation* elicits considerable sensitiveness in the majority of cases, though during the colicky pains pressure with the palm of the hand often affords relief. Fluctuation may be detected if the intestines contain much fluid. *Percussion* gives an exaggerated tympanitic resonance, varying, however, with the tension of the bowel. Splenic enlargement has been described by Fischl.

The *general symptoms* are often entirely wanting save for a slight feeling of weakness due to the diarrheal discharges. Severe forms of infectious origin

often disturb the general health considerably. The patient is languid, and prostration is prominent; he suffers much from headache, and pyrexia is common, the temperature often reaching 100° to 103° F. (37.7°–39.4° C.). The higher temperatures are seen among children. Additional evidences of a systemic infection are sometimes observed, such as painful enlargements of certain joints, severe muscular pains, and albuminuria.

Complications.—The symptoms of gastric catarrh (vomiting, nausea, and pain immediately after feeding) are often associated with those of enteric catarrh; the combination is then spoken of as *gastro-enteritis*. Acute nephritis has been noted as a sequel.

Special Forms.—Though the anatomic limits in the more or less local forms of intestinal catarrh cannot be made out definitely, yet the different clinical pictures observed often enable us to fix the location of the disease with considerable accuracy; it is important, moreover, from the standpoint of the treatment, to accomplish this whenever possible. The following may be briefly described.

(a) *Duodenal catarrh (duodenitis)*, in which form constipation, often obstinate, is present in the place of diarrhea, the colon not being affected; merely local pain, tenderness on palpation, and uneasiness are complained of. These symptoms may frequently be overshadowed by those referable to the stomach when gastric catarrh coexists (*gastroduodenitis*). Without *jaundice* (usually present) due to the occlusion of the common bile-duct in consequence of the swelling of the duodenal mucous membrane, we cannot render a positive diagnosis.

(b) *Localized catarrh of the jejunum and ileum* cannot always be distinguished. The condition is often found to be a more or less prominent feature in general enteric catarrh, in which complaint diarrhea is a prominent symptom. The existence of this special variety may be safely inferred when certain enteric symptoms are combined with marked gastric disturbance. Under these circumstances the symptoms indicative of inflammation of the small intestines are rumbling noises (*borborygmi*), colicky pain, swelling, and slight tenderness over the abdomen in the vicinity of the umbilicus or over other regions occupied by the small intestine. Finally, an *examination of the stools* furnishes valuable points for differential diagnosis. It must be kept in remembrance that in catarrh of the small intestine the stools may be quite solid, despite the increased peristalsis caused by the catarrhal process (*vide ante*). More frequently, when the ileum is the seat of catarrh the colon is also implicated, this combination being attended with diarrhea, even if it be of minor severity. The thin stools “contain food remnants that point indubitably to implication of the small intestine.” As the result of increased peristalsis of the small intestine its contents are passed into the large bowel with undue rapidity; hence the latter contains undigested food constituents and other substances that are normally found in the small intestine. These pass from the rectum unchanged. They are mainly starch, fat, and masses of meat-fiber, the latter of which may be of sufficient size to be seen by the naked eye. This would be pathognomonic evidence of the form of catarrh in question if it were not true that increased peristalsis of the small intestine, due to other conditions, as anemia, extreme nervousness, and fever conditions, that are not seen in ileojejunal catarrh, causes the same fecal peculiarities. An acid reaction of the dejecta points to catarrh of the small intestine. *Microscopically* the stools show hyaline particles of mucus, giving rise to a speckled appearance.

In health the contents of the small intestine give the characteristic color reaction for bile-pigment, while the contents of the large bowel and the stools do not. There is quite often a large admixture of undecomposed bile-pigment

(Strümpell) that responds to Gmelin's test,¹ a fact of considerable value in diagnosis. Nothnagel has called forcible attention to the fact that *bile-stained* stools and small *pigmented* masses of mucus are met with, and are highly characteristic of the diarrhea that marks catarrh of the small intestine.

(c) *Colitis*.—The joint appearance of abdominal pain and diarrhea is almost pathognomonic of this condition. These symptoms, in the absence of the more prominent and above-mentioned clinical features that have special reference to inflammation of the small intestine, point to the fact that the large intestine is the chief seat of the disease.

Physical examination is only partially confirmatory of the rational symptoms. The chief sign is tenderness on palpation over the track of the colon. An *ocular examination of the stools* furnishes important practical results. They may contain blood and mucus, and the latter often in masses large enough to be readily visible to the naked eye; it is not intimately mixed with the feces, as in catarrh of the small intestines, but forms separate masses. The feces are often of the consistence of soup. "If the catarrh affects the lower portion of the large intestine chiefly, it may be that the intestinal contents are already formed" in firm lumps, which may sometimes be wholly or partly enclosed in a layer of mucus (Strümpell).

Such *general symptoms* as loss of flesh, weakness, and sallowness of the skin are often observed. Simple diarrhea, lasting but a few days, as a rule, is to be classed with catarrh of the large intestine, since these affections imply increased peristalsis of the large bowel. It is not always easy, however, to discriminate diarrhea due either to purely functional influences or to catarrh of the rest of the intestinal tract.

(d) *Proctitis*, or inflammation of the rectum, is characterized by painful tenesmus and by the presence of large quantities of mucus and pus, particularly in the dejections. The disease may be primary, though more often it is secondary to morbid lesions either in organs that are adjacent to or in the rectum itself.

Chronic intestinal catarrh may, comparatively rarely, be a *primary disease*, developing gradually. It may also be *secondary* (*vide* Pathology) at times to one or more attacks of acute intestinal catarrh. Generally there are no other local symptoms to call attention to the condition than *chronic diarrhea*. More rarely there are, in addition, colicky pain and tenderness over the abdomen. The diarrhea often alternates with constipation, and this is most apt to be the case when the disease is of idiopathic origin and affects only the large intestine (Nothnagel). *Constipation* is constant in those cases in which *atrophic alterations* occur in the glandular and muscular coats, as well as in those in which the lesions are in the small intestine. When constipation is not present the stools are thin, pale, sometimes fermented, emitting offensive odors, and vary greatly in number and quantity. There is commonly present visible mucus. When the small bowel is also implicated food-remnants are found in the dejections (*bienteric diarrhea*). *Microscopically*, the picture does not differ from that of the acute form. That form of diarrhea occurring in *organic diseases of the heart, liver, and lungs* demands brief special mention. Here the serum of the blood is made to exude into the intestines, owing to mechanical obstruction to the return of the venous blood, and this results in a liquefaction of the feces. The stools are apt to be most copious and numerous during the morning hours. Sometimes an irresistible desire to evacuate the bowels seizes the patient as soon as his feet strike the floor on rising in the morning; two or more serous discharges follow each other at short intervals. Subse-

¹ This consists in bringing a few drops of nitric acid in contact with the intestinal contents, when the characteristic play of colors appears. (See also Methods of Diagnosis, p. 830.)

quently, all discharges cease until the following morning, when the same symptoms are repeated. The *general nutrition* suffers visibly in chronic enteritis, and emaciation eventually becomes pronounced. I have also noticed slight pyrexia in the evening hours.

Differential Diagnosis.—Among the diseases likely to be confounded with acute catarrh of the intestines are *typhoid fever*, *dysentery* (diseases in which diarrhea is a cardinal symptom), *peritonitis*, and *colic*. The chief differential features between simple colic and enteric catarrh may be contrasted thus:

ENTERIC CATARRH	COLIC
Diarrhea is generally present.	Constipation is present.
Fever may be slight or marked.	No fever.
Pain is griping, and followed by diarrheal stools.	Pain is colicky, more severe, and is not followed by diarrheal discharges.
Tenderness in the intervals between pains.	No sensitiveness on palpation.

From *peritonitis* we may readily distinguish catarrh of the intestines by the more intense pain and tenderness, by the constipation, the greater tympany, the constitutional disturbance, the anxious face, thoracic respiration, and immobility of the patient, all of which characterize the former disease. The characteristic symptoms of *typhoid fever* (the typical temperature-curve, swelling of the spleen, eruption, Widal test) and of *dysentery* (scanty, frequent stools, tenesmus) are easily separable from enteric catarrh. In children, however, the diagnosis between typhoid fever and simple catarrh of the bowels offers considerable difficulty; but the temperature record, the enlargement of the spleen, the characteristic eruption, and the Widal reaction, taken unitedly, will warrant the diagnosis of typhoid fever and exclude acute enteritis.

In diagnosing chronic intestinal catarrh we may have difficulty in eliminating *lardaceous disease of the bowels* and *ulcerations*. The latter condition will be excluded hereafter. Boas recommends lavage in the diagnosis (about 1 liter of lukewarm water through a rectal tube); the funnel is then lowered and the dejecta siphoned off. If the recovered fluid contain mucus, catarrh is present. *Amyloid degeneration* is a general disease, affecting primarily other organs than the bowel, and hence lardaceous diarrhea is always preceded by the clinical indications of disease (enlarged viscera, albuminuria) elsewhere. The condition also gives a definite *etiology* as a rule.

The **prognosis** in uncomplicated cases is favorable, though the possibility of merging into the chronic form must be borne in mind. Occurring in weakly subjects and in the course of debilitating affections, *acute catarrh* of the intestines may endanger life. Its duration varies much—from three to ten days or more—according as the type of the individual case is mild or severe.

The prognosis in the *chronic forms* is moderately good as to life, though as to cure it is not so, the disease often enduring for many years together, or as long as the chronic conditions producing it remain unremoved. It sometimes exhausts the systems of those suffering from serious causal affections of a chronic nature, and occasionally it ultimately proves fatal. The prognosis will depend largely upon the character of the etiologic affection, but intestinal catarrh invariably renders the prospects of life more gloomy.

Treatment.—Respecting the treatment of this affection the views of the profession have undergone many changes, even within recent years; hence it may be reasonably inferred that our present therapeutic methods are by no means satisfactory.

Hygienic and Dietetic Management.—In the not uncommon mild cases, due to errors in diet, a mild purgative, followed by proper *dietetic treatment*, is all that is required. Albuminous food in liquid form, such as skimmed milk,

weak broths, and even semi-animal articles of diet, as eggs, oysters, sweet milk with seltzer, are usually well borne. In the severe forms predigested liquid food only should be allowed. When the chief seat of the disease is in the large intestine we may allow easily digested starches and certain green vegetables (arrow-root, sago, lettuce, water-cress); the coarser vegetables, all fats, and most fruits should be withdrawn absolutely. Lassablière has obtained brilliant results from the use of 1 part of condensed milk in 4 parts of rice-water, allowing from 1 to 2 quarts of this milk-rice-water per day. *Rest* in bed is especially beneficial in that it serves to keep the abdomen warm and mitigates the pain and diarrhea, and, in short, cures the disease. Sinapisms should be applied at the outset until the skin is reddened, succeeded by light linseed poultices until the local sensitiveness has, in a great measure, subsided; after this a flannel band may be applied. The local abstraction of blood by a few leeches, applied to the abdomen or anus, is beneficial in the early stages in severe types of enteric catarrh, provided the patient's strength is good.

Medicinal Treatment.—It is sound practice to prescribe a mild cathartic (castor oil, calomel, or rhubarb, followed by a saline) with a view to getting rid of decomposable intestinal contents. Combined gastric lavage and high intestinal irrigation has recently yielded excellent results in my hands; it is an appropriate method of overcoming the fermentative processes that tend to excite and maintain the condition.

If the chief tenderness be localized in the right iliac fossa, corresponding to the course of the colon, a simple enema, slowly given, will stimulate the bowel sufficiently and cleanse it more effectually than a cathartic. Subsequently, chief reliance is to be placed on intestinal antiseptics and astringents, though it must be recollected that the selection of internal remedies must, in part, be influenced by the etiologic indications. For instance, if the cause has been exposure to cold or wet, besides the efforts directed at the local condition diaphoretics and febrifuge mixtures are serviceable. I have found the following combination to be of benefit in controlling the local inflammatory action:

R.	Phenylis salicylatis,	℥ss (2.0);
	Bismuthi salicylatis,	℥j (4.0);
	Creosoti,	℥xx (0.6).
	M. et ft. cap. No. xx.	
	Sig. One every three hours.	

If pain be troublesome, opium or acetphenetidi may be combined with the above formula.

In many instances the secretions of the intestinal tube are decreased for a considerable period after the most active symptoms have been subdued. Here we must supplement the natural juices of the bowel; this may be satisfactorily accomplished by the following agents in a salol-coated capsule:

R.	Pancreatini,	℥j (4.0);
	Sodii bicarb.,	℥ij (8.0).
	Ft. cap. No. xii.	
	Sig. One an hour after meals.	

In cases in which the large intestine is chiefly affected, and when the condition does not yield to internal medicines, treatment by medicated colonic irrigations is useful. When there is reason to suspect that the main lesion is in the large bowel, small enemas of starch-water (℥ij—60.0), with laudanum (℥xx to xxx—1.33—2.0), every four to six hours, are also efficacious. If

colicky pain be severe, morphin (gr. $\frac{1}{8}$ —0.008) should be given hypodermically in addition to the measures before suggested. If the diarrhea shows no tendency to abate after forty-eight hours of the general treatment above outlined, large doses of bismuth (gr. xxx to lx—2.0—4.0) every three or four hours should be tried. In my own hands lead acetate (gr. ij—0.3), with the extract of opium (gr. $\frac{1}{8}$ —0.008) in pill form, has proved a most efficient combination. The thirst is best relieved by chipped ice in small quantities or by carbonic acid and Apollinaris waters. For distressing flatulence we may prescribe the alkaline carbonates, or spirits of ammonia, and some carminative. The oil of cajuput is a most valuable drug in the treatment of excessive fermentation (Murrell).

In *chronic catarrh* of the intestines the local treatment is of paramount importance. Daily irrigation of the bowel with a weak solution of some antiseptic agent, as salicylic acid (gr. v to \mathfrak{z} j—0.3—30.0), boric acid (gr. x to \mathfrak{z} j—0.6—30.0), creolin (π v to \mathfrak{z} j—0.3—30.0), or with some such astringent as tannin (gr. v to \mathfrak{z} j—0.3—30.0), or finally with an alterative, such as silver nitrate (gr. $\frac{1}{4}$ to \mathfrak{z} j—0.016—30.0), will be found to be serviceable. The latter solution is a most excellent remedy, but sometimes excites pain if too concentrated. I often use a mild antiseptic or astringent with the foregoing, giving each on alternate days, and thus obtain happy results. The only appliance needful is a fountain syringe with a soft-rubber end-piece, which should be gently introduced for a considerable distance into the bowel. The fluid used should be warmed to 90° F. (32.2° C.), and the quantity administered at each sitting should be not less than 2 to 3 pints (1—1.5 liters); this should be allowed to flow into the bowel slowly. The patient should, as a rule, assume the dorsal decubitus, though if the fluid is to be carried as high up as possible, the knee-elbow position may be assumed or the patient may be placed on the left side with the hips elevated. Again, turning him from side to side during the irrigating process may be warmly recommended.

The same careful attention must be paid to *hygienic details*, and especially to the diet, as is directed in the acute form. In addition, flannel should be worn next the skin both in winter and summer. If the strength will admit of it, cold baths are useful.

A stay at a suitable spa (Saratoga, Bedford, Virginia Springs, Carlsbad, Kissingen) often produces most satisfactory results.

Among internal agents, zinc oxid (gr. v to x—0.3—0.6—t. i. d.), silver nitrate, lead acetate, and alum, given with tonics, such as strychnin, arsenic, and iron, are especially to be recommended.

The management of this troublesome malady depends upon the indications furnished by the causative affections. No method of treatment, however, can succeed that is not carried out patiently, systematically, and over long periods of time.

DIARRHEAS OF CHILDREN

ACUTE GASTRO-INTESTINAL CATARRH

(*Acute Gastro-enteric Infection; Summer Diarrhea; Gastro-enteritis; Cholera Infantum; Mycotic Diarrhea*)

Definition.—This is the usual intestinal trouble that prevails during the warm summer months. It usually takes the form of an epidemic, and its course is manifested by a sudden onset, high fever, irritability of the stomach, frequent watery evacuations, and symptoms of nerve involvement. This form of diarrhea usually follows an attack of acute indigestion, in which it very

frequently has its origin (*acute dyspeptic diarrhea*), Acute gastro-intestinal catarrh (*cholera infantum*) stands midway between acute indigestion and ileocolitis.

Etiology.—Two important conditions seem to be necessary to influence the disease—*temperature* and *diet*. A general and well-recognized belief associates special danger with the second summer of children. Out of nearly 2000 fatal cases collected by Holt, only 3 per cent. were exclusively breast fed. Generally speaking, the disease has its origin in some irregularities in artificial feeding. Heat and season are important elements in the continuation of the disorder when once commenced.

It is seen from May to September, the greatest prevalence occurring in July. The pauper element of large cities furnishes most instances.

Flexner and Holt¹ assert that the *Bacillus dysenteriae* may be isolated from the intestinal discharges, and from the intestinal mucosæ in a large percentage of cases developing along the Atlantic coast of the United States, during the summer months. Holt found *Bacillus dysenteriae* in 50 per cent. of cases at the Babies' Hospital of New York. The Flexner-Harris type of bacillus is most often encountered, while the "Shiga" type is but occasionally recovered. It is common for cultures to develop streptococci in connection with the *Bacillus dysenteriae*, and both organisms appear to grow luxuriantly together, which renders it impracticable to decide whether the lesions of the intestines and the general symptoms depend upon one or both of these organisms.

Booker, Jeffris, Baginsky, and Metchnikoff affirm that the proteus class of bacteria are commonly present, and that they are pathogenic. The *Bacillus dysenteriae* reacts with the serum of infected children.

Pathology.—A catarrhal swelling of the mucosa of the large and small bowel is present; the mucosa itself is pink in color from capillary congestion. Peyer's patches are enlarged. The whole intestinal tube shows an early stage of inflammation (ileocolitis). In addition, there is most likely some involvement of the sympathetic nerves, leading to dilatation of the capillaries and transudation of serum into the intestine, and to alterations of the pulse, temperature, and respiration. Its nature is paralytic, and closely resembles in its results experimental sections of the sympathetic nerves. The changes in the other organs are slight. Bronchopneumonia frequently occurs. The spleen is often swollen, the brain is anemic, and the kidneys are congested.

Symptoms.—Clinically, there are three forms of acute enteric infection:

(1) Acute dyspeptic diarrhea; (2) cholera infantum, and (3) ileocolitis.

(1) *Acute Dyspeptic Diarrhea.*—There may be merely an increase in the number of stools, with or without fever; restlessness is usual at night. This condition may continue for two or three days, when the stools become more frequent and offensive, containing undigested food and curds. The *odor* by this time is very pronounced. Frequently the disease has a sudden onset, with vomiting, griping pains, and fever, which may quickly rise to 104°, 105°, or 106° F. (40°–41.1° C.). *Convulsions* may be the commencement of the attack. The abdomen is sensitive and swollen, and the child lies with its legs flexed on the stomach. The *stools* consist of grayish or greenish-yellow feces (mixed with curds, portions of undigested food) and some fluid. In children two years of age and older the stools may contain unripe fruit or large curds from excessive drinking of milk. Relapses are frequent, and during hot weather the frequency of the attacks may lead to a persistent enterocolitis.

In delicate children a severe attack, especially if it is accompanied by convulsions, may prove fatal.

(2) *Cholera Infantum.*—The *initial* symptoms are sudden. The child

¹ Rockefeller Inst. Med. Res., 1904.

voids immense stools, at first fecal, if no preceding diarrhea have been present. Soon they become watery, light yellow or greenish in color; frequently they are so thin and colorless as to pass through the napkin without leaving a stain. At times they contain a few yellow or greenish flocculi or a mass of mucus, and in all cases they are odorless. Very often the stools are brown and liquid, with a small quantity of fecal matter, having a peculiar musty odor that clings to the napkin and child for days. The number of stools per diem may vary from six to thirty, and a most remarkable feature is the fact that they are evacuated with considerable force.

The *stomach* becomes irritable, refusing everything; even ice is rejected as soon as swallowed. The vomitus at first contains bile, while later it becomes serous. The *appetite* is, of course, entirely lost; intense thirst prevails, the little patient drinking at every chance and following the receding glass with eager eyes. The *tongue*, moist at first, soon becomes dry and pasty; the abdomen is collapsed. The *temperature* is always high—105° or even 108° F. (40.5°–42.2° C.); and the *pulse* small and very frequent—130 to 180 beats per minute. The *breathing* is shallow and irregular, and the expression anxious and staring, but soon becomes dull. The urine becomes dark and scanty, and frequently shows the presence of acetone.

With this array of symptoms there is a striking and appalling change in the child's general appearance. Within a few hours it can scarcely be recognized; the face has become pale and pinched, the eyes and cheeks sunken, the eyelids and lips wide apart from loss of muscular control, the muscles flabby, the bones prominent, and the skin greenish or cadaverous, hanging in loose folds from the wasted frame.

Collapse comes on soon: the hands, feet, nose, and breath become cool, the respirations more unequal, and there are drowsiness and utter apathy. When life is near its close, vomiting stops, the whole surface becoming cool and clammy as the patient sinks into a state of coma, with injected eyes and contracted pupils. At last the end is reached quickly, preceded perhaps by a slight convulsion. The *duration* of the disease is short; it may prove fatal in from one to four days.

(3) *Ileocolitis*.—This may follow acute dyspeptic diarrhea, cholera infantum, or complicate the acute infections of childhood. The *symptoms* develop acutely. At the outset there may be vomiting, but it is not persistent, and the stools are greenish, feculent, often showing masses of casein. Later the discharges are increased in frequency, are small, and contain also blood and mucus. In severe cases pain and straining are distressing features. The abdomen is prominent and there is tenderness along the course of the colon. The disease presents high fever.

The *course* is variable. It may be acute—three to six days—terminating either in convalescence or death due to exhaustion. In other instances the acute symptoms subside, particularly the fever, while moderate diarrhea continues and is attended with wasting and debility. Gradual recovery may ensue, though more commonly relapses occur and death follows from bronchopneumonia or an intercurrent acute attack.

The **treatment** of *acute gastro-intestinal catarrh* divides itself into hygienic, dietetic, and medicinal measures. If a child is attacked in the city during the summer and does not yield to treatment in two or three days, it should be sent to the country or seashore. In the case of a child under two years this is absolutely imperative. Fresh air is important in all diarrheal disorders, and all cases should be kept out-of-doors as much of the time as possible. Children should be kept quiet. Bathing is soothing, insures cleanliness, and, what is very important, reduces the temperature.

Dietetic treatment is of great importance. It should be remembered that digestion is arrested in the early stage, hence to give food at this stage is to do harm. Thirst may be controlled by ice- or albumin-water, toast-water, or gum-water, with a little brandy. Buttermilk twice daily has given excellent results.

Medicinal Treatment.—The first step is directed against the acute indigestion and the active putrefaction going on in the intestines. The indication, therefore, is to empty thoroughly the alimentary tract as soon as possible, and no other treatment should be considered until this end has been accomplished. Whenever vomiting persists, the stomach should be washed. In older children emetics will favor complete emptying of the stomach, but are never to be given to infants under two years. For the intestines calomel and soda may be used; for the colon, irrigation: this is advisable in all cases, as it hastens the effect of the calomel, and removes at once much irritating and offensive material. At this time bismuth, as per the following formula, for a child two years of age is useful:

R. Bismuthi subnitratī, ʒj (4.0);
 Liquor antiseptici, fʒss (15.0);
 Misturæ cretæ, q. s. ad fʒij (60.0).—M.
 Sig. "Shake." Teaspoonful in water every two hours.

Opium should not be used until the whole intestinal tube is cleansed, and then cautiously. Spirits of chloroform, or camphor, is a better remedy for the pain than opium in any form. In older children the hypodermic injection of morphin and atropin in appropriate doses frequently controls the symptoms. Bowles has used lactic acid in the maximum dose of $1\frac{1}{4}$ grains (0.08) every hour, and found it to control the symptoms in from twenty-four to forty-eight hours. Thus far the results of serum treatment have been disappointing.

Treatment of Cholera Infantum.—In this form of infection of the intestinal tract we are likely to forget that we are called upon to treat a case of acute poisoning. The toxic material acts both powerfully and quickly as a cardiac and systemic depressant. It also acts toxically upon the nerve-centers, and paralyzes the vasomotor nerves. According to Holt, the leading indications are: (a) to empty the stomach and intestines; (b) to supply the body with fluid to offset the great loss by vomiting and purging; (c) to counteract the effect of the poison on the heart and the nervous system; (d) to reduce temperature, and (e) to treat the symptoms as they arise. In the first condition thorough stomach and intestinal cleansing is absolutely necessary. Moreover, we cannot depend on emetics or purgatives to arrest pain and to limit the effect of the poison on the nervous system; a hypodermic injection of atropin and morphin is essential. Morphin must be given with discrimination to young children, especially when the vomiting and purging are slight; it is especially contraindicated when stupor or collapse seems near. Small doses repeated are better than larger single doses. Holt gives gr. $\frac{1}{1000}$ (0.0006) of morphin, with gr. $\frac{1}{8000}$ (0.00008) of atropin, as the first dose in a child one year old. In supplying fluid to the exhausted tissues it is useless to attempt to give them by the mouth, or even by the rectum, as by both avenues it would be rejected. An injection into the cellular tissues of the buttocks, back, or thighs of a saline solution (40 grains—2.59—of common salt to a pint of sterilized water) is the best way to meet the drain. One pint ($\frac{1}{2}$ liter) may be used every twenty-four hours, and larger quantities may often be used with advantage. Baths must be given to control temperature, and ice-bags should be placed to the head. Ice-water injections will aid in the control of temperature, and ice-

suppositories act efficiently when the water is not retained. Stimulants may be given hypodermically. During the active stage nothing should be allowed by the mouth except iced brandy or champagne.

The dietetic management and internal treatment of *ileocolitis* are similar to that of the preceding variety. A dose of castor oil or of calomel is to be promptly administered and followed in a few hours by copious irrigations of the colon, preferably with tepid saline solution (strength 7 : 1000). Later a small quantity of a thin starch solution, to which πj to $ii j$ of laudanum has been added, may be gently thrown into the rectum, to be repeated once or twice daily. After the acute stage is over a weak silver nitrate solution may be employed.

CELIAC DISEASE

(*Diarrhœa Alba; Diarrhœa Chylosa*)

Definition.—A form of intestinal catarrh marked by copious fetid and frothy discharges resembling gruel.

Pathology.—Although ulcers have been noted in the intestine, the pathology of the disease is not known. Says Osler: This affection resembles somewhat the disease in adults known as “hill diarrhea” or the “white flux” of India.

Etiology.—The disease is limited chiefly to children from one to five years old. The *Filaria sanguinis-hominis* has been found in the feces in cases of diarrhœa chylosa.

Symptoms.—The disease is of slow development, and the characteristic feature consists of copious *diarrheal* (though not watery) *stools*, resembling gruel or oatmeal-porridge. These are also frothy (*frog-spawn*) and horribly fetid. The *physical signs* consist of a moderate distention of the abdomen and a boggy sensation that is imparted to the palpating finger. The *general features* may be summated in gradually increasing emaciation, debility, and pallor. The disease terminates fatally as a rule.

The **treatment** is purely symptomatic unless the presence of parasites be suspected, when large antiseptic enemata should be given.

PHLEGMONOUS ENTERITIS

This is a suppurative inflammation of the submucous layer of the intestines. It is among the rarest of grave maladies, especially as an irrelative disease. It may be diffuse or take the form of a circumscribed abscess. Rarely it occurs as a complicating condition in septicopyemia and in malignant types of the exanthemata, resulting in the formation of abscesses that usually have their seat in the duodenum. Phlegmonous enteritis may be secondary to strangulated hernia or intussusception.

Symptoms.—The *local signs* simulate closely those of peritonitis. Among the symptoms *vomiting* is prominent, though not diagnostic; it is always severe and may become stercoraceous. *Pain* and *tenesmus*, when due to obstruction, are intense. Rigors more or less severe have been observed. The *temperature* is high, and its curve is somewhat typical of the fever of suppuration. The disease is very fatal, the patient passing from a condition of extreme prostration to one of utter collapse.

Treatment.—The physician's task is confined to an attempt to support the powers of the patient and to relieve his inordinate suffering. The surgeon's aid should be invoked early in cases of obstruction.

CROUPOUS OR DIPHTHERITIC ENTERITIS

Definition.—An intense inflammation of the intestinal mucosa, accompanied by a croupous exudate; it occurs in connection with a variety of conditions. If from any cause the epithelial covering is destroyed, agents that set up local inflammation may excite a croupous exudate.

Pathology.—There are two sets of morbid lesions to be distinguished: (1) The first and most important class exhibits a croupous deposit varying greatly in thickness and in area. Its color is variable, being sometimes of a *grayish* or *grayish-white* hue, frequently *grayish yellow*, and rarely *blackish*. I have almost invariably seen these lesions in the colon. (2) In the second group the solitary follicles alone are inflamed and covered with diphtheritic deposit.

The *etiologic* factors may be: (a) mechanical irritants (impacted feces, intestinal sand, gall-stones); (b) chemical irritants (ammonia, acids, mercury, arsenic); (c) secondary to acute infectious and certain chronic complaints (Bright's disease, pyemia, carcinoma, diabetes, tuberculosis, and anemias).

Symptoms.—When mechanical irritants give rise to symptoms they do not differ from those due to stercoral ulcers, and there is no way of recognizing the croupous deposits unless they be discharged *per rectum* and are detected in the stools. In cases that arise from the action of irritant poisons vomiting and purging are well marked and the dejections contain blood-stained mucus. We cannot be certain about the presence of croupous deposits in toxic cases unless they be found in the discharges. When phlegmonous enteritis occurs as a complicating condition in infectious diseases the symptoms are almost completely veiled. The symptomatology of the follicular variety cannot be separated clinically from that of follicular ulceration.

The **treatment** is that of the causal conditions or affections.

SPRUE

(*Psilosis*)

This has been defined as "an insidious, chronic, remitting inflammation of the whole or part of the mucous membrane of the alimentary canal, occurring principally in Europeans who are residing or have resided in tropical or sub-tropical climates" (Manson). It occurs in the Southern States of this country, where it is frequently confused with pellagra (*vide* p. 433), and has been most carefully studied by Bailey K. Ashford in Porto Rico.

The principal **morbid changes** consist in patchy or general destruction of "the surface of the mucosa in all degrees, from slight erosions to complete disintegration of the villi, glands, and follicles." Congestive, catarrhal, ulcerative, and cirrhotic changes may all be combined.

Etiology.—Ashford states that Bahr's opinion that sprue is due to a *Monilia* is correct, and has described a *Monilia X*, which he claims is constantly present. Residence in hot climates and previous affections of the alimentary tract are the main predisposing causes.

The leading **symptoms** are, according to Manson, irregular action of the bowels, and the passage of copious, pale, drab-colored, yeasty looking, sickly smelling stools. The complexion is dark or muddy; there is emaciation and the abdomen is distended. Weakness, loss of memory, and irritability of temper are common. The oral cavity is inflamed and the seat of erosions, cracks, and superficial ulcerations. Schmidt's hydrobilirubin test was very

weakly positive in 3 cases (Hiatt and Allan).¹ Brunton has pointed out that Indian Hill diarrhea differs from sprue in that soreness of the mouth and anus is absent in the former.

Early appropriate **treatment**, which is principally dietetic (milk-diet) and hygienic, checks the progress of the disease.

CHOLERA MORBUS

(*Cholera Nostras; Sporadic Cholera*)

Definition.—A self-limiting disease, characterized by serous vomiting and purging, colicky pains, and often muscular cramps.

Pathology.—No constant anatomic changes have been noted. They are analogous to those seen in acute gastro-enteritis, though cases have terminated fatally in which no morbid lesions were found *postmortem*.

Etiology.—Among predisposing causes, the *age* and the *season* exert the most prominent influence. The condition may appear in subjects under two years, when the term “cholera infantum” is employed; but it is oftener met with in older children and adults. It is almost invariably seen during the heated term in temperate zones, from the latter part of June to September, and is especially prevalent during the months of July and August. Bad hygienic environment, foul air in particular, has a noticeable effect, and, though not as yet absolutely proved, it may be safely inferred from the symptomatology and general clinical course of the affection that it is of microbic origin. Among other factors are improper food, particularly unripe fruit, cucumbers, egg-plant, and exposure to cold and wet. Various *organisms* (especially the Finkler and Prior spirillum) have been found present. Virulent specimens of the *Bacillus coli communis*, and even of the streptococcus, have been noted.

Clinical History.—The *onset* is often sudden, and is marked by abdominal pain, vomiting, and diarrhea. At first the *vomit* consists of food, and later of bile and mucus. The *dejections* are fecal in character at the onset; though they soon become watery, and may resemble the rice-water stools of Asiatic cholera.

Physical examination reveals only tenderness on pressure over the abdomen, and particularly over the epigastric region.

General Symptoms.—Cramps in the calf muscles are common. The temperature varies greatly, ranging from 100° to 106° F. (37.7°–41.1° C.). The skin surface, however, and more particularly that of the extremities, feels cool, and owing to this fact the rectal temperature should be recorded. The pulse becomes rapid and feeble as the case progresses. The face is pale or even cyanotic, and the features look pinched. The extremities lose their plumpness, and the patient usually appears prostrated and mentally dull. The urine is scanty, high colored, and sometimes albuminous, and thirst is extreme. There is a group of cases that develop subacutely, and in these the symptoms tend to persist.

Differential Diagnosis.—The symptoms of cholera morbus resemble so closely those of *Asiatic cholera* as to preclude the possibility of a differential diagnosis from the symptoms. A bacteriologic examination of the stools, however, permits a certain discrimination; and during a cholera epidemic the distinction between these affections is thus made. The effects of certain direct irritants, as in poisoning by ptomains and toxic doses of arsenic, must be excluded by the history.

¹ *Jour. Amer. Med. Assoc.*, August 1, 1914.

Prognosis and Duration.—The duration of the disease varies from three to four hours to two days. It is rarely fatal, though in persons suffering from such chronic affections as Bright's or cardiac disease, and also in the aged, the prognosis is only guardedly favorable. An element of danger is profound collapse. Otitis media is occasionally seen, although most cases without sequelæ recover.

Treatment.—The *diet* must be rigorously restricted, and predigested milk and animal broths are to be prepared as lightly as possible until convalescence has been fairly established. The comfort of the patient is much enhanced by keeping him at absolute rest. *Local measures* are useful in combating pain and vomiting. A large mustard-paste applied to the stomach and abdomen, followed by linseed-poultices that are to be worn constantly, has a strong influence in accomplishing the relief of the symptoms before mentioned. If indigestible substances have been taken prior to the attack, prompt though mild laxatives are to be given at the beginning of the treatment. For the excessive thirst chipped ice, over which a little brandy has been sprinkled, is effective. For controlling the morbid sensitiveness, on which the pain, nausea, and the diarrhea depend, we have a remedy *par excellence* in the hypodermic administration of morphin. The dose should vary (gr. $\frac{1}{4}$ to $\frac{1}{2}$ —0.016–0.032) according to the severity of the symptoms, and I have rarely found it necessary to give a second dose. Not only are the pain and diarrhea subdued, but the circulation is re-established. It has also been recommended to administer opium by the mouth for these symptoms, but the results are less satisfactory. The other points in the treatment of this affection are identical with those discussed under the treatment of Gastric and Enteric Catarrh.

INTESTINAL INFARCTION

A few instances of occlusion of the superior mesenteric artery by an embolus have been recorded recently. The condition produces hemorrhagic infarction of the small intestines, and is marked by grave and usually fatal symptoms. Its *causes* are sometimes obscure. The cases that have come to autopsy have shown intense congestion, with a swollen, blood-infiltrated state of the jejunum and ileum. Osler has seen three instances: in one there were numerous vegetations on the mitral valves from which the embolus was probably derived; in another the superior mesentery was plugged at its orifice, and in the third the artery was blocked by a portion of the fibrous clot of an aneurysm of the aorta near the diaphragm. The *symptoms* are urgent. Quite often diarrhea is present from the first, the defections sometimes becoming blood tinged. Soon the characteristically grave symptoms of intestinal obstruction supervene—viz., *great pain, vomiting, and constipation* (less commonly diarrhea), with *tympanitic distention* of the abdomen (generally). The condition cannot be recognized from the symptoms on account of their resemblance to the various forms of obstruction, yet its probable existence may be inferred from the presence of the known causes.

INTESTINAL ULCERS

FOLLICULAR ULCERS have already been described under Catarrhal Enteritis (*vide* p. 783), and they have a similar pathology and etiology. When present in goodly numbers they give rise to a symptom peculiarly their own, and hence

may be dignified by a separate though brief mention. The *symptoms* of the condition arising in the course of chronic enteritis often escape observation for a long time. The most characteristic manifestation is the appearance in the stools of conical shaped masses of mucus resembling "boiled sago." Marked weakness and emaciation rapidly ensue. Among children the disease is common and assumes an aggravated form, the little sufferers quite frequently reaching their end as the result of inanition. An unfavorable termination may be due to perforation followed by suppurative peritonitis. The *treatment* coincides with that of chronic enteritis.

STERCORAL ULCERS are the result of the mechanical effect of hard fecal scybala (often enteroliths, due to a deposit of lime-salts) upon the intestinal mucous membrane. They occupy the sides or tops of the normal folds in the colon.

Symptoms.—There is, as a rule, a clear history of *chronic constipation*, though the physician is often called on account of the presence of *diarrhea*; this is caused by the retained hardened feces finding their way into the rectum. A *digital exploration* will now clear up the diagnosis. There are *tenesmus* and *colicky pain* in the abdomen, the latter symptom being also complained of when diarrhea is absent. The pain often occurs in severe paroxysms that may be attended with the discharge of flaky mucus, pus, and sometimes blood. Enteroliths may lie in the intestines for years together, or they may finally be discharged with the stools. The ulceration that is thus caused often passes unrecognized.

Physical Examination.—Palpation may reveal the presence of a sausage-shaped tumor and localized tenderness over the seats of ulcers.

The **prognosis** is good if the condition be not overlooked.

The **treatment** consists in thoroughly evacuating the bowels by salines and simple enemata, persistently used. Subsequently these cases are to be treated as other non-specific ulcers of the bowels.

SIMPLE ULCERATIVE COLITIS is a not uncommon complaint, and one that is frequently associated with chronic intestinal catarrh. The ulcers may be quite extensive, removing the greater portion of the mucous membrane, though I observed several cases at the Episcopal Hospital that were superficial. The muscular layer of the gut was greatly hypertrophied and its lumen increased in all. The non-ulcerated portions of the mucosa looked, in part, quite pale, and in part quite dark.

The **etiology** is obscure. The disease is met with most frequently in persons past middle life, and it is quite probable that chronic enteritis sustains a causal relation. Those whose constitutions have been enfeebled by previous disease or an improvident hygienic environment are the chief sufferers.

Symptoms.—The clinical features are ill defined at the onset, and are often erroneously ascribed to indigestion. *Diarrhea* (lienteric in character) is its most prominent symptom, and with it constipation may alternate. Pus and blood are usually absent. The general health soon suffers greatly, the patient becoming weak and emaciated.

The **course** of the disease is subacute, tending to become chronic.

The **diagnosis**, apart from a consideration of the symptoms above mentioned, requires the elimination of *dysentery*—an easy task, as a rule. The disease resembles closely the amebic form of dysentery, hence in dubious cases a microscopic examination of the feces should be made.

Prognosis.—This is unfavorable during the earlier stages in the aged. The tendency to chronicity of the disease must be considered.

The **treatment** embraces: (a) a careful regulation of the diet, consisting in a restriction of the patient to liquids and semisolids during the acute stage;

(b) the administration of a gentle laxative, followed by antiseptics and astringents (bismuth gr. xxx—2.0—combined with phenyl salicylate gr. v—0.324—every four hours); (c) the more serviceable local measures in the form of enemata among the best being silver nitrate (gr. $\frac{1}{4}$ ad $\frac{3}{4}$ —0.016–32.0) or creolin (2 per cent.).

SOLITARY ULCERS.—"Two instances of ulcer of the cecum, both with perforation, have come under my observation, and in one instance a simple ulcer of the colon perforated and led to fatal peritonitis" (Osler).

The **DIFFUSE CATARRHAL ULCER** is inseparable from acute enteritis; the **CANCEROUS ULCER**, **TUBERCULOUS ULCER**, and **AMEBIC ULCER** are alluded to under their respective heads.

APPENDICITIS

Definition.—A catarrhal, ulcerative, or interstitial inflammation of the appendix vermiformis. It must be confessed that, according to our present views, appendicitis is a surgical rather than a medical affection, particularly from the standpoint of treatment. Knowing from personal experience and observation, however, that general practitioners are constantly meeting with cases of appendicitis, its prompt clinical recognition by the latter is not only a matter of interest, but also of great practical importance for two reasons: First, in order that surgical intervention can be instituted at the proper moment; and second, because appendicitis is the leading serious disease of the intestinal tract.

The term "appendicitis" includes the affections *typhlitis* (inflammation of the cecum) and *perityphlitis* (a similar involvement of the connective tissue behind the cecum) by reason of the fact that with few exceptions when the symptoms of the latter affection are presented the appendix vermiformis is the part primarily affected. To the physicians and surgeons of America belongs the credit of having first established the truly important rank of appendicitis.¹

Anatomic.—Without any known function the human appendix vermiformis represents the remains of the enormous cecum of inferior animals, especially rodents and herbivora. Clado asserts that the vermiform appendix is kept in position by two folds of peritoneum, a meso-appendix, which is attached to the iliac fossa, and a second fold, perpendicular to the first, which is attached to the posterior portion of the small intestine. A lymphatic gland generally occupies the angle formed by the appendix, cecum, and the small gut; this receives all the lymphatic vessels of the appendix. In the female a lymphatic connection may exist between the appendix and the right ovary. The size of the appendix varies greatly. Ferguson, after measuring 200 appendices, gave as the average length $4\frac{1}{2}$ inches (11.4 cm.), and as the diameter that of a No. 9 English sound—about $\frac{1}{4}$ inch (0.63 cm.) Berry's studies, which are partly based upon personal examination of 100 bodies, and partly upon comparison of his own results with those obtained by other investigators, gives the average length in all the observations as 9.2 cm. (3.6 inches). The caliber is ordinarily of the size of a goose-quill. Very exceptionally, as in a case reported by Swan, there is a congenital absence of the appendix. Its two fibromuscular coats (external longitudinal and internal circular) are thick; its mucous membrane contains lymphoid elements in abundance. The blood-supply is derived from the ileocolic artery at the valve, a single branch running to the end of

¹ The following names will long be connected with this disease: Pepper, Fitz, McBurney, Porter, Willard Parker, Weir, Sand, Bull, Warren, Keen, Morton, White, Price, Deaver, Senn, and many others.

the appendix, while the nerves are derived from the superior mesenteric plexus of the sympathetic. Shortly after middle life the cavity of the appendix becomes obliterated. Its blind extremity points most frequently toward the spleen. The appendix may lie behind the cecum, and sometimes partly to its inner side, its tip almost touching the liver or the gall-bladder. In not a few instances it dips downward, passing over the brim of the pelvis. There is no adjacent organ to which it may not become adherent, and in rare instances it is twisted like a loop around the small gut, causing constriction or even strangulation.

Pathology.—Three pathologic varieties are recognized:

(1) **Catarrhal or Obliterative Appendicitis.**—This may be acute or chronic. The term "catarrhal inflammation" is still retained, though scarcely applicable, since, as a rule, appendicular inflammation tends to spread quickly to all the coats, including the serosa. Obliterative appendicitis is descriptive and in every way preferable. The *mechanism* of the inflammation is briefly as follows: The mesentery being too short, the exit is too small, and in consequence of swelling of the coats (especially the mucous) the venous return is greatly impeded, then the arterial, followed often by abscess formation. In the female a branch is supposed to be furnished by the ovarian artery, making a more perfect blood-supply. The appearances are, in the beginning, identical with those of catarrhal inflammations elsewhere in the bowel. Within twenty-four hours all the layers are swollen, with marked cellular infiltration, causing the appendix to become firm and often rigid. The mucosa may be denuded of its epithelium and present a granular surface. The external coat (serosa) is usually hyperemic, and not uncommonly the seat of fresh or old adhesions. The tube may become completely obliterated by pressure, resulting in a union between the granular surfaces, in this manner rendering subsequent attacks impossible (Hawkins). It is in cases in which this fortunate result is not reached, however, that acute appendicitis leads to the chronic form with relapses. Two additional terminations may be observed: First, an obliteration of the lumen may occur near the valve, in which case the appendix becomes dilated, and sometimes enormously so (cystic). The contained liquid may be either serous or purulent. Second, obliterative appendicitis may lead directly to ulceration of the mucous membrane, and often in the absence of a fecal concretion or foreign body. Again, the cystic appendix may ulcerate, with or without perforation. Obviously, the more marked the stenosis of the appendix, the less favorable the conditions for natural drainage, and the greater the liability to recurrences of attacks of appendicitis. This variety then may end in resolution, complete obliteration, stenosis, or ulceration, and the latter sometimes in perforation.

(2) **Ulcerative Inflammation.**—Like the preceding, this variety may be acute or chronic. It may be a sequel of the obliterative form, and often accompanies chronic obliterative appendicitis. More commonly, however, it is seen in connection with concretions, and sometimes with foreign bodies also. By no means invariably, however, does the presence of these substances excite ulceration of the appendix. Micro-organisms play an important rôle in this variety (*vide* Etiology). The submucosa or muscularis usually forms the base of the ulcer. The termination may be in healing, with tendency to stricture. Again, the ulcer may extend in depth until perforation occurs.

(3) **Interstitial or Parietal Inflammation.**—This may be preceded by the obliterative or the ulcerative form, which may be followed by anemic necrosis and sloughing. Concretions or foreign bodies are often found, though specific bacteria are of greater etiologic importance. The gravest, most common, and hence the most important lesions are the gangrenous, which are usually

limited to a circumscribed part of the tube. Interstitial inflammation has a single termination—perforation—and leads to appendicular peritonitis of a virulent and infectious type.

It may be that neither necrosis nor gangrene may supervene. When perforation occurs, one or more openings, ranging in size from one to several millimeters, may be observed, while the remainder of the appendix may present no abnormalities; more often, however, it is blood-injected and swollen. The appendix may slough *en masse*. The histopathologic changes may be characterized by intense cellular exudation, necrosis, or purulent inflammation. Pathologically considered nearly all cases are suppurative. The muscular coat is hypertrophied, and chronic thickening of the appendix may result.

Consequences of Perforation.—A common result of all forms of appendicitis is a localized peritonitis, and this is a constant effect of the severer forms, either leading to (a) circumscribed peritonitis or to (b) acute diffuse peritonitis.

(a) *Circumscribed Peritonitis.*—At first the surface of the peritoneum is opaque and velvety. Soon a fibrinous exudation covers the appendicular peritoneum, and quickly establishes adhesions between the appendix and the adjacent parts (abdominal wall, intestinal coils). The process may not proceed any further. Generally, however, it is soon followed by a serous or sero-fibrinous exudation, which becomes sero- or fibrinopurulent, and often forms the so-called perityphlitic abscess. The seat of the abscess is always near the tube, and is as varying as the position of the appendix; its size is also extremely variable, as it sometimes contains enormous amounts of pus. Among the most common locations are—McBurney's point, the vicinity of the cecum, the coils of the small intestines (near the umbilicus), and, more rarely, in the pelvis below. The pus contained in the abscess is rarely thick, grayish-yellow in color, and emits a fecal odor; more commonly it is thin, turbid, dark gray or greenish in color, and has an extremely fetid or even gangrenous odor. The process of gangrenous sphacelation *en masse* is often completed after the limiting wall of adhesion has formed, when the entire appendix is found free in the pus cavity.

The abscess may be *subperitoneal*, as when perforation occurs into the retrocecal connective tissue, and the term "iliac abscess" was formerly applied to these *extraperitoneal* purulent collections. They are rare, however, since the early operation has been employed. Their situation and dimensions depend upon the direction taken by the appendix. The latter may pass downward, and the pus is then apt to accumulate in the lower part of the iliac fossa, and may point and finally burst in the neighborhood of Poupart's ligament, with subsequent recovery. Occasionally under these circumstances a fistula remains for an indefinite period of time. The appendix may touch various abdominal structures, and the pus in following the line of least resistance may cause spontaneous rupture into the rectum, bladder, or the vagina when it points inward; and into the perinephric region or into the pleural cavity (through the diaphragm) when it points upward; or even into the cecum or colon. The contents of the abscess may also find their way through the abdominal wall in the vicinity of the umbilicus. The psoas muscle may conduct the abscess downward, and it may then point at the hip-joint or gain the gluteal regions or the scrotum, producing the so-called "scrotal appendicitis." The appendix has also been found in a hernial sac. Among the rare lesions to be noted are erosion of one of the arteries of the iliac region (causing fatal hemorrhage) and pyelephlebitis. From the thrombi in the mesenteric veins in the latter condition infectious emboli may be conveyed to the liver, giving rise to hepatic abscess; this occurred in a case of my own at the Episcopal Hospital, Philadelphia. The abscess may also be due to an extension of the

thrombophlebitis of the mesenteric veins that lead from the appendix to the portal vein. Thrombosis of the iliac veins with edema of the corresponding leg may also arise, and these veins may, during the process of healing, become compressed, with a resulting edema of the leg, as in 2 of my cases. It rarely happens that suppurative processes are both extra- and intraperitoneal.

(b) *Acute Diffuse Peritonitis*.—This follows perforation when previous adhesions have not taken place, or when, having formed, they yield. Generalized peritonitis may also follow the circumscribed form, the lesions being propagated to the entire membrane by extension. The morbid changes are described under Acute Peritonitis (*q. v.*). Since the early operation has been employed peritonitis has been the result, usually, of direct perforation before protective adhesions have been formed.

Etiology.—Predisposing Causes.—(a) Doubtless certain *congenital structural defects* aid in the production of appendicitis. Among them are unnatural length, location, and arrangement of the organ; also the shape of the meso-appendix and Gerlach's valve. These factors tend to obliterate the lumen of the canal by producing kinks and twists, thus favoring the collection of material within the appendix. (b) *Strictures*, particularly near the cecal end of the tube, and old adhesions, especially peritonitis, operate in the same manner as (a), only with greater power. (c) *Fecal concretions* are the main cause in nearly one-half, while *foreign bodies* play a small rôle, having been present in 7 per cent. only of 1400 cases (J. F. Mitchell). The calculi form in the appendix itself (Rochaz). The foreign bodies are very various, and consist of seeds, worms, gall-stones, pills, bristles, and, more rarely, pointed bodies, as fish-bones or pins. The presence of fecal concretions and foreign bodies is often tolerated by the appendix without symptoms or local pathologic changes; hence they are looked upon rather as a predisposing than as an exciting cause. (d) *Ulcers* (tuberculous, typhoid, and, rarely, actinomycotic) may also produce this affection. (e) *Straining Efforts and Traumatism*.—Not uncommonly excessive muscular exertion, traumatism, or jarring of the body, as in jumping, act as favoring causes. (f) *Age*.—The disease is especially frequent in young adults between the fifteenth and thirtieth years. It is not infrequent in childhood after the third year, and it has been seen in persons over seventy years of age. (g) *Sex*.—Appendicitis attacks males oftener than females (4 to 1); this fact has been explained (*vide supra*). In the female it is rarely of adnexal origin. Adhesions between the tube and ovary and the appendix may occur, the morbid process then extending to the latter. (h) *Gastro-intestinal Disturbance*.—Indiscretions in the diet may precede a primary attack, and are of paramount etiologic importance in the recurrent forms of the malady. (i) *Heredity*.—That this plays a rôle in cases of appendicitis I have long felt convinced. This serves to explain cases in which syphilis, rheumatism, and uricacidemia seem to act as causal agents. (j) Evidence to show that influenza and other affections may cause appendicitis is not wanting. (k) It is not improbable that *poor blood-supply* and retrogression of the organ plus torsion and the like are the leading predisposing factors. Any slight interference with the circulation tends to block it, with dire consequences. (l) The negro enjoys comparative immunity. (m) The immoderate use of meat (MacLean). (n) Roseñow claims that appendicitis may be of hematogenous origin—secondary to distant foci of infection (tonsillitis, etc.).

Bacteriology.—The combined results of several experimentalists show that no special organism plays an exclusive rôle in this disease, but the studies of Hodenpyl indicate that the *Bacillus coli communis* is most generally present: it is well known, moreover, that this bacillus becomes pathogenic when it escapes into tissues in which it does not naturally belong. A. O. J. Kelly found

this organism present alone in 73.4 per cent. in 94 instances of acute appendicitis; alone in 89.71 per cent. of 107 cases of chronic appendicitis. Barbacci emphasizes the etiologic importance of the passage of the intestinal contents into the peritoneal cavity—*i. e.*, the chemical factor. Of other specific bacteria, those of *typhoid* and *tuberculosis* are not uncommonly found to be present. The *Streptococcus pyogenes* may also produce the most virulent infection, and the *Staphylococcus pyogenes aureus*, the *proteus*, and other organisms have been found. The great frequency of appendicitis is rendered appreciable by the numerous favoring factors (including the congenital conditons) acting upon the appendix, which naturally has an exceedingly low vitality; also by the constant presence of organisms that are known to become pathogenic in the presence of a slight lesion.

Clinical History.—Doubtless many cases are overlooked because of the extreme mildness of the symptoms. These are often attributed to intestinal indigestion or to a “cold,” to which the patient pays little attention unless he displays unusual susceptibility.

The onset of acute appendicitis may be slow and gradual, but oftener it is *quite sudden*. A clear history of some obvious cause (an error in diet or muscular effort) may be obtainable. Again, preceding the onset of the definite symptoms and extending over a day or two, there may have been *certain prodromes*, as impaired appetite, nausea, constipation, or diarrhea. In slow cases the local and general symptoms are at first slight, but gradually increase in severity. Indeed, in the latter class the patient may go about his customary duties during the attack with ill-defined rational symptoms, while in reality suffering from periappendicular abscess. These patients run two serious dangers—first, spontaneous rupture of the abscess into the peritoneal cavity may occur; and second, the slow septic absorption may suddenly overwhelm the system. As a rule the sudden cases develop in seeming perfect health, and are sometimes heralded by a rigor or chilliness.

The characteristic features of the invasion are *abdominal pain, fever, tenderness over McBurney's point, circumscribed resistance, gastric disturbances, and, as a rule, constipation*. The pain varies in intensity from a mere feeling of soreness to that of the most agonizing suffering. It may be paroxysmal, though oftener it is constant, with moderate exacerbations. Severe pain points to an involvement of the peritoneum and signalizes a danger of perforation. At first the pain may be referred to any point in the abdomen for the reason that the superior mesenteric plexus, that furnishes the nerve supply to the appendix, sends numerous twigs to the small intestines; later, within forty-eight hours, it becomes more distinctly localized in the ileocecal region.

Elevation of Temperature.—The exacerbations may at first touch 102°, 103°, or even 105° F. (38.8°–40.5° C.), and particularly in children; more commonly they range from 100° to 102° F. (37.7°–38.8° C.). The degree of fever is unreliable, however, as a criterion of the severity of the case, since the worst cases may show a subnormal temperature.

An elevation of temperature, however trivial, is most significant, pointing as it does to inflammation as the cause of the local symptoms. The pulse-rate is somewhat higher than the elevation of temperature would lead one to expect, and in bad cases the pulse is usually much quickened. Sometimes, however, it remains at 80 to 90 per minute, and may be full and soft, even though the patient be practically moribund.

Fixed tenderness is practically constant on pressure over a limited area, midway on a line between the anterior superior iliac spine and the umbilicus (*McBurney's point*), and is a valuable sign. The seat of the tenderness may be found at other points rarely, depending upon the location of the appendix.

I have twice observed it in the lumbar, once in the right hypochondriac region, and once far below the usual point, in the right iliac fossa. It has been found in the umbilical and left iliac regions, in the pelvis, and in the groin. In several instances, although I have found it elsewhere in the early stage, it has shifted to McBurney's point later. On the other hand, it may move from the usual position in cases that are allowed to drag on. When the sensitive area is at McBurney's point, as is the rule, the gentlest pressure often suffices to elicit exquisite tenderness, but when it is situated elsewhere firmer pressure with the finger-tips is usually required. Deep pressure always reveals localized tenderness at some point in the abdomen if the case is one of appendicitis. *Palpation* also detects an abnormal rigidity of the right rectus abdominis muscle. On or about the second day a *circumscribed induration* manifests itself, followed soon by a fulness and swelling tending to obliterate the depressions above and in front of the anterior iliac spine. The position of the indurated area varies according to the location of the appendix. Sometimes a questionable mass the shape of an enlarged appendix is palpable. In such cases peritoneal

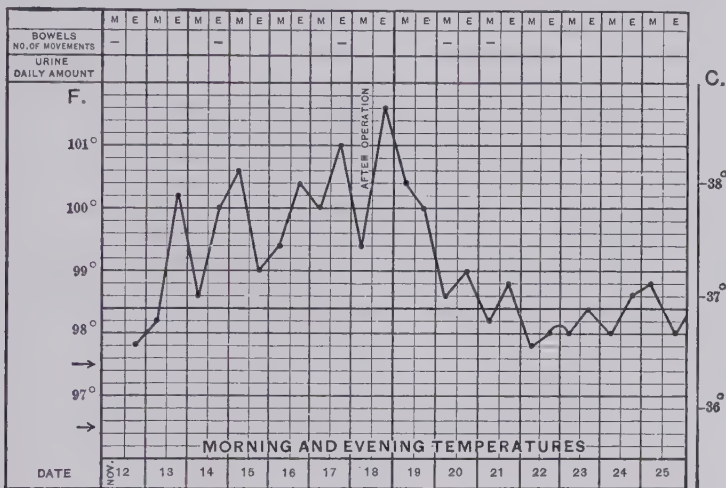

Fig. 53.—Temperature-chart of a case of appendicitis. M. M.—, aged thirty-five years; motorman. Laparotomy, by Prof. E. Laplace, disclosed catarrhal appendicitis with adhesions.

exudation has not as yet occurred to any great extent. Induration may gradually assume the circumscribed form; it may, moreover, be so deeply seated as not to be appreciable. The degree of tenseness of the two recti muscles—right and left—should be compared, though an absence of tension of the right rectus does not eliminate appendicitis. The results of *percussion* furnish no certain guide.

Vomiting usually occurs at the beginning unless there be diarrhea, and is attended by more or less nausea; it may continue throughout the course of the attack. In most cases after a few paroxysms of vomiting the symptom disappears, although it may recur if errors in diet be committed or if peritonitis supervene. Constipation is the rule during the attack, though diarrhea, which sometimes precedes appendicitis, may also occur at a late stage as a septic symptom. There is anorexia and the tongue is coated. The *decubitus* is dorsal, with the right leg flexed. Frequent micturition (early) and retention of urine (later) are not uncommon, the urine having a deep color tint, and sometimes containing albumin. Moderate leukocytosis (*e. g.*, 10,000 to 15,000 per cubic

millimeter) usually exists, but may be absent. Daniells,¹ in 120 cases of uncomplicated appendicitis, found that a rapidly increasing leukocytosis means that the inflammation is increasing and extending.

The case may follow a mild *course*, terminating in resolution with recovery; or it may be of a severe type and develop perforation, with the formation of abscess or diffuse peritonitis. It is impossible to obtain statistical evidence of the relative frequency of these alternatives, and hence the frequency of treatment by abdominal section. In more than one-half of the cases it is probable that the course is favorable.

If not operated upon early the fever may continue for three to five days, and then subside, with simultaneous abatement of the severe local and general symptoms and with the establishment of convalescence. The same amelioration of the symptoms may be brought about by free purgation early as the result of salines or, less often, spontaneously. In these instances resolution takes place even after invasion of the peritoneum. Small abscesses may be absorbed, and usually in cases terminating in resolution perforation has not occurred. Infection of the peritoneal membrane directly through the appendix is not uncommon.

In severe attacks perforation may occur, with the development of localized peritoneal abscess or generalized peritonitis (vide Pathology), and it must be remembered that cases that begin gradually may also show a tendency toward perforation. When this event occurs during the course of appendicitis, the symptoms of local or general peritonitis are superadded. If early, the symptoms pointing to peritonitis are intense; the abdomen swells quickly, and is exquisitely tender, while the physical signs of a tumor are absent. The temperature often falls, when vomiting and circulatory collapse appear. The generalization of the peritonitis is usually marked by less violent symptoms. Starting from the seat of circumscribed inflammation, the pain and tenderness advance noticeably from day to day until every portion of the peritoneum has been invaded. Besides progressive augmentation in the local features, including the pain, there is a gradual failure in cardiac power, as shown by the condition of the pulse; vomiting also returns, and at last becomes fecal. Death results from asthenia, and sometimes suddenly when unanticipated. If perforation occurs later, sufficient time has been allowed usually for the inflammation to become circumscribed, in which case the localized abscess is generally intraperitoneal; it may, however, rarely be extraperitoneal. The local symptoms intensify, the pain becomes excruciating, and the spot of tenderness may rapidly extend itself in all directions, particularly downward. Vomiting sets in, and may become troublesome, and constipation is absolute, not even gas escaping.

Physical Signs of Localized Abscess.—*Inspection* shows distention of the belly, the affected area being prominent, with an obliteration of the natural depression in the right iliac region. A dark and swollen appearance of the subcutaneous and deeper veins has been noted by Skinner. *Palpation* discovers induration and great tension that soon yield to pressure (doughy), and edema of the skin. If the abscess is superficially seated, fluctuation may be appreciable. Deep-seated tumors are not uncommon, and then fluctuation is detected with difficulty. An examination *per rectum*, with a view to determining whether the abscess occupies the pelvis, is important, and in doubtful cases bimanual examination should not be neglected. *Percussion* reveals dulness if the abscess be superficial. A tympanitic note, however, is often elicited, and is due to an intervening coil of intestine.

If active peritonitis and septicemia do not develop, the constitutional as

¹ *Columbus Med. Jour.*, September, 1906.

well as the local symptoms may abate, and the patient leave his bed, carrying with him, however, the abscess. The latter may point somewhere in the right lower quadrant of the abdomen or in the lumbar region. Spontaneous rupture into the rectum, bladder, vagina, or cecum may also occur. Often, preceding the discharge of pus into these organs, the latter display marked irritability, particularly the rectum and bladder. There is always the danger that the contents of the abscess may find its way into the general peritoneal cavity. The symptoms of hepatic abscess may develop. The pus may traverse the abdomen in the upward direction until it touches the diaphragm, when the symptoms of subphrenic abscess may be manifested. Extension through the diaphragm, causing pleurisy or pericarditis, and a pleurofecal fistula may occur.

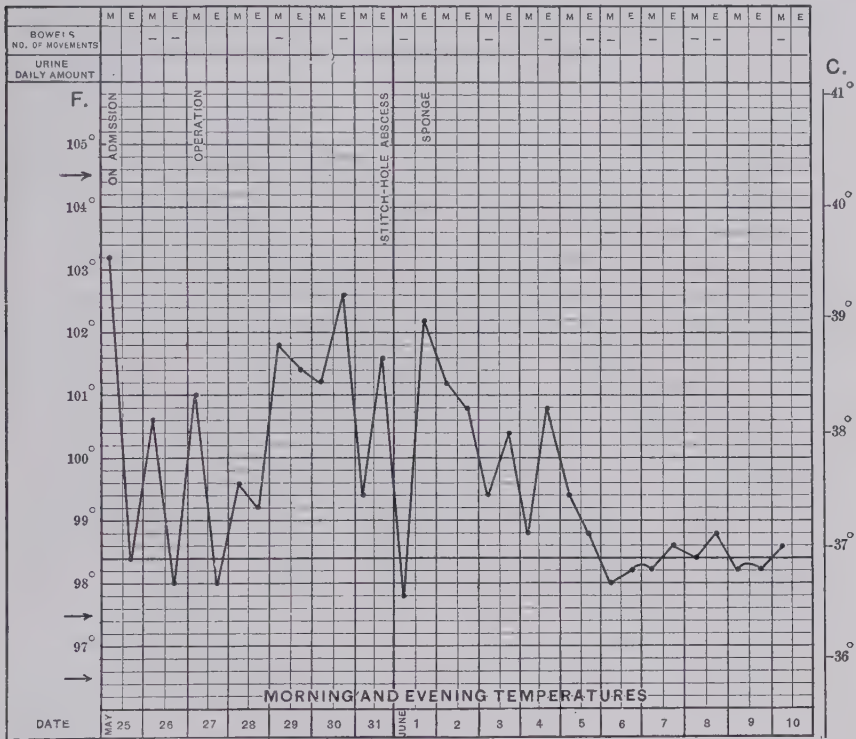

Fig. 54.—Temperature-chart of a case of appendicitis. R. C.—, aged nineteen years; carriage-builder. A peritoneal abscess was found, while the appendix was becoming gangrenous.

The lung complications originate, as a rule, from emboli. Sonnenburg found that out of 740 cases of appendicitis, 28 had some lung complication, and of these, 14 were cases of thrombosis. The early recognition of the postoperative lung emboli is important.

The general symptoms undergo a modification, due to the *suppurative process*. Rigors or a decided chilliness may occur. Diarrhea often succeeds to previous constipation, and drenching sweats to a dry skin. Improvement and even spontaneous cure may ensue if spontaneous rupture into one of the outlets of the body should occur. The fever (Fig. 54) may be either remittent or intermittent, and if the localized inflammatory process be active, the usual pronounced features of septicemia are predominant in the clinical picture.

The latter specially grave condition often drifts into an extreme typhoid state with a hopeless course.

Diagnosis.—Typical cases of appendicitis are readily diagnosticated. Their recognition rests upon a few cardinal symptoms—viz., the acute development of severe pain in the right iliac fossa, coming on in a person previously healthy and usually under forty years of age; appendicular tenderness, unilateral induration, fever, vomiting, and constipation, or, more rarely, diarrhea. Atypical cases, however, may offer difficulty, although it is my belief that errors in diagnosis are less frequent than in almost any other disease. The pain may for a time be referred to a circumscribed area far removed from the site of the appendix, and rarely it continues without a change of situation throughout the attack. In the latter case the morbid lesions may occupy the usual position, or more often perhaps some quite unusual position. Thus, when the pain is referred “due east,” or to the left iliac fossa, with bilateral induration, the appendix will be found in the pelvis (Deaver). In such instances a rectal and bimanual vaginal examination are imperative. It should be an unvarying rule in all cases of severe abdominal pain to palpate with the fingertip every square inch of the abdomen if necessary, to find the localized tenderness when it is not found at McBurney’s point. The degree of tenderness sustains a close relationship to the severity of the local inflammation as long as the condition remains strictly localized, but this relationship is lost when generalization occurs. Pain following rapid removal of the hand after it has been applied to the spot to induce pressure (Blumberg’s sign) is confirmatory. It is not, however, a specific sign, Nikolaieff having found it in every case of peritoneal irritation. With the appearance of a circumscribed induration and of the intense local tenderness and pain it is reasonably sure that perforation either has occurred or is impending. Perforation may occur without local induration, however, and even after subsidence of the acute pain and excessive tenderness. Gangrenous appendicitis is *most deceptive*. The very acute symptoms, including the fever, may disappear, and unless the physician be upon his guard the patient will be considered convalescent and be allowed to go about. Rupture of the abscess now occurs unexpectedly into the peritoneal cavity, intestines, or some other direction, or a large-sized abscess develops with the usual signs and symptoms. In dubious cases the roentgen rays should be employed for diagnostic purposes.

Differential Diagnosis.—*Typhlitis, and Especially the Massing of Feces in the Cecum.*—These are truly rare conditions. According to McBurney, 99 per cent. of all typhlitic abscesses are of appendicular origin, and of 400 autopsies by Einhorn 91 per cent. had this origin. Ball and others have performed laparotomy for ulcerative cecitis, but this condition cannot be recognized during life. Stercoral typhlitis is discriminated from true appendicitis by the precedent constipation, which may become absolute, by the dragging character of the pain, the late-appearing fever, and the physical signs, which indicate the presence of a superficial, sausage-shaped tumor that is often doughy and extends vertically from a point near the right costal border “southward.” Percussion elicits dullness over the seat of the tumor. The localized tenderness and circumscribed resistance of acute appendicitis are wanting.

Renal Colic.—There is an absence of fever and of a localized spot of tenderness and induration. On the other hand, disturbed micturition followed by hematuria occurs and pain radiates into the groin and testicle.

Indigestion.—Digestive disturbances, and particularly pain and vomiting, accompany appendicitis. When they occur independently of appendicitis, however, they can be relieved, and the appendicular region remains free from fixed pain, tenderness, or tumor.

Cholecystitis with Distention.—This gives rise to a superficial, mobile, pear-shaped tumor (the distended gall-bladder), with or without jaundice—features not met with in appendicitis. The tumor in appendicitis is generally below the level of the umbilicus, but when the appendix extends upward the tip may almost touch the gall-bladder, in which case a diagnosis cannot be rendered.

Perinephric Abscess.—Without a clear history the differentiation cannot be made except by exploratory incision.

Pneumonia.—The pain in the earlier stages of pneumonia may be referred to the appendix. Physical examination will prevent error.

Acute Peritonitis Due to Ovarian or Tubal Disease.—When the appendix occupies not its usual seat in the iliac region, but the pelvic fossa, then the distinctions between salpingitis and appendicitis are not easily drawn. Right ovaritis, owing to the presence of pain, tenderness in the right iliac fossa, and fever, often closely simulates appendicitis. In the former tenderness is less pronounced and the organs of uterogestation manifest certain disturbances of function. A clear history, coupled with a careful pelvic examination, will usually complete the clinical separation of these two conditions.

Extra-uterine Pregnancy.—In this condition the menstrual history furnishes important information. There is, in addition, profound collapse, due to hemorrhage, when rupture of the adhesions occurs. Elevation of temperature is absent. The localized tenderness and increased resistance are lower in the pelvis than in appendicitis.

Acute Tuberculous Peritonitis.—As in appendicitis, so in tuberculous peritonitis, pain, tenderness, and fever are present, but in the latter the onset is more gradual, and the signs of tumor and increased resistance in the ileocecal region are absent. Movable dullness may be present in the tuberculous affection, but not in appendicitis until the peritonitis is generalized. The lungs generally show lesions in tuberculous peritonitis.

Acute Intestinal Obstruction.—When this is due to intussusception there may be signs of a tumor, but not at McBurney's point; the tenderness over the site of the mass is less intense, while the frequent bloody discharges that are seen in this condition, accompanied by tenesmus, do not characterize appendicitis. When obstruction is caused by strangulation stercoraceous vomiting is apt to occur, and is absent in appendicitis. Pain, local tenderness, and, not uncommonly, signs of a tumor appear, but elsewhere than at McBurney's point.

Intestinal Lithiasis.—This can be diagnosticated, as a rule, by the presence of intestinal sand in the movements (Bottentuit). Circumscribed resistance is absent in this connection.

Acute Hemorrhagic Pancreatitis.—This affection simulates appendicitis with generalized peritonitis. But the deep-seated epigastric pain, followed by circumscribed resistance in the same region (a grouping absent in appendicitis), should arouse strong suspicion of pancreatitis.

Hip-joint Disease.—In both hip-joint disease and appendicitis the dorsal decubitus with flexed leg is noted. If the patient be anesthetized, however, full extension of the leg and a normal condition of the hip-joint are easily demonstrable in appendicitis.

Typhoid Fever.—Mild cases of appendicitis with accompanying diarrhea bear a close superficial resemblance to typhoid fever. In typhoid fever, however, the onset is more gradual and the fever-type more continuous than in appendicitis. In typhoid the stools are somewhat peculiar, the spleen is swollen, there is dulness of intellect, bronchitis and the characteristic eruption attend—all features that are absent in appendicitis. The diazo-reaction would strengthen the diagnosis of typhoid, and a response to Widal's test would be conclusive.

In appendicitis the local features, and in typhoid the general, are predominant.

Dietl's Crisis.—In a case of movable kidney which I saw recently all the symptoms pointed to appendicitis. An operation was about to be performed when a sudden subsidence in the local induration occurred and the kidney was detected in an abnormal location.

CHRONIC APPENDICITIS

(Relapsing Appendicitis—Recurrent Appendicitis)

Relapses occur in nearly one-half the total number of persons who have suffered from a primary attack of appendicitis. In most of these cases there is constantly present a slight local discomfort during the interval. When successive attacks occur in the same individual at intervals of considerable duration (*e. g.*, a year or more), each new attack is spoken of as a *recurrent appendicitis*. Severe attacks may succeed light ones and even prove fatal, or, conversely, mild recurrent may follow severe primary attacks. The *local symptoms* in those having had an antecedent peritonitis are more pronounced than in the first attack, but after a number of recurrences the symptoms are likely to be less severe with each new attack. The most constant symptom between attacks is a subacute form of *pain* that is liable to manifest exacerbating periods with slight fever. Physical fatigue, a strain, and errors in diet, causing gastro-intestinal disorder, are very likely to induce a relapsing or recurrent appendicitis. Chronic appendicitis strongly favors the retention of fecal matter in the cecum, thus forming so-called *stercoral typhlitis*.

In the intervals between the attacks the appendix can be readily appreciated on *palpation*, the method employed by Edebohls being preferable: "The patient lies upon his back with the examiner at his side; the latter places his right hand upon the patient's abdomen over the right rectus muscle, opposite the anterior superior spine of the ilium, and presses the left hand upon the right, so that no force is used by the right hand and the tactile sense of its fingers is left undisturbed. The hands are drawn slowly outward, allowing the contents of the abdomen to slip from underneath them. The coils of intestine can be felt as they escape from under the hand as it presses against the posterior abdominal wall." In this way the appendix may be felt as an elongated tumor of the size and shape of the little finger. If there be only a slight exudation present the appendix often appears to be immediately beneath the abdominal wall. It may, however, be deep seated, even though the exudation with adhesions be absent. *Bastedo's test* in suspects—the passing of a colon-tube 10 or 12 inches into the rectum and injecting air by means of an atomizer bulb. If now pain and tenderness to finger-point pressure become apparent at McBurney's point, there is chronic appendicitis. Both pain and tenderness are pronounced, and particularly if pus be present. Goodman and Lüders hold that this test should be regarded merely as an aid in diagnosis.

Here should be mentioned a form of appendicitis which is chronic from the start and not preceded by acute attacks. The inflammation, slowly developed, may be due to various causes, such as influenza (rare), floating kidney (common), and errors of diet, which produce a condition of enterocolitis to which the chronic appendicitis is secondary. The symptoms are: an unpleasant, dull pain accompanied by a dragging sensation, which may affect the entire right side of the abdomen or be circumscribed in the region of the appendix, obstinate constipation, emaciation, and marked neurasthenic features. Attacks of appendicular colic, with or without vomiting, may arise from time to time. A differential leukocyte count and frequent thermometric observations, which may

show slight elevations of temperature, are aids to the diagnosis. The *physical examination* reveals tenderness on deep pressure over the vermiform appendix, with which an equal degree of tenderness, however, up near to the costal arch (suggesting gall-bladder disease) may be associated. More or less resistance may also be noted, but seldom a tumor.

In so-called *appendix dyspepsia*, in which the appendix is the seat of chronic inflammation, the symptoms exhibited may be those of gastric or duodenal ulcer. The mimicry is due to an exaggerated action of the pylorus (Moynihan). Removal of the inflamed appendix is generally followed by relief of the foregoing dyspepsia. Sailer¹ states that many cases of movable cecum, due to kinks or folds that give rise to partial or complete obstruction, are wrongly diagnosticated chronic appendicitis. The removal of appendix is not followed by relief of the symptoms. Hausmann² holds that there are various forms without a characteristic clinical picture even when the anomaly is causing symptoms.

The results of chronic appendicitis upon the general health and nutrition of the patient are quite noticeable, and tend to augment as time passes, if the attacks be frequent or the intervals between them grow shorter. The chief symptoms are those of a nervous type; emaciation and debility are also observed. The associated nervous symptoms are those of neurasthenia. These patients often become introspective and exceedingly irritable, principally owing to the overhanging danger of a fresh attack with serious possibilities.

Differential Diagnosis.—*Carcinoma of the Appendix and Cecum.*—This presents many points of similarity to chronic appendicitis. I have under my care at present a lady aged sixty years suffering from chronic appendicitis, whose case had been diagnosticated as carcinoma of the cecum, and for a considerable time my own view coincided with that of my predecessor. The occurrence, however, of relapses, during which the feces were massed in the cecum and fever arose, soon indicated the correct diagnosis. Besides the absence of periodic attacks of fever, the general features—loss of flesh and strength, anemia—are more steadily and rapidly progressive in carcinoma of the appendix or cecum. The history of the mode of onset also aids in the distinction. Pain, tenderness, and a resistant tumor are common to both affections. Lane's kink of the ileum may present symptoms simulating chronic appendicitis, especially marked constipation, colicky pains, and meteorism.

Hypochondriasis and Hysteria.—Hypochondriasis and hysteria may lead to the manifestation of morbid feelings simulating those of appendicitis. Such cases may show merely a greatly exaggerated uneasiness, or such an increase of sensibility as to cause the patient to complain of pain in the right iliac fossa. In addition, there may be localized tenderness. I recently witnessed the removal of the normal appendix from an hysterical female in whose family two genuine cases of appendicitis had occurred not long previously. Hypochondriasis and hysteria distinguish themselves by the antecedent history and by the absence of a tumor mass and of increased resistance; there is also an absence of localized tenderness if the patient's attention be withdrawn. In such the irritation of the right ureter by the passage of crystals of calcium oxalate as mentioned by Cabot, may explain the localizing of the discomfort (Wood and Fitz). I saw a case of this sort in a medical student.

Prognosis.—Unlike many of the acute infectious diseases, the height of the temperature and, to a lesser degree, the rate of the pulse are unreliable guides in appendicitis. Broadly speaking, however, in the severer forms the local process exhibits a strong tendency to spread; the temperature and pulse are relatively high, and there is an intense appendicular intoxication. These

¹ *Amer. Jour. Med. Sci.*, February, 1912, p. 157.

² *Mitteilungen aus den Grenz. der Med. u. Chir.*, Jena, 1913, xxvi, No. 4.

are the cases that suppurate or result in perforative peritonitis and in pericecal abscesses. Of this fatal group of cases not less than 68 per cent. die before the eighth day. The development of *fulminant peritonitis* or of a peritoneal abscess after perforation is attended by a falling temperature, though subsequently the latter may mount high or become markedly irregular.

On the other hand, in the mild forms that are included in the name *catarrhal appendicitis* recovery is the unvarying rule. These lighter cases often lead to adhesive peritonitis—a circumstance that strengthens the view that they are of an infectious nature. The temperature is only moderately elevated as a rule, and the pulse-rate correspondingly quickened. Both pulse and temperature indicate marked improvement on the third or fourth day, while the pain and localized tenderness disappear. In this connection the deceptiveness of gangrenous cases must be recollected (*vide supra*, Diagnosis). The complications and antecedent and associated conditions may decidedly influence the issue. As to age, “the younger the child, the worse the prognosis” (Finney). The general mortality of appendicitis is about 14 per cent. (Fitz). Improved methods, chiefly surgical, of dealing with the disease have, however, greatly reduced its death-rate. The prognosis in *chronic appendicitis* is most uncertain; after the patient has survived several attacks it is, on the whole, more favorable.

Treatment of Appendicitis.—Whether imminent danger of perforation exists or not, the physician who is called to a case of appendicitis should at once request the services of a competent surgeon. Few surgeons subscribe to the doctrine that all cases demand operation; but, since it may become necessary to perform celiotomy at any hour thereafter, the latter should help to settle the important question: “When is it necessary to operate in the case?” The physician who does not pursue the course above recommended falls short of his duty, both toward the patient and toward the surgeon on whose skill he relies to remove safely the source of danger. Surely, in a disease that so often baffles both physician and surgeon, suddenly developing, as it sometimes does, a fatal virulence without previous unfavorable symptoms, they should stand guard together from the moment the case is diagnosticated or appendicitis is strongly suspected. Unfortunately, both the medical and surgical treatment of appendicitis have each been recommended with great earnestness by their respective advocates.

With rare exceptions, prompt surgical intervention should be recommended. The indication for an immediate operation is undoubted in all cases of acute appendicitis, whether marked by sudden and severe or mild invasion symptoms, if seen at the beginning of the attack. A waiting policy and medical treatment are also perilous in doubtful cases. Obviously, the conditions are less favorable for operation after a case has progressed to the beginning of abscess formation—*i. e.*, from the third to the fifth day of the illness. It is at this period that the peritoneal inflammation tends to circumscribe itself by the formation of adhesions. Hence, as Richardson states, it is “too late for an early operation, and too early for a safe late operation,” since there is great risk of infecting the general peritoneal cavity. Whether it is wise to allow the appendix to remain after adhesions have been formed in some cases, and merely to drain, cleanse, and pack the cavity, cannot be discussed here. The lightest grades of appendicitis, in which doubt may surround the diagnosis and all factors possessing an unfavorable prognostic import are absent, scarcely require immediate operation.¹ The mild attacks that develop in the course of chronic appendicitis after numerous previous seizures need not excite alarm. In relapsing and in recurrent appendicitis operation should be undertaken between attacks, when

¹ “Factors Influencing Mortality in Appendicitis, from a Medical Viewpoint,” *Arch. of Diag.*, January, 1911, by J. M. Anders.

the mortality is practically *nil*. On the other hand, in cases that have been allowed to drag on until general peritonitis has set in, treatment by operation is not advisable. Moreover, the most ardent advocate of immediate operative treatment is sometimes compelled to rest satisfied with medical measures. Such cases are those in which there are associated chronic affections (advanced diabetes, Bright's disease), not to speak of those in which the patient declines operation. Appendectomy alone does not cure in patients with chronic constipation, a long dilated cecum, or enteroptosis.

General Management.—The patient should be kept in bed in a quiet, well-ventilated apartment, and in no affection is the value of *absolute rest* in the treatment of inflammation greater than in appendicitis. Neither food nor drink should be allowed from the moment the patient is first seen until early convalescence. At the start, and particularly if a sausage-shaped tumor be present, intestinal irrigation, oft-repeated, with a view to removing the fecal matter, must be carried forward carefully. I avoid the use of high enemata in *progressive* cases, since they are apt to induce rupture of the sac. To relieve thirst, enteroclysis by the drop method may be employed, and when stimulants are needful, whisky or liquid meat extracts may be added to the saline solution.

As regards the use of opium professional opinion is not united, though a general tendency toward the limitation of its use to the minimum amount necessary to alleviate pain is happily noticeable; unless demanded by excessive suffering it had better be omitted altogether. When necessary, it is best administered hypodermically in the form of morphin (gr. $\frac{1}{12}$ to $\frac{1}{8}$ —0.0054–0.0081). The greatest objection to the use of opium is its effect in veiling the symptoms that assist the physician in forming a judgment as to the prospects and progress of the case. Gastric irritability may be sufficiently marked to demand special measures, such as the swallowing of small pieces of ice, spirits of chloroform, menthol, and the well-known combination of cerium oxalate (gr. iij—0.02) and cocaine (gr. $\frac{1}{8}$ —0.008) every third hour may be used.

Local Measures.—The suspended ice-bag is an excellent means of combating the pain, and often obviates the necessity of an internal use of opium. Instead of the ice-bag, cloths wet in cold water may be applied and changed every few minutes. In the early stage a few leeches may be beneficial in their effect upon the local inflammation. Blisters, however, are rarely advisable, and are particularly objectionable should the patient afterward be submitted to an operation. Mild forms of counterirritants (mustard-paste) are preferable, though these also render the skin and underlying tissues hard and leathery.

Management of Convalescence.—The patient should not be allowed to leave his bed for several days after the disappearance of all symptoms; even the mildest forms of exercise should not be undertaken for at least one week subsequent to getting out of bed. During convalescence the diet must be carefully guarded, and the bowels, at all hazards, kept in a soluble condition. It is questionable whether drugs will aid in the absorption of the exudate or assist in resolution.

DIVERTICULITIS

An inflammatory process of a diverticulum from the intestinal canal sometimes occurs, either as an acute or a chronic intra-abdominal condition, with symptoms that are often very vague. The lesion is usually situated in the left lower quadrant of the abdomen, the diverticulum opening out from the sigmoid. The acute *symptoms* closely resemble appendicitis: pain, tenderness, rigidity, fever, leukocytosis, but with the local symptoms on the left instead

of the right side of the abdomen. The chronic types of the disorder, usually found in persons past middle life, are characterized by recurring mild attacks of pain in the left abdomen, which, if they do not light up into an acute exacerbation, may gradually incapacitate the patient, who becomes easily tired out, subject to attacks of mucous diarrhea alternating with constipation, suffers from neurasthenic and hypochondriac symptoms, with anorexia, headache, and, at times, evening rise in temperature. Locally there may be tenderness and slight rigidity of the left rectus, and at times a distinct mass. The diagnosis is further aided by roentgenologic studies.

Treatment in the early and mild cases consists in keeping the colon well emptied by the use of enema and the heavy petroleum oils, with a very mild diet. The severe acute cases and the chronic ones require operative procedure.

TYPHLEITIS

By typhleitis is meant inflammation of the cecum without involvement of the appendix (rare); and in some cases ulceration due to pressure by retained fecal matter or foreign bodies ensues. The history of previous constipation or of some dietetic error is frequently obtainable.

The *symptoms* are pain of a dull character, nausea, and obstinate constipation with moderate fever. The *physical signs* are: a prominence in the ileocecal region, tenderness to pressure, and those of a doughy, sausage-shaped tumor in the cecal region. After two or three days the tumor gradually diminishes, also the active symptoms, but tenderness persists for a week or longer. When ulceration attacks the inflamed cecum a pericecal abscess is the usual result. To this condition the term "perityphleitis," which is now practically obsolete, was formerly applied.

The *treatment* of typhleitis is that of obstinate constipation. Eserin (gr. $\frac{1}{80}$ every fourth hour) has proved serviceable. For this purpose enemata administered high in the bowel are most effective. We may employ the so-called "ox-gall" enema, as follows:

R.	Powdered ox-gall,	gr. xx (1.3);
	Glycerin,	f℥j (30.0);
	Water and soapsuds (105° F.—40.5 C.),	Oj (500.0).

My own best results have been obtained from the use alternately of an enema of olive oil (℥viij at a temperature of 100° F.—37.7° C.) administered through a rectal tube high in the bowel while the patient occupies the left lateral prone position, and one composed as follows:

R.	Sulphate of magnesia,	℥iss (45.0);
	Glycerin,	f℥j (30.0);
	Spirits of turpentine,	f℥ij (8.0);
	Hot water (100° F.—37.7° C.),	Oj (500.0).

The diet should be of the blandest sort, such as albumin-water, peptonized milk, and the like, given at stated intervals in small, fixed quantities. Arterial stimulants may be required during the later stages.

INTESTINAL CALCULI

Intestinal calculi are rarely passed with the feces, and may be in the form of small concretions, hepatic calculi that have entered the intestine, and as sand which is formed in the saccules of the colon and folds of the cecum and rectum. Their origin may depend upon the deposition of calcium and magnesium salts upon particles of undigested food.

A teaspoonful or more of gritty sand may escape with each stool. But 4 cases of true enterolithiasis have been reported. The condition is likely to arise when the diet is exclusively milk. "Sand" may be produced through the ingestion of the banana (Myer and Cook).

INTESTINAL OBSTRUCTION

(*Ileus*)

Definition.—An acute or chronic, complete or partial, occlusion of the intestinal canal.

Pathology and Etiology.—The causes of intestinal obstruction may be divided, at once most simply and practically, into the (1) *acute* and (2) *chronic* forms. In the former variety the narrowing or closure develops very suddenly or rapidly, and usually in the small bowel; in the latter the large bowel is commonly affected by pathologic conditions that develop gradually and narrow its lumen (usually in advanced years).

Acute.—(a) *Strangulation.*—In the order of frequency, this is first among the causes of acute intestinal obstruction. It is produced most often by bands of adhesion the result of a former recent or remote peritonitis, and is most commonly situated in the right iliac fossa. Incarceration of the bowel from flexions and adhesions not rarely follows upon abdominal section for the treatment of pelvic disease in women.

The usually free end of Meckel's diverticulum is sometimes attached to the abdominal wall, and may thus cause constriction of a loop of bowel. This diverticulum is the remains of the fetal omphalomesenteric duct, and arises from the ileum about $\frac{1}{2}$ meter (1.64 ft.) from the ileocecal valve. A similar constricting band is formed by a cord representing one or more of the obliterated omphalomesenteric vessels. The adhesive attachment of the free end of the appendix vermiformis may also form an opening through which the bowel may be caught.

Internal strangulation (hernia) may be the result of forcing a portion of bowel through a slit in the omentum or mesentery, or into peritoneal diverticula and openings, such as the duodenojejunal fossa (*Treitz's retroperitoneal hernia*) or the foramen of Winslow.

Diaphragmatic herniæ are not of extreme rarity, and may be either of congenital or traumatic origin. Most cases of intestinal strangulation occur in males during early adult life.

(b) *Intussusception.*—*Invagination* is the descending "telescoping of one section of the bowel into another," probably caused by a circumscribed, irregular peristalsis of the intestine. The effect of the latter state in producing invagination may be either a thrusting forward of the receiving portion by a contraction of the longitudinal muscular coat (Nothnagel), or a thrusting inward and downward of the portion immediately above by means of an increased or spasmodic peristaltic action. Thus, a cylindric or sausage-shaped tumor results, varying from $\frac{1}{2}$ inch to over 1 foot (1.3–30 cm.) in length. The layers

met with in intussusception are the outer or receiving, called the *intussuscipiens*, the middle or returning layer, and the inner, called the *intussusceptum*. The seat of invagination is most commonly at the ileocecal valve, though it is often found in either the ileum or colon alone. Sometimes the intussusception is detected in the rectum. A lateral or partial invagination may also occur due to the attachment of a tumor within the bowel.

The intussuscepted portion of intestine is usually the seat of peritoneal adhesions, so that in pronounced cases the parts are so firmly agglutinated that reduction is wellnigh impossible. The engorgement may pass into an intense local inflammation, with final necrosis and sloughing, and even the discharge *per rectum* of the invaginated portion.

Intussusception occurs most frequently in children prior to ten years of age, and males suffer more than females. Invagination is an occasional consequence of the operation of circular enterorrhaphy (Robinson).

(c) *Volvulus*.—Twists of the intestine are met with most commonly at the sigmoid flexure of the colon. An unusually long or relaxed mesentery predisposes to the condition, so that the axis of twisting may either consist of the mesentery itself or frequently of the bowel. Not rarely the pedicle of the volvulus contains both a twist and a sharp bend in the bowel, causing complete acute strangulation. The latter condition may be pronounced in such cases, or at least be hastened, by the accumulation of the intestinal gas and of masses of feces—by bowel adhesions to an adjacent stump of omentum (Nieberding). The passive reactive pressure of the coils of intestine and of the abdominal walls tends also to further confine the enormously dilated and twisted loop of bowel to its abdominal state. Knots may be formed by the association of loops of the ileum with each other or about the pedicle of a twisted cecum.

Males between forty and sixty years are especially the subjects of volvulus. Acute intestinal obstruction invites bacterial invasion, which is the probable cause of the general symptoms.

Chronic.—(a) *Fecal Impaction*.—*Intestinal Concretions*.—Accumulation of feces (*coprostasis*) is a common cause of intestinal obstruction, the impaction taking place usually in the cecum or sigmoid flexure.

Though not infrequent in children, fecal obstruction is more common in adults (particularly in females), in the hysteric, the demented, and the hypochondriac. Congenital dilatation of the colon may predispose to coprostasis, and an acquired dilatation, which in some cases becomes enormous, is often the result of paresis of a portion of bowel caused by overdistention for a long period of time.

Among other causes of obstruction due to abnormal contents may be mentioned *enteroliths*. These are intestinal concretions formed of various nuclei, as gall-stones, hardened feces, phosphates of lime and magnesia, various foreign substances, and organic derivatives. Balls of tangled ascarides may mass sufficiently to cause obstruction.

Foreign bodies, as pins, buttons, coins, fruit-stones, may also cause obstruction of the bowel. It is stated that even insoluble mineral medicines, as bismuth or magnesia, have caused obstruction.

(b) *Tumors* cause a form of chronic obstruction that may at any time develop suddenly into the acute type. They may do so either as—(1) *new growths* in the wall of the intestine itself, or by (2) *compression and traction from without*. Again, the intestinal neoplasms may be *malignant* or *benign* in nature. *Carcinoma* of the bowel is at once the most frequent and important of these. It may be either circumscribed and annular, causing a gradual narrowing of the bowel lumen, or a diffused infiltration of the intestinal wall, commencing

either in the mucosa or in its glands (cylindric epithelioma). Its most common seat of growth is the large bowel, about the sigmoid flexure.

Sarcoma usually attacks the small bowel, starting* beneath the mucosa, and is of the recurrent variety. Regional infection of the mesenteric and retroperitoneal glands (*Lobstein's cancer*) is also a usual consequence of sarcoma. It may occur in children or in young adults.

Benign tumors may be polypoid, adenomatous, fibromatous, and lipomatous. Intestinal obstruction due to compression or traction may be caused by tumors (omental) or by adhesions of the pelvic viscera.

(c) *Cicatricial strictures* cause chronic intestinal obstruction, as after the healing of various ulcers, the cicatrices of which slowly contract. Cicatricial stenosis of the colon is commonly due to the cicatrization of dysenteric ulcers. In the rectum the stenosis is usually a result of a syphilitic lesion. Tuberculous and, rarely, typhoid ulceration may be followed by stricture of the small intestine.

(d) *Congenital stricture* is rare, and is more purely surgical than the preceding cases. It is often an occlusion or an imperforate condition of the anus (*atresia ani*), and is only mentionable in this connection.

(e) *Paresis of Peristalsis*.—This condition—called also *adynamic obstruction*—while it is a functional affection, is held to be either a circumscribed or diffuse paresis of the intestinal muscular coat. It is caused by some such inflammatory disturbance as enteritis or peritonitis, or even by the manipulations employed in abdominal sections. Here the obstruction is due to an accumulation of feces and gases in the parietic portion of the bowel, causing tympanites, vomiting, and constipation.

Special Pathology.—The pathologic changes that accompany nearly every form of intestinal obstruction are briefly stated as follows: Accumulative dilatation—with hypertrophy in chronic cases—of the intestine above the seat of disorder, and an emptiness, narrowing, and even atrophy below the obstruction. The affected walls of the bowel are inflamed, and there is a surrounding acute or chronic peritonitis. Catarrhal and sometimes diphtheritic inflammation of the mucosa may develop. Gangrene, ulceration, and perforation of the bowel, with resulting generalized peritonitis, may also ensue.

Symptoms.—Acute Obstruction.—There is a suddenly developed *abdominal pain* that may follow some abrupt or severe exertion. *Early vomiting* and *absolute constipation* are also conspicuous and important symptoms. If the obstruction is high in the small bowel, distressing hiccup and eructations may precede the vomiting. Except for the possible discharge of the intestinal contents below the seat of obstruction, the constipation is usually complete and obstinate. The early symptoms, however, are caused by strangulation rather than by obstruction. Accompanying the latter condition there is tympanites, which is most marked in obstruction of the colon. Intermittent and colicky at first (partial obstruction—Treves), the *pain* soon becomes agonizing and constant. *Vomiting*, also, alternating with *painful retching*, is more constant and severe after several hours. The *material* at first ejected is gastric and mucous; it then becomes bilious, and finally is characteristically stercoraceous.

The *constitutional symptoms* develop early, are intensely threatening to life, and cause rapid and profound collapse. In general, the higher the obstruction in the intestinal tract, the more severe and the more acute are the constitutional symptoms. The pinched and pallid features, cool and moist skin, Hippocratic expression, rapid and feeble pulse, the usually subnormal temperature, shallow and accelerated breathing, marked thirst, scanty urine, great anxiety and prostration—all indicate the gravity of the condition. Cooke,

Rodenbaugh, and Whipple showed that intestinal obstruction with signs of acute intoxication gives a high non-coagulable blood nitrogen. If the reading be high, it indicates a dangerous grade of intoxication, but a fatal outcome may be associated with a low reading. McClure's experiments show the symptoms to be due to absorption of bacterial toxins through the lesions produced. Gurd, as a result of experimental investigations, concludes that the substance responsible for the intoxicating symptoms is due to tissue autolysis rather than a bacterial product. Draper states that recent studies point to aberrant activity of the duodenal and probably pancreatic cells as the immediate cause of death. Whipple and his co-workers by producing a closed loop of the duodenum isolated from this a toxic substance, a proteose, which they believe is elaborated from the duodenal mucosa, the disturbance of the circulation increasing the production of the noxious substance and its subsequent absorption. Hartwell considers the symptoms to be due to loss of liquids, and combated successfully high obstruction experimentally produced, by injections of water. More recently Dragstedt and his associates have apparently shown that the toxemia is due to occlusion of the circulation, with subsequent necrosis of the portion of the intestine cut off from the circulation plus the action of bacteria.

The *physical examination* will discover a swollen, extremely tender, and tympanitic belly. Exaggerated peristalsis of the intestine above the obstruction may be visible on the surface of the abdomen. Borborygmi, gurgling, and splashing may be heard on auscultation.

Chronic Obstruction.—The symptoms are more dependent upon the special causes operating than in acute obstruction. The fact that early in the case only partial obliteration of the intestinal lumen may be rightly inferred in many of the chronic forms of obstruction has given rise to the discriminating term of *intestinal constriction*. In general, the clinical history is one of *increasing* and *intractable constipation*, sometimes alternating with diarrhea, due to catarrhal inflammation of the mucosa above the obstruction. Paroxysms of colicky pain and, later, augmenting tympanites, vomiting, and prostration, attend. These symptoms may merge suddenly into those of the acute form of obstruction. The bowel movements in chronic obstruction are irregular, infrequent, slight, and sometimes accompanied by pain and tenesmus. The stools consist often of small, hard, ribbon-like, or scybalous masses, and may contain blood and mucus. When the stenosis is in the small intestine the constipation is less apt to occur on account of the fluidity of the contents. Sometimes, and particularly in old people, the rectum becomes distended with hardened accumulations of feces; there is in such cases a constant feeling of fulness and a harassing desire to defecate, but the attempts thereat are ineffectual (*vide* Typhlitis, p. 812).

In *cicatricial stenosis* there are a prolonged and variable history of constipation, occasional vomiting, localized pain, and meteorism.

Physical Examination.—*Inspection* shows the abdomen to be distended from meteorism, the movements, and contour even, of the coils of intestine in active peristalsis above the seat of stricture being evident. A tumor or the throbbing aorta (excited, perhaps, by pressure of the distended bowel or growth) may be *palpated*. Tympany and borborygmous noises may also be noted.

Diagnosis.—**Locality of the Obstruction.**—Given the symptoms of a sudden, severe, and exacerbating pain in the abdomen; of marked and, later, feculent vomiting; of absolute constipation, and of tympanites and profound, early, systemic depression—a diagnosis of acute intestinal obstruction may be made. The determination of its seat is often very difficult. First may be mentioned the *differential diagnosis* between obstruction occurring in the small

and in the large intestine. In the former vomiting occurs early, is scanty, and later feculent, while in the latter there is less vomiting and the vomitus is seldom feculent. Again, in obstruction of the small gut the distention is both less marked and higher situated, while in that of the large gut tympanites is often quite marked, is more central, is associated with tenesmus, and sometimes with mucus and blood. If the cause of obstruction be a tumor or stricture, the locality may be successfully palpated or the lower limit of the active coils of hypertrophied intestine may be defined.

Examination *per rectum* with the finger or with the rectal tube, by means of liquid distention or gaseous inflation of the colon, may enable us to determine the seat of obstruction in certain cases. The detection of a deeply seated incarcerated hernia (in the abdominal fossæ and pouches, diaphragm, or obturator foramen) is often made only *postmortem*.

Nature of the Obstruction.—This is even more difficult of discovery than the preceding. The following causes of obstruction with their differentiation may be referred to in attempting a diagnosis: *Strangulation* often affords a previous history of peritonitis or abdominal section or of recurrent attacks of abdominal pain, occurring mostly in young adults. Early fecaloid vomiting is common.

Intussusception usually gives a negative previous history. The suddenness of the attack, without appreciable cause, occurring in a child, and associated with colicky pain, tenesmus, and the presence of mucus and bloody stools, and of an elongated cylindric tumor in the right iliac or umbilical regions often render this condition easy of diagnosis. It is to be noted that absolute constipation and meteorism are here unusual. The intussusception may be felt in the rectum.

In *volvulus* it may be helpful to elicit a history of former constipation and flatulence, with evidences of atony of the bowel, in persons of advanced years, along with marked abdominal tympany, tenderness over a distended coil, which may perhaps be outlined (Wahl), a rigid abdomen, and sometimes dyspnea from great gaseous distention.

The history in cases of *fecal obstruction* is nearly always one of obstinate, habitual constipation, and occurs especially in females and neurotic subjects. The onset is gradual; pain is less acute; and tympany and fecal vomiting are less prominent and late in appearance.

Obstruction due to *large enteroliths* or *foreign bodies* may be only surmised; especially is this true when symptoms of appendicitis arise.

Biliary calculi may give a history of previous attacks of hepatic colic and of recurrent jaundice.

In the chronic obstructive form of *stricture* of the bowel due to cicatrices or neoplasmata the history of dysentery, tuberculosis, sarcoma, or carcinoma should be considered (*vide* Carcinoma intestinalis).

In obstruction caused by *intestinal paresis* there is generally a history of a previous enteritis, peritonitis, or celiotomy. The abdomen is smooth, though tympanitic throughout, and there is no perceptible peristalsis.

Not rarely it will be of therapeutic as well as of diagnostic importance to ascertain whether an attack of acute obstruction is primary, or whether it is the terminal exacerbation of a chronic condition, such as carcinoma of the bowel. Here a study of the past history of the patient, as well of the present signs of a probable nature, will afford considerable aid.

Differential Diagnosis.—Acute intestinal obstruction must be discriminated from *acute generalized peritonitis*.

ACUTE GENERALIZED PERITONITIS

ACUTE INTESTINAL OBSTRUCTION

Etiology

There is a history of causal conditions or diseases (ulcer, appendicitis, pelvic infection).

An early and considerable rise of temperature; later variable or may be absent.

Pain continuous and diffuse and increased by movements.

Vomiting, but not stercoraceous.

Collapse occurs late.

In septic cases, leukocytosis with increase in polynuclear cells.

Distention of the abdomen is usually general and marked.

Visible peristaltic waves absent.

Tenderness decided and general.

Signs of effusion appear.

Auscultation negative.

There is a history of previous chronic obstruction or hernia. (The young are most liable to intussusception.)

No early rise (except in volvulus), but later with advent of peritonitis, and subnormal temperature develops later.

Pain in short paroxysms and localized.

Vomiting becomes characteristically stercoraceous early.

Earlier onset of collapse.

There may be increase in number of leukocytes.

Less marked, unless the obstruction be situated in the lower segment.

Present and pronounced when the seat of obstruction is low, and course of wave may be reversed.

Tenderness localized and usually slight.

Less common, due to secondary peritonitis.

Loud gurgling and splashing sounds audible over the abdomen (colon).

It must also be differentiated from *acute enteritis*, in which (particularly when due to toxic minerals) there is more apt to be diarrhea with considerable mucus and blood, an elevated temperature, intense gastric pain, associated with traces of the poison in the vomitus, and an absence of marked tympanites and fecal vomiting.

The various forms of *abdominal colic*, as enteralgia, hepatalgia, and nephralgia, should not be mistaken for acute intestinal obstruction.

Course, Complications, and Prognosis.—A case of acute obstruction usually terminates within from two to seven days. The chronic form may last weeks, and even months, with progressive emaciation and anemia, until the superaddition of more or less acute symptoms, lasting from ten to fourteen days. The *prognosis* is unfavorable in the acute cases unless recognized early. The chronic forms, due to fecal or other impaction, often recover. Life may be prolonged by surgical interference in certain cases if they are taken in their inception.

Complications that may occur, as secondary peritonitis, gangrene, perforation, septicopyemia, and enteritis, are all grave.

The **treatment** of acute intestinal obstruction is surgical. The only indication for therapeutic interference in acute obstruction is presented by the *incessant vomiting*. For this symptom no other measures are comparable to gastric lavage and starvation. It is well in most cases to withhold food for some hours to prevent retching and aggravation of the condition. The lavage is strongly advised by Kussmaul, who claims that both the tension above the seat of stricture and the inordinate peristalsis are thus greatly diminished and exceptionally cured. It may be repeated every six hours. The loss of water may be replaced by the subcutaneous administration of physiologic saline solution, *e. g.*, continuous hypodermoclysis (Hartwell and Hoguet).¹ Hypodermic injections of morphin for the pain induce deceptive tranquillity. When the cause or character of the obstruction is unknown, cathartics should absolutely not be given. If it has been determined that fecal impaction is the trouble, it is still prudent to avoid purgatives until the main mass has been

¹ *Jour. Amer. Med. Assoc.*, 1912, lix, 82.

moved, as in many cases there are both paresis and inflammation at the seat of impaction, so that this class of agents would in most cases at least be useless, if not harmful. High rectal injection, copious, steady, and regularly repeated, are to be practised, using for this purpose preferably "warm saline solution of olive oil" (particularly if scybala be present) administered while the patient is in an inverted position by means of a fountain syringe, so that the flow is readily controllable. The abdomen should be methodically kneaded and the patient at times well shaken. This method of treatment, by hydrostatic pressure, can and must be carried forward without undue violence, and if it be unsuccessful, the intestines are to be inflated from a large india-rubber bag with air or hydrogen gas (Senn), of which 2 to 3 gallons may be cautiously introduced. Thorough manipulation of the abdomen from below upward, particularly if it be a case of intussusception, may be combined. In the latter condition inflation, early and perseveringly applied, cures the majority of instances. If not promptly relieved, immediate operation is to be encouraged and advised. Although the statistics of Fitz show the mortality in cases without operation to be lower (69 per cent.) than with operation (83 per cent.), I am convinced from personal observation that the less favorable results from abdominal section would not obtain if it were performed in due time.

In chronic obstruction the treatment of the underlying or etiologic conditions and various complications is to be conducted on general principles. Additionally, the patient's dietary is to be arranged with care, and the bowels moved with unflinching regularity, by the use of unirritating laxatives and enemas. If total obstruction persist despite medical treatment, surgical treatment—enterectomy, enterotomy, or other operation, as the circumstances of individual cases may dictate—is required.

The after-treatment consists in keeping the bowels active and regular by habit, diet, and an aperient pill if needed. Massage and electricity to the abdomen are found useful at this time.

Stenosis of the Duodenum.—Duodenal stenosis invariably develops secondarily upon morbid processes either in the duodenum or adjacent organs. Extensive studies of the subject have been made by Leichtenstern, Perry and Shaw, Wilms, Boas, Laffer, and others. The *causes* are principally intraduodenal ulcer of the duodenum (53.44 per cent.), carcinoma of the duodenum, sphincteric action of the muscular layer of duodenum, and gall-stones. Among extra-duodenal factors are "diseases of the pancreas, compression by the root of the mesentery, adhesions, morbid growths, kinking, and gall-stones."¹ *Symptoms.*—When the stenosis is suprapapillary or at the ampulla of Vater, marked dilatation of the stomach and of the duodenum above the stenosis usually occurs. When at the ampulla, obstruction may show acholic stools containing enormous numbers of fatty acid crystals and jaundice. Neither blood nor bile are found in the vomitus as a rule. Stenosis below the ampulla of Vater is characterized by absence of meteorism, biliary, but never fecal, vomiting, the temporary disappearance of meteorism in the epigastrium after vomiting and early anuria. Stenosis due to kinking causes sudden severe pain, frequent vomiting, and decided shock. The *prognosis* is dependent on the special cause, while the *treatment* is appropriately surgical.

¹ *Amer. Jour. Med. Sci.*, September, 1912, by J. M. Anders.

CARCINOMA OF THE INTESTINES

(Carcinoma Intestinalis)

Carcinoma of the intestines is the commonest cause of chronic intestinal obstruction. The stenosis is usually partial. Primary intestinal carcinoma is rare in comparison with that of gastric carcinoma.

Pathology.—When carcinoma attacks the intestines it is usually in the form of a cylindric-celled epithelioma, although it may assume the various forms as found in carcinoma of the stomach—namely, scirrhus, medullary, and colloid. The growth may be annular or semipolypoid, or it may occur as a diffuse infiltration of the bowel walls. Ulceration of the surface of the carcinoma may take place, and the glandular structures of the abdominal cavity may reveal metastatic growths. The most frequent seat of intestinal carcinoma is the rectum, and next in order of frequency are the sigmoid flexure, the transverse and descending colon, the *papilla duodenalis*, the ascending colon, and the lower and middle portions of the ileum. The bowel is dilated above the constriction and filled with fecal matter. The muscular coat is hypertrophied. Below the narrowing the intestines may be atrophied. Rectal adenoma may develop into carcinoma (adenosarcoma).

Etiology.—Heredity and advanced age are of chief importance as predisposing causes. Antecedent intestinal ulceration may afford a nidus for carcinomatous growths. Carcinoma may invade the appendix. Harte, from statistics based on 101 cases, concludes that carcinoma occurs in from $\frac{1}{3}$ of 1 per cent. to 1 per cent. of all cases operated on for chronic appendicitis.

Symptoms.—A description of the course of *rectal carcinoma* belongs to surgical works. The symptoms of carcinoma of the bowel *above the rectum* are often vague, and vary according to the portion involved by the neoplasm. With or without an appreciable tumor in the abdomen the history is usually that of *chronic obstipation* of the intestines. There are irregular attacks of *sharp, colicky pains*, especially a few hours after eating, distressing defecation, obstinate constipation, perhaps alternating with diarrhea, sometimes vomiting, which may be feculent, and not rarely slight meteorism. The special symptoms of carcinoma of the *papilla of Vater* are vomiting, jaundice, and colic. The progressive emaciation and debility are marked. In advanced cases of stenosis the *feces* are passed in small, compressed lumps resembling sheep's dung.

Physical Examination.—*Inspection* of the abdomen may show the presence of a tumor along the line of the sigmoid flexure or colon; peristalsis may be seen above the site of the carcinoma, communicating its movements to the abdominal walls. *Palpation* may be resorted to in order to confirm the above, and the growth is then frequently found to be nodulated. A sign which is practically diagnostic of stenosis is a sudden appearance of small coils of bowel which vanish very quickly and reappear again (Boas). *Percussion* may give either dulness or a muffled tympany over the tumor and for some distance above (often sharply defined), on account of accumulated masses of feces.

Diagnosis.—This may rest, in some cases, upon heredity, the age, the evidences of the cancerous cachexia, sharp, radiating abdominal pains, bloody stools, and the detection of a firm and nodular tumor. Patchy pigmentation of the skin and small angiomas are corroborative features. Persistent occult blood in the stool is a particularly valuable finding in suspicious cases. A roentgen-ray examination often proves a great aid in the diagnosis. The prospects for early diagnosis are unfavorable (J. Boas¹).

Differential Diagnosis.—(a) Carcinoma of the bowel above the rectum needs to be discriminated from other abdominal tumors. For example,

¹ *Fortschr. der Med.*, February, 1906.

sarcomata, *fibromata*, *myomata*, *adenomata*, and *cystomata* may produce symptoms of obstruction like those due to carcinomatous growths. The cancerous cachexia may be simulated by other conditions. The advanced age of the patient and the rapid and downward progress of the disease will, however, point toward malignancy. *Enteroliths*, *foreign bodies*, and old *peritonitic adhesions* may need to be excluded also. Fecal masses may exist above and overshadow the presence of carcinoma.

(b) *The portion of the bowel involved* by the neoplastic growth is also difficult of definite diagnosis. The locality of the tumor as detected by palpation, associated with special symptoms, is of value in arriving at a diagnosis of the diseased portion of the bowel. Heulin has studied carefully primary cancer of the duodenum, and asserts that the comparative frequency of duodenal involvement is due to limited motion of the organ, being thus subject to injury. When it occurs above the papilla of Vater the symptoms greatly resemble those of *dilatation of the stomach*. An important point separating carcinoma above from that below the papilla is the presence or absence of bile in the vomit, being absent if situated above. When the carcinoma involves the papilla of Vater symptoms of biliary obstruction necessarily follow. A hard, nodular mass may sometimes be felt in the lower epigastric region; this coupled with increasing gastric dilatation and marked persistent jaundice would indicate carcinoma of the duodenum. It is apparent, however, that *carcinoma of the pylorus*, of the left lobe of the liver, or of the omentum or mesenteric glands, or a thickened cecum might all be easily confounded with carcinoma of the bowel at various adjacent parts of its course. The injection of fluid into the bowel may be resorted to in locating the probable situation of the growth. Thus, if obstruction from carcinoma exists in the sigmoid flexure, liquid will be arrested there and the rectum distended; while, if the stenosis be high up in the large or small intestine, the colon will be found comparatively emptied of feces and will be distended with the injected liquid. Carcinoma of the appendix usually gives rise to the symptoms of appendicitis with slight fever. These cases generally occur between the ages of twenty and thirty years (Kernhadjian).

Course and Complications.—Carcinoma of the intestine sometimes runs a rapid course, and may last but a few months; in the scirrhus variety, however, the disease may last two or three years.

Intestinal carcinoma may perforate the bowel and cause fatal purulent peritonitis. Or, owing to extreme distention by fecal accumulation between a cancerous stricture of the sigmoid flexure, for instance, and the resistant ileocecal valve, rupture of the colon, followed by peritonitis, may result. Extension of the growth into surrounding tissues, with ulceration, may lead to cellulitis, phlebitis, and pyemia; and extension from the rectum may cause purulent vaginitis and cystitis.

The **prognosis** is almost hopeless.

Treatment.—This, from a strictly medical standpoint, is simply palliative. The diet should be highly nourishing and easily assimilable, but when the symptoms of acute obstruction supervene the administration of food by the mouth is contraindicated. Opium or *cannabis indica* for the pain, and stimulants for the depression, may also be serviceable.

Lavage of the stomach gives decided relief for regurgitation on account of the damming back of accumulated food detritus.

Carcinoma of the bowel may be treated surgically by colotomy, excision, lateral anastomosis of the bowel, enterostomy, and, if the growth be situated in the rectum, by extirpation by means of sacral resection (*Kraske's operation*). Operability does not necessarily depend upon the duration of the disease.

HABITUAL CONSTIPATION

(Intestinal Stasis; Costiveness)

Definition.—Chronic fecal retention, habitual infrequency, irregularity, difficulty, or insufficiency of the evacuations of the bowels.

Although constipation is a symptom, and although habitual constipation is frequently a symptom of chronic disease, the causal elements of the latter may be so indefinite and obscure that the former takes on all the individual importance of a functional affection. I describe habitual constipation, therefore, as a disease *sui generis* ("idiopathic").

Etiology.—In the majority of cases habitual constipation is the direct effect of a lack of expulsive or peristaltic power, and also of a deficiency of the hepatic and intestinal secretions. Schmidt, Strasburger, and Lohrisch claim that too thorough digestion and absorption of food-stuffs is one of the primary factors in the production of habitual constipation. The more recent investigations of Pletneu,¹ however, throw doubt upon the latter theory; he thinks that the more rational explanation is a deficient secretion in the gastrointestinal tract. Two sets of causes operate to bring about these conditions of abnormal defecation:

General Causes.—(a) *Temperament*: it has been observed often that people of a nervous and "bilious" or motive temperament, of the dark type, are much troubled with constipation. Anemic brunets—persons having pale skin and dark hair combined—are particularly so affected, although alternating periods of diarrhea may supervene, owing to the hydremic state of the blood. "Torpid liver" and "sluggish bowels" are commonly held to be synonymous with these physical characteristics. (b) *Habit*: a sedentary life conduces to secretive inactivity. Thus, a lazy life, in which the calls of nature are irregularly attended to or habitually neglected, leads to frequent overdistention of the rectum and paresis, a common cause of chronic constipation. Again, the feminine false modesty (so called) that prompts a postponement and suppression of the desire to defecate in public places tends to obtund the sensibility of the rectum to fecal masses. The accumulation of these fecal masses causes paralytic overdistention, their hardening into scybala, and difficulty of expulsion. (c) *General bodily weakness, and diseases*, as neurasthenia, hysteria, anemic brain and spinal-cord affections (causing inhibitory disturbances of the intestinal nerve-supply), acute fevers, hepatic disorders, especially the presence of jaundice, and the habitual dependence upon and use of purgatives. (d) *Diet*: the constant use of concentrated articles of food, as meats, in which little residual matter is left to stimulate the bowel to peristalsis. On the other hand, a very coarse diet may leave such an excess of residue as to cause fecal impaction. (e) A change of drinking-water, or water from chalky regions. Constipation is also caused by the use of an insufficient amount of water during the intervals between meals. (f) *Abundant and prolonged diuresis and diaphoresis* also may induce chronic constipation.

Local Causes.—(a) *Atony of the abdominal muscles* from obesity or, in females, as a result of improper dress and many pregnancies. (b) *Atony of the large bowel* (the sigmoid flexure in particular) from chronic colitis, (c) *Pressure by tumors, e. g., enlarged prostate.*² (d) The presence of *intestinal stenosis* from external or internal constriction. Under this head may be grouped the various local congenital or chronic inflammatory bands, membranes, and kinks, on which Lane lays so much emphasis as a cause of intestinal stasis. They may not produce a true stenosis or narrowing of the bowel, but retard the

¹ *Zeitsch. f. Experim. Therap.* 1908, v, 186.

² *Amer. Jour. Gastro-enterology*, April, 1912, p. 9, by J. M. Anders.

progress of the fecal stream. (e) *Congenital stricture* or *giant growth* of the colon, with coprostasis (as in Formad's case). (f) Tonic contraction of the muscular coat, as in basilar meningitis and lead-poisoning. (g) Enteroptosis; notably cecum mobile associated with ptosis of the ascending colon. (h) Retention of the gastric contents. (i) Clinical evidence of stasis in the terminal ileum is almost always associated with ileocecal valve incompetency (Case). (j) Antiperistalsis (anastalsis) is held by some observers to be responsible for failure of the fecal mass to leave certain portions of the intestines with normal rapidity. (k) Dyschezia, or incomplete emptying of the rectum, is present in about 60 per cent. of cases of chronic constipation. It may be caused by any of the general causes of constipation, as a result of which the rectum has lost its normal expulsive power. (l) Keith holds that mechanical factors play but little part in the production of stasis. He considers the intestinal canal as consisting of four zones, each with its own pace-maker and rhythmicity. These various zones must co-ordinate one with another in order to have the food propelled along in a normal manner. Blocking of the impulses from a pace-maker as a result of disease produces not only inefficiency of the intestinal musculature of the affected zone but also of the other zones.

Symptoms.—In cases in which there is no adequate cause for habitual constipation other than a constitutional or inherent peculiarity there may be the true appearance of perfect health. Nothing is complained of save the fact that an evacuation of the bowels occurs too infrequently. The term "constipation" is, individually speaking, almost wholly a relative one—*i. e.*, one person may enjoy good health with but one evacuation every other day, another with two passages per diem, while still another must have one stool a day, *cæteris paribus*, to feel perfectly well. The last is usually considered an average normal state with most people.

Symptoms of habitual constipation may be direct or reflex. *Direct* or *local* troubles are seen in the feeling of fullness, weight, and pressure in the perineum and abdomen. Flatulence, colicky pains, and alternating diarrhea occur not infrequently. The hurried and inattentive performance of defecation gives rise to the so-called "cumulative constipation," in which the accumulated feces are but partially evacuated with the movement, and the rectum consequently is not emptied. A sense of fullness then remains, and complete relief is not felt in these cases.

Reflex and *general* symptoms are malaise, languor, hebetude, irritability of temper, headache, facial flushing, palpitation, cold extremities, anorexia, vertiginous attacks, paresthesia, menstrual distress in women, sleeplessness, and bad dreams. Pressure on the sacral and visceral nerves may cause neuralgias. The tongue is coated. Palpation of the abdomen often shows the presence of doughy-like fecal tumors at the cecum or at the hepatic, splenic, and sigmoid flexures, or of bologna-like masses at intervening places. In marked cases attacks of nausea and vomiting, with diarrhea, may ensue; fever may also be present.

Complications and Sequelæ.—Hemorrhoids, ulcerative colitis, perforation, and enteritis may be associated with chronic constipation. Not rarely we have as results dilatation of colon or sacculation, with the presence, in old people mainly, of *enteroliths* (calcified scybala); intestinal obstruction and typhlitis, or cerebral hemorrhage or hernia from violent straining efforts.

Diagnosis.—Bearing in mind the relativity of constipation in different individuals, the diagnosis is read at sight. The detection of the causes is not difficult, though sometimes tedious. An etiologic diagnosis may require modern methods, such as a roentgen-ray examination, the examination of the feces according to Schmidt, and the procedure known as rectoromanoscopy.

"In spastic constipation, hypertonicity is found in the distal portion of the colon, and normal tonicity with hypermotility in the proximal portion" (Singer and Holzkecht). Hypochondriasis or melancholia should be carefully placed either as precedent to or consequent upon chronic constipation, the nervous condition often acting to produce the latter, and *vice versa*.

The **prognosis** is usually favorable, but should be guarded.

Treatment.—Hygienic.—Causative factors must, of course, be removed, modified, or lessened. Systematic regularity as to time and frequency and sufficiency of movements of the bowels should be enjoined upon and practiced by the patient. Exercise is of signal value, and particularly horseback riding or gymnastic motions that bring the abdominal muscles into play. Attention to the calls of nature should be esteemed a duty, and proper time and heed must always be given to the completeness of defecation. The *dietetic regimen*, if properly looked after, often avails much in relieving this affection, and foods calculated to be easily digestible, but leaving a moderate residue after digestion, are to be recommended. Such are bread made of unbolted flour, plenty of vegetables and fruits, butter, and such laxative articles as figs or honey. Certain substances which swell from imbibing water, but are not digested or absorbed, such as agar-agar, liquid vaselin, coarse, raw, wheat bran, and the like, may be advantageously taken with the food. Prof. L. B. Mendel, experimenting with agar-agar, found that the greatest part of it was excreted in the feces unchanged; this substance resists intestinal enzymes and bacterial decomposition, and is recommended for chronic constipation. Gomperts¹ has had experience of its use, and advises 15-gram doses twice daily, eaten with milk or cream, the same as a modern breakfast food. After regular movements of the bowels have begun, the dose of agar is reduced. Luke² has had good results with the use of sour milk. A glass of cold water taken regularly at bedtime and in the morning before breakfast is efficacious and a point of common knowledge.

Remedial.—The methods and means offered for the cure of chronic constipation number legion. From the little aperient pill or "peristaltic persuader" to the cannon-ball rolled externally along the course of the large bowel is made up such a list of drugs and measures as to leave untenable any pleas of lack of resource. *Drugs occupy a subordinate part in the treatment of habitual constipation.* Their use should be restricted to those periods when the bowels become unusually obstinate. The constant use of laxative drugs tends to a confirmation of the condition.

I have found of value to dyspeptic subjects the laxative bitter waters (Hunyadi Janos, Kissingen, Friedrichshall, Carlsbad).

Among those laxatives and cathartics most commonly used may be mentioned aloes, rhubarb, Rochelle and Epsom salts, compound licorice powder, castor oil, jalap, senna, mercury, colocynth, and podophyllin. Important adjuncts in combination with one or more of the above are the extract of nux vomica (or strychnin) and the extracts of belladonna, hyoscyamus, and physostigma. The following much-used capsule can be employed for a considerable length of time in the hope of stimulating a normal intestinal and sphincteric activity, and thus inducing even a cure in some cases:

R. Strychninæ sulph.,	gr. ss (0.032);
Extr. belladonnæ fol.,	gr. ij (0.130);

Sulphur in confection, along with the official pill of aloes and iron, has been recommended for the habitual constipation of anemia. In senile atony of the bowel, with much flatulence, a laxative pill having in combination asafetida or capsicum is often beneficial.

The subjoined formulæ are also serviceable:

R. Extr. belladonnæ fol.,	gr. ij (0.13);
Extr. physostigmatis,	gr. iij (0.20);
Extr. nucis vomicæ,	gr. iv (0.26);
Extr. rham. pursh.,	gr. xxx (2.00);
Extr. gentianæ,	q. s.

M. et ft. cap No. xx.

Sig. One at night, or night and morning.

(Aloes, gr. j (0.065), or podophyllin, gr. ii to iij (0.13–0.19), or extr. colocynth. comp., gr. ii to iij (0.13–0.19), may be substituted for cascara in the foregoing formula). Spastic constipation (*e. g.*, that due to lead intoxication) may at times be relieved successfully by the use of sedatives, such as bromids, valerian, asafetida, and opium. Liquid paraffin is effective in many cases; it acts mechanically, is neither absorbed nor toxic in the least. The dose is from 1 to 2 ounces once or twice daily on an empty stomach.

The **mechanical** means of relieving habitual constipation, as by *enemata*, are injurious if long continued, by reason of their irritating effect on the rectal and colonic mucous membrane. At times when the stomach is weak or irritable, a loaded bowel may be relieved by an ordinary enema of soap and water or by one containing $\frac{1}{2}$ to 1 ounce (16.0–32.0) of castor oil, with 1 or 2 drams (4.0–8.0) of oil of turpentine if there be some flatulence. Glycerin enemata, containing from $\frac{1}{2}$ to 2 ounces (16.0–64.0) of the agent, may be used. Fleiner has suggested oil injections. From 2 to 4 ounces of sweet oil warmed to body heat by standing the containing bottle in a vessel of hot water, may be injected slowly through a piston-syringe on retiring and retained until next morning. Riesman,¹ who has had a considerable experience of their use, speaks strongly in favor of oil injections. *Suppositories* of soap, molasses candy, or glycerin are included in the armamentarium. *Massage* also claims an important part in the relief of habitual constipation. It acts by stimulating the peristalsis and the abdominal muscles, and should be employed at set times in the day preceding a desired evacuation of the bowels. The hand of the *masseur*, or that of the trained patient even, when systematically used in this way, may be effectual when all other means have failed. In constipation in the aged male Hollis recommends pressing the gerontal right index-finger on the perineum just behind the symphysis to relieve the pressure of an enlarged prostate on the rectum during defecation. The regular rolling of a metal ball along the course of the greater gut may be mentioned for its novelty as well as for its undoubted efficacy. The application of the faradic current to the abdominal walls or galvanization of the lumbo-abdominal circuit deserves proper trial in many cases. Hydrotherapeutic measures or cold sponging and baths are nearly always useful adjuncts.

INTESTINAL TOXEMIA

This condition is closely associated with constipation, and, as a rule, is responsible for the symptoms, at least for the systemic manifestations, that

¹ *The Therapeutic Review*, February, 1904.

arise in this disorder. Although not a pathologic entity, it is readily recognized clinically and is supposedly due to the absorption into the circulation of toxic bodies which are formed during intestinal digestion. Such toxic bodies may arise from injuries to the mucous membrane; they may be produced by the bacteria that normally inhabit the intestines, though soluble toxins are, in all probability, not formed by the normal flora of the intestines; they may be elaborated by decomposition of food-stuffs with production of toxic substances which may be subsequently absorbed. This latter cause is probably the one that operates in the majority of cases. Thus it has been shown that, during the process of digestion of proteins, the amino-acids that are formed are capable of producing exceedingly toxic substances, possibly with bacterial assistance, by the removal of one carbon dioxid complex. Such toxic amins include hydroxyphenylethylamin and beta-aminazolyethylamin. It is to be presumed that with abnormal conditions of the intestines such toxic bodies are absorbed at times in great excess with the production of acute sudden symptoms, or they may be more or less persistently absorbed in minute quantities with the production of mild chronic symptoms, as well as chronic degenerative changes of the arteries, kidneys, and other organs. That such is the case is dependent very largely upon clinical observation. As is so often the case with purely clinical criteria, confusion exists. Many men deny the possibility of the intact intestinal wall absorbing toxins, and others claim that toxic products cannot be produced there. That the intestinal absorption of toxins is possible is shown by the fact that anaphylatoxins introduced into the intestines of a sensitized individual may cause various skin rashes, asthmatic attacks, angioneurotic edema, and other manifestations of protein poisoning or anaphylaxis. Even if toxic substances are elaborated, fortunately for mankind certain protective functions often prevent the development of intestinal intoxication. Thus the liver destroys the toxic bodies as a rule, but deficient hepatic function leads to their formation in excessive amounts. Again, the digestive tract, skin, and especially the kidneys are normally active in the elimination of these poisonous substances. The condition inducing intestinal toxemia may be any of the causes of constipation, for the two conditions are extremely closely related. Chronic appendicitis or any other pathologic lesion of the intestine may be responsible.

Satterlee¹ believes that the principal causative factor in the chronically inflamed colons of chronic intestinal toxemia is the colon bacillus.

Diagnosis.—"The physician should never make the diagnosis of intestinal intoxication until he has made a careful differential diagnosis eliminating everything else" (Forchheimer). The group of symptoms most commonly observed is as follows: Headache (often of the type of migraine), vertigo, a high-tension pulse, constipation, signs of hepatic congestion, flatulence, indicanuria, at times albuminuria, furred tongue, and various neurasthenic manifestations. Unless the indican and conjugated sulphates in the urine be excessive in amount, they cannot be regarded as indicative of intoxication. Furthermore, indicanuria may be absent, though marked symptoms of intestinal toxemia be present. Indican, indoxyl sulphate, is merely indicative of abnormal bacterial decomposition in the small intestine. In a considerable proportion of cases vomiting and often diarrhea are associated with fever, or arthritis resembling rheumatism, or distressing myalgic pains occur. The constipation may alternate with diarrhea or mere irregularity of bowel action exists. "A careful *physical examination* of the colon, more particularly by light percussion, will indicate the presence of an overfilled condition of the bowel, most commonly in its descending portion. Palpation may detect a doughy mass or masses in one or more sections of the colon, and after removal of these fecal accumula-

¹ *Jour. Amer. Med. Assoc.*, December 9, 1916, p. 1729.

tions more or less thickening of the intestinal walls, due to a catarrhal state with infiltration, may be detectable."¹ The nervous manifestations most prominent in the clinical picture are a feeling of languor, insomnia, loss of physical and mental energy, vertigo, and irritability, with occasional headaches. Autogenous colon vaccines in doubtful cases are an aid to differential diagnosis (Barnes).

Treatment.—In the *acute form* the treatment of the cause suffices as a rule. Purgation by means of mercurials followed by a saline are indicated first of all. The *diet* must be fluid and much restricted in amount, milk and gruels being especially serviceable. Water is to be taken freely, if retained. In the *chronic form* digestible solids, composed principally of vegetables, milk (particularly sour milk), bread, and cereals should form the protein in the diet. These, with fruits, bacon, and butter, in right proportions, will give 65 grams of protein daily. Recent experience justifies the belief that in the fermentative cases the carbohydrates (sugar, starch) must be much restricted, *e. g.*, dry toast or stale bread. Laxative articles of food and such as leave a maximum residue in the intestines are efficacious in overcoming constipation. The use of two or three glasses of cold water or mineral water on retiring, on rising, and between meals favors elimination, both through the bowels and kidneys.

The function of the latter is of the highest importance as a channel of elimination. If the above suggestions do not afford thorough relief daily to the bowels, warm saline laxatives before the morning meal are to be advised. Among the most efficient are sodium phosphate and sodium sulphate, or the aperient waters, as Hunyadi, Apenta, Carlsbad, Veronica, and the like. It may be necessary to administer a mercurial from time to time to maintain biliary secretion. Gastric lavage and colonic irrigation should be resorted to in the acute gastro-intestinal attacks. The mouth condition and gastric features must be treated as recommended in appropriate sections of this work. Cutaneous elimination is to be aided by hot baths or Turkish or Russian baths; they must be carefully adapted to the individual cases. Physical exercise deserves proper trial in most cases and massage is also a useful adjunct when active exercise is unsuitable.

For the flatulence which often proves annoying, intestinal antiseptics are indicated. Of some value for this purpose are beta-naphthol, phenyl salicylate, and menthol. These remedies should be administered as suggested by Forchheimer, namely, in the form of an intestinal pill or one dissolved only in an alkaline medium, and Waldstein recommends a coating with an alcoholic solution of shellac containing salol to accomplish this object. Kaolin in large doses, 4.0 to 8.0 grams, three times a day after meals, makes an efficient intestinal antiseptic, depending not upon its antiseptic properties but upon its mechanical action, the bacteria adhering to the minute particles of the clay and being carried along with the fecal stream. It has been suggested to raise the content of *Bacillus coli communis* in the bowel "by instillation either of the autogenous mixed forms or strains from other individuals" (Bassler). Satterlee advises vaccine therapy in the treatment of this condition, as follows: "(1) Mild chronic toxemias which do not respond to diet; (2) all severe chronic toxemias; (3) operative cases (*a*) before and (*b*) after operation." The underlying and etiologic conditions and complications must receive due attention in every case.

¹ *Jour. of the Indiana State Med. Assoc.*, July, 1908, by J. M. Anders.

DILATATION OF THE COLON

(Ectasia of the Colon)

This is usually a chronic condition, though not rarely it is acute. It may also be general, but in the majority of cases it is confined to the colon, and particularly to the sigmoid flexure. The *postmortem* findings are those of hypertrophic dilatation of the bowel, and rarely ulcerative and catarrhal lesions of the intestinal mucosa are noted. The sigmoid flexure is prone to become dilated in subjects in whom it is congenitally elongated. Atony of the muscular coat is a leading causative element. The most distinctive features are *constipation*, which generally dates from infancy, and great *abdominal distention*. Peristaltic waves may be visible upon the surface. The condition may exhibit constipation alternating with regular daily movements, and the distention changing to a normal softness of the abdominal parietes. I have recently seen a case of this kind in a male aged twenty-seven. In the *treatment* of the constipation, lavage of the intestine with a very long tube is superior to laxatives or purgatives. A *diet* calculated to prevent or relieve constipation is indicated. Vegetable foods leaving a gross residue should be prohibited. Massage, galvanism, and hydrotherapy are all capable of beneficial effects in suitable cases. Strychnin is a valuable remedy, as is also beta-naphthol for its antifermentative action, and in cases attended with constriction surgical measures should be considered.

NEUROSES OF THE INTESTINE

As in the case of the stomach, these embrace derangements of (a) secretion, (b) sensation, and (c) motion.

(a) SECRETORY DISTURBANCES

Unquestionably the intestinal secretion may, through a purely nervous influence, be augmented. This manifests itself most frequently in the primary morbid secretion of mucus (*mucous colic*) and in membranous enteritis. Moreover, the fact that an actual catarrh of the intestinal mucosa may supervene as a secondary event is undeniable.

MUCOUS COLIC

(Colitis Colica; Enteritis Membranacea)

Definition.—A peculiar pathologic condition, chiefly of the large intestine, attended by a morbid secretion of mucus.

Pathology.—In the truly primary form there are no morbid lesions discoverable in the mucosa. From mucous colic we must distinguish membranous enteritis, which is associated with an inflammatory process of the mucosa accompanies typhoid fever, dysentery, and many other affections. This is a catarrh of the colon, while true mucous colic, the disease under consideration, is a functional (secretory) disturbance.

Etiology.—Sex has a decided influence, 80 per cent. of cases are observed in neurotic women. It is rare in children. Direct mechanical irritation of the rectum (horseback-riding, bicycle-riding, hardened scybala, etc.). Bacteria are believed to play a causative rôle, particularly the *Bacillus coli communis*. By many it is held to be a manifestation of abnormal vagus irritability.

Symptoms.—I have found the condition associated with a constipated habit—a fact that may, in part, explain its occurrence, since time is thus allowed for cast-formation. The important feature is the *passage*, at *varying intervals*, of *long, ribbon-like threads of mucus*, or of more or less *perfect casts of the gut*, with *tenesmus* and severe *colicky pains*. The stools consist of a turbid ground substance, which, on the addition of acetic acid, becomes opaque and striped; cellular detritus, consisting partly of granules and partly of cellular elements, including blood. Symptoms of neurasthenia are present and are often quite pronounced.

The individual paroxysms vary in *duration* from one to ten days or more. In one case observed by me the attacks lasted about two days, recurring regularly at the end of every three months. Ordinarily the recurrence is after a shorter interval.

Diagnosis.—A microscopic examination of the pieces of membrane insures the diagnosis. It is to be recollected, however, that membranes are not passed with every attack, and that there is a complete absence of the signs of organic disease between the attacks of colic.

Course and Prognosis.—The disease pursues a very chronic course and lasts for many years. The bodily nutrition suffers considerably if the attacks are frequent and severe, but, as a rule, this does not occur until a late stage in the affection. The risk to life is slight.

(b) SENSORY DISTURBANCES

It may be noted here that the sensory nerves of the intestines, as well as the inhibitory and vasomotor dilators, are traceable to the splanchnics. Increased sensibility of the sensory nerves produces—

ENTERALGIA

(*Neuralgia of the Intestine*)

Etiology.—This is commonly met with in hysteric, neurasthenic, and anemic subjects. It occurs as a reflex neurosis, as in the case of cold, gout, and irritative lesions of the pelvic organs (kidneys, liver). Enteralgia is symptomatic of many local affections and conditions that induce direct irritation of the sensory nerve-filaments of the intestine; among these are inflammation of the mucosa, foreign bodies, gall-stones, abnormal distention with gas, and enteroliths. Under these circumstances the condition is associated with increased activity of the motor nerves or heightened contraction of the muscularis, forming true intestinal colic. In lead-colic it is probable that the lead acts directly upon the nerves or their ganglionic cells. I have repeatedly observed the action of certain exciting causes (*e. g.*, nervous shocks).

Symptoms.—Enteralgia may develop very *suddenly*, but oftener it sets in less abruptly, and is then attended with eructations of gas, expulsion of flatus, and the like. In the fully developed attack the *pain* may attain great violence, causing the patient to “bend double” or even faint, and its character is variously described as boring, tearing, or cutting. The pain may be confined to a circumscribed spot or may be diffuse. The attacks are sometimes brief, or they may be characterized by a sudden subsidence. At other times they last for days or perhaps weeks, and then subside gradually. *Recurrences* are common.

Hypogastric neuralgia is a term applied to neuralgia affecting the sensory nerves lying in the most dependent segments of the intestine. Here the nerve-fibers entering into the hemorrhoidal plexus are involved. It is caused chiefly

by tabes, by hemorrhoids, and by the neurotic state so common to females. This form of neuralgia has its seat in the hypogastric region, and is accompanied by a distressing sensation of pressure in the rectum and bladder, and by an irresistible desire to go to stool; pains also radiate to the sacrum, thighs, and perineum.

Diagnosis.—The various organic diseases and conditions mentioned under Etiology, in the course of which colic is a common symptom, must be separated from the true neurotic enteralgia. The former are distinguished from the latter by a group of symptoms peculiar to themselves (fever, aggravation of the pain upon pressure, vomiting, constipation, or diarrhea), and by the usual definite causes furnished by the history.

Renal and *hepatic colic* bear a superficial similarity to enteralgia. The former conditions, however, are distinguished first by the seat and direction of the pain, and second by the appearance of jaundice in hepatic colic and of hematuria in renal colic. *Rheumatism* of the abdominal muscles is easily eliminated, since it is generally combined with rheumatism in other parts of the body; the pain is also greatly increased upon throwing the muscles into contraction, as in stooping or rising; finally, it vanishes in response to the action of the salicylates.

DIMINISHED INTESTINAL SENSIBILITY

This implies diminished peristalsis or constipation. A greater or less degree of anesthesia of the bowel attends, with a loss of desire to go to stool and an accumulation of feces in the rectum. This is a usual concomitant in many diseases of the brain and cord, with which paralysis is associated. Motor innervation may remain intact, and when atony of the intestine is absent spontaneous movements of the bowels occur; when atony is present, however, to a marked degree (motor paralysis) the feces must be artificially removed.

(c) DISTURBANCES OF MOTILITY

When the contractility of the muscularis is increased from purely nervous causes the result is—

NERVOUS DIARRHEA

This condition presents no morbid lesions. The increased contractility results from an exaggerated irritability of the motor nerves of the bowels. It may also result from morbid processes in the central nervous system and in other organs of the body; in short, the condition may be a reflex one.

Examples of this sort are caused by tabes, by gastric disturbances, as after certain foods and drinks, by dentition, and the like. Most cases, however, are encountered in persons having an abnormally irritable nervous organization—*i. e.*, the neurasthenic and hysteric classes. In such the effect of mental excitement, of fright, and similar psychic influences is to induce diarrheal evacuations.

Symptoms.—The *stools* vary in number from 2 to 3 to 24 or more daily. In rare instances they are soft—not truly diarrheal—and formed, yet they may be quite frequent. Blood and mucus, pus, and other morphologic elements are absent from the dejections. It is characteristic of nervous diarrhea that the stools follow one another in rapid succession, usually during the morning hours, and then discontinue for the greater part of the day. The bodily nutrition is often well preserved.

In the **diagnosis** organic affections of the bowel are to be carefully eliminated.

ENTEROSPASM

(Spasm of the Intestine)

By this term is meant a concurrent spasm of both the longitudinal and circular muscular fibers, usually inducing spasmodic constipation, and sometimes total, though temporary, occlusion of the bowel.

Its *causes* are similar to those of nervous diarrhea, and the condition is *clinically* related to enteralgia. Neither pain nor constipation, however, is a constant feature. The stools may assume the form of a ribbon or of large rounded masses (sheep's dung), but they are not pathognomonic. They may also be covered with mucus. Ewald distinguishes between an idiopathic and a secondary or symptomatic spasm, the latter being a concomitant of basilar meningitis and of chronic lead-poisoning (see also Constipation, p. 822). Another variety affects the rectum (*proctospasm*), and is generally secondary to some other rectal affection, as fissure of the anus; it may, however, occur as a neurosis in the hysteric and nervous class of subjects.

The *diagnosis* of true functional enterospasm can only be made after all organic causes that may produce spasm of the bowel have been excluded.

CONSTIPATION

This is a common condition as a neurosis. It is due to an abnormality of function of the intestinal nerves that leads to a weakened peristaltic action, and is met in hysteria, neurasthenia, and the various forms of psychoses. Central nervous affections often manifest atony of the intestine as a symptom; hence this form is not a disease *sui generis*. Cases of this class do not respond to any variety of cathartics (Ewald).

Paralysis of the external sphincters is a common concomitant in a great variety of local (catarrhal) and central nervous diseases. Under these circumstances the act of defecation may be purely *reflex*, owing to loss of control of the voluntary muscles; or it may be *voluntary*, except when the person affected is not upon his guard, or during mental excitement, micturition, sneezing, and like influences.

Treatment of Intestinal Neuroses.—A suitable change of environment, including an appropriate arrangement of the dietary, is of primary importance, and is uniformly applicable in this class of sufferers. Further, the treatment of special cases has peculiar reference to the character of the nervous derangement. After making an accurate diagnosis a search for the factors of the greatest etiologic importance should be made, and these must then be vigorously assailed.

In the *secretory neuroses* an associated mucous colic must be corrected, the digestion is to be improved if faulty, and the obstinate constipation overcome. For the latter symptom enemata containing ox-gall, either alone or in combination with salines, are especially serviceable. Kussmaul and Fleiner have obtained the best results from regular large oil-enemata administered once or twice daily. During the painful attacks copious enemata of normal saline solution to which has been added oil of peppermint (5 drops to the pint at a temperature of 100° F.) will sometimes bring speedy relief from the pain and other distressing colonic symptoms, and will assist nature's efforts at separating the cast-formations. Pain must be at times relieved by morphin. The results of treatment of mucous colic, however, are unsatisfactory. Surgical measures have been adopted in selected cases.

In the *sensory disturbances* in which the activity of the sensory nerves is increased (enteralgia and hypogastric neuralgia) the treatment may be considered under two headings: first the relief of the neuralgic pains; and

second, the correction of the causes or conditions on which the enteralgia depends. If the pain be severe, opium or morphin may be required. Especially good as an antispasmodic is codein, which may suffice in all save the severer cases. The object should be to give the minimum amount of the opiate that will meet the necessities of the case, with a view to obviating a resultant constipation. In hypogastric neuralgia I have found suppositories containing opium to be little short of magical in their effects.

In cases in which there is constipation due to diminished sensibility, with a loss of motor innervation (atony of the bowel), the feces must be artificially removed unless the underlying condition can be successfully overcome. It is especially important that the environment—physical and psychic—be so regulated as to bring about an improvement in the general condition of the patient. It may become necessary to employ tonic preparations of strychnin, iron, or arsenic.

The treatment of nervous diarrhea involves the same principles, so far as the indication presented by the peculiar nervous organization is concerned, as in the sensory and secretory neuroses. It is especially important to prevent the operation of the direct causes—fright, mental excitement. Astringents and intestinal antiseptics are not called for unless the bodily nutrition be affected thereby. Enterospasm is to be met by the same remedies that are used to control enteralgia.

IX. DISEASES OF THE LIVER

ANOMALIES IN SHAPE AND POSITION

Altered Shape.—**Malformations** of the liver may be either the result of disease or of pressure of adjacent structures. The former "may be due to syphilis, fetal peritonitis, or possibly to tuberculosis" (Rolleston). Of the latter class the most important cause is tight lacing, met with almost exclusively in women and producing the so-called "corset-liver." The lower part of the right lobe of the liver is usually the part affected; the hepatic parenchyma is atrophied owing to continued compression, and shows deep grooves that correspond to the position of the lower ribs. The connective-tissue capsule and the peritoneal coat are both thickened at this point. In marked cases the right lower lobe may become converted into a dense fibrous band. Among other acquired causes of anomalies in shape may be mentioned deformities of the vertebræ and ribs, or tumors of the ribs or adjacent structures (pylorus) pressing against the liver. Moser invites attention to multiple lobulation, as many as 16 lobules having been found; this is due to pathologic causes and is not a morphologic phenomenon.

Diagnosis.—Rarely, clinical symptoms are present. "A constant *sensation of pressure and pulling* is felt in the hepatic region, and sometimes, as a result of venous stasis, there is a temporary but decided swelling of the isolated portion, and, possibly, *violent pain* and indications of irritation of the peritoneum, such as *vomiting* and an approach to *collapse*. Jaundice is rare in consequence of this deformity" (Strümpell.) The danger of this condition lies in possibly mistaking it for an *abdominal tumor* (Pepper), *amyloid disease*, *passive congestion*, or *new growths* of the organ (Strümpell).

Primary alterations in the shape of the organ may be due to congestion, hereditary syphilis, hypertrophic or atrophic cirrhosis, acute yellow atrophy, carcinoma, abscess, or hydatid cyst. The accompanying *symptoms* would be those of the special disease causing the deformity.

Anomalies of position are not infrequently met with, the organ being displaced upward, downward, or laterally. The most common cause of lateral displacement is an abnormal lengthening of the suspensory ligament. The organ may occupy the epigastric region or be displaced into the lower part of the abdominal cavity, but a change in the posture of the patient or external pressure is often sufficient to replace the organ. The *symptoms* (if present at all) consist of a dragging sensation, often amounting to pain and referred to the right shoulder. On *physical examination* palpation may reveal a fissure between the right and left lobes, together with a movable tumor presenting the size and normal outlines of the liver, which by manipulation may be repositioned. Percussion gives tympany over the normal hepatic area, which changes to flatness when the organ is pressed, or falls into its natural position.

Displacement upward may result from gastric or intestinal distention, marked ascites, or an abdominal tumor; while downward displacement may be due to a mediastinal tumor, emphysema, or a pleural effusion.

Diagnosis.—Among the conditions likely to be confounded with movable liver may be mentioned *carcinoma of the omentum* or of the *pylorus*, *dermoid cysts*, *tumors of the ovary and uterus*, *hydro- or pyonephrosis*, *tumors of the kidney*, and *chronic proliferative peritonitis*. By a careful study of the symptomatology, and in the absence of the normal physical signs over the hepatic area, the diagnosis can usually be established, although marked fatty degeneration or atrophic cirrhosis may coexist with any of the above conditions and cause marked diminution in the area of hepatic dullness. Steele's careful studies of 100 cases of floating liver show that colicky pains, often accompanied by jaundice and simulating *hepatic colic*, occur in nearly 40 per cent. of the cases.

The **treatment** of movable liver is merely palliative, and consists in the application of a suitable bandage for preventing the displacement.

JAUNDICE

(*Icterus*)

Definition.—A condition in which the tissues and secretions are stained with bile-pigments. Jaundice is not a disease, but a symptom.

Hepatogenous or *obstructive jaundice* is more commonly seen in: (1) Inflammatory swelling of the duodenum or of the lining membrane of the duct, which is by far the most common factor in its causation, and demands separate consideration (*vide infra*, Catarrhal Jaundice). (2) Foreign bodies within the ducts, as gall-stones or parasites. (3) Stricture or obliteration of the duct. (4) Tumors within the duct or obstructing its orifice. (5) Pressure on the duct from without, as by a tumor of the liver, stomach, pancreas, or omentum; also by fecal accumulations, displaced organs (*e. g.*, floating kidney), a pregnant uterus, enlarged glands in the fissure of the liver, and, more rarely, by abdominal aneurysm. (6) Lowered blood-pressure in the vessels of the liver favoring resorption of bile, as in simple icterus of the newborn (Frerichs).

Toxic (hematogenous) jaundice, so-called, has usually for its lesion extensive catarrh of the intrahepatic bile-ducts from their origin. Here duodenal catarrh is not necessary for the production of jaundice. It was formerly assumed that the pigment (hemoglobin) was liberated in the blood; but Stadelmann and others have shown that the bile containing the poison, or its irritant products (toxins), excite inflammation of the finer ducts. However, Whipple has been able to produce jaundice with the liver cut off from the circulation by introducing laked blood into extrahepatic circulation. While

in various hemolytic anemias, notably the so-called chronic hemolytic anemia, jaundice is apparently produced by increased blood destruction without lesions of the liver and bile-passages other than those produced by the increased hemolysis.

CATARRHAL JAUNDICE

(*Hepatogenous Jaundice; Icterus Catarrhalis; Duodenocholangitis; Inflammation of the Common Bile-duct*)

Definition.—A condition characterized by a discoloration of the tissues from retention and absorption of bile, and resulting from a catarrhal inflammation of the mucosa of the ducts and of the duodenum.

Pathology.—On examining a liver and gall-bladder *in situ* the former is usually found enlarged, lighter in color than normally, and of a distinct icteroid tint. On making a longitudinal section, drops of bile can be collected on the edge of the section-knife.

The gall-bladder is found distended with bile, and on firm pressure a tough plug of mucus is usually expelled from the common duct into the duodenum, after which bile flows into the intestine freely. The mucosa lining the *ductus communis* is swollen and inflamed, and the catarrhal process may extend to the cystic, and in some cases to the hepatic, duct. As a rule, that portion of the common duct lying in the intestinal wall is more frequently and more deeply involved. If the disease becomes chronic, a formation of connective tissue occurs owing to the irritation caused by the retained secretion, and atrophy of the liver cells, with biliary cirrhosis, may result. Suppuration is rare.

Etiology.—Simple catarrhal jaundice results in the majority of cases from extension of inflammation in gastroduodenal catarrh, though it may be a primary mildly contagious disorder, and the principal *predisposing causes* are as follows: (a) Exposure to cold and wet; (b) the use of improper foods, including faulty cooking and improper mastication; (c) the excessive or prolonged use of irritants (tea, coffee, alcohol); (d) prolonged anxiety and mental or physical overwork; (e) certain acute diseases, as pneumonia, relapsing fever, streptococcic septicemia, typhoid fever, and malaria (toxic jaundice, *vide supra*); (f) certain types of anemia associated with increased blood destruction, paroxysmal hemoglobinuria, black-water fever, the injection of hemolytic substances (*e. g.*, toluylendiamin) are examples of acute hemolysis associated with jaundice the result of simultaneous destruction of the red cells and changes in the bile capillaries; (g) portal obstruction, occurring in chronic heart or kidney disease; (h) it has occurred in epidemic form (V. Weil's disease). Barker and Sladen¹ found that food (probably meat) was the most likely source of the infectious agent in an epidemic.

Symptoms.—Preceding the development of the distinctive features by several days, dyspeptic symptoms are in evidence (*vide* Gastrohepatic Symptoms). The symptoms of jaundice are, in general, those of the causative condition rather than the result of the deposition of bile-salts in the tissue *per se*. The principal symptoms in detail are: (a) *Icterus*, or tinting of the body surface, may be the first symptom noticed in this condition, appearing usually on the forehead and neck and rapidly spreading over the entire body. The conjunctivæ also early become discolored, and the general hue, though variable, is commonly a bright lemon yellow. In chronic cases the color is apt to change to a bronzed or deep green tint.

(b) *Secretions and Excretions.*—The urine and sweat are often found to contain bile-pigment, the patient's linen frequently being discolored. In extreme

¹ *Bull. Johns Hopkins Hosp.*, October, 1909.

cases the urine may be dark green in color, while in those of average severity it is of a lighter or deeper greenish-yellow hue. The shaken specimen foams, and the froth has a yellow color tint. Often the presence of bile is detected before any noticeable coloring of the conjunctivæ occurs. In cases of intense or long-standing jaundice albumin and tube-casts may be present, and the latter may be bile stained.¹ Hylaine casts are often found.

The bowels are constipated, and the stools are pale drab or slate colored; they are usually very fetid. Diarrhea, however, may be present owing to the production of irritating substances and decomposition.

The tears, saliva, and milk are rarely stained with bile-pigment. The expectoration also is rarely tinted unless pneumonia or some form of pulmonary infiltration coexists.

(c) *Circulation*.—The pulse, although not appreciably altered in volume or tension, is usually slow (often 30 or even 20 beats per minute), though this is not an unfavorable symptom. Windle found a pulse-rate of 40 and below in some cases, but in these the heart-rate was double that of the pulse. He questions whether the jaundice is responsible for either the infrequency or irregularity. Stewart and King have shown that this is due to stimulation of the vagus by the bile-salts.

(d) *The temperature* is usually normal, although slight elevations may occur (100° to 101° F.—37.7°–38.3° C.).

(e) *Gastrohepatic Symptoms*.—Dyspeptic symptoms—viz. anorexia, a sense of fulness after eating with flatulence, acid eructations, nausea and vomiting, accompanied by a dull, heavy pain over the hepatic area, with some tenderness on pressure—are present. These often develop insidiously; rarely they occur suddenly with a severe rigor or chill, violent headache, and vomiting—*e. g.*, at the onset in the epidemic form.

(f) *Cutaneous Phenomena*.—Pruritus or itching often becomes a troublesome symptom, being more common, however, in the chronic forms. Lichen, urticaria, furuncles, and sweatings (diffused and localized) may develop, the latter being often limited to the skin covering the abdomen and the palms of the hands.

A peculiar disease of the skin called *xanthelasma* or *bita higoidea* may also occur. It consists of bright yellow spots, slightly elevated, appearing on the eyelids, and rarely on other parts of the body.

In the severer forms ecchymoses and sometimes profuse hemorrhages may occur into the skin and mucous membranes. These are usually associated with symptoms of a grave type and are indications of increased blood destruction. In chronic obstructive forms the coagulation time of the blood is much delayed.

(g) *Nervous Symptoms*.—Headache and vertigo are common; irritability of temper, despondency, and wakefulness or mental dullness almost equally so. With the oncoming of darkness vision may grow indistinct (*hemeralopia*) or it may attain unnatural clearness (*nyctalopia*). Rarely, objects look yellow (*xanthopsia*). The nervous phenomena observed in catarrhal jaundice are attributable to the effects of the bile-acids. In certain cases, however, associated with destruction of the hepatic substance, as in acute yellow atrophy, carcinoma, cirrhosis, and fatty degeneration, grave cerebral symptoms (acute

¹ *Tests for Bile*.—*Gmelin's test*, or the play of colors, consists in bringing a few drops of urine in contact with the same quantity of commercial nitric acid on a plain white slab, whereupon various shades of yellow, green, red, and violet are produced.

Rosenbach's test is made by filtering the suspected urine and touching the filter-paper with a drop of nitric acid. If bile be present a green circle will form at the point of contact. (See also Choluria.)

delirium, convulsions, and coma) may develop suddenly and prove fatal. This class of symptoms has been named *acholia*, *cholemia*, or *cholesteremia* (the latter owing to the mistaken supposition that cholesterin is the poisonous product). The true nature of the toxic agent in the blood is unknown. In some fatal terminations of this character death was due directly to renal complication.

The **physical signs** in a case of simple catarrhal jaundice show on palpation and percussion an increase in the hepatic area, the lower border of the liver projecting in some instances several fingerbreadths below the ribs. Rarely, the distended gall-bladder projects below the lower lobe of the liver, as when there is complete obstruction near or at the duodenum, and then it can be distinctly palpated.

Diagnosis.—The etiology, a history of previously existing gastro-intestinal catarrh, the age of the patient (young adult life), and the appearance of the jaundice unaccompanied by pain or general emaciation, together with an absence of symptoms pointing to *cirrhosis*, *carcinoma*, or *acute yellow atrophy*, form a characteristic grouping of clinical indications. Examination of the bile removed by the duodenal tube sometimes gives distinct diagnostic aid.

Duration and Prognosis.—The *duration* of catarrhal jaundice varies from two to eight weeks. If the symptoms continue longer than two months, grave doubts may be entertained as to the case being one of simple jaundice. The prognosis is guardedly favorable. A rise of temperature usually indicates mischief (Pepper), while hemorrhages of the skin and mucous membranes always influence the issue unfavorably.

Treatment.—The *diet* and *hygiene* are the first considerations in the treatment. Rich, highly seasoned foods, rich pastries, fats, and sweets, are to be interdicted; starchy foods, lean meats, bread, soups (containing no fat), and green vegetables may, however, be used in moderation. Skimmed milk, butter-milk, and alkaline drinks (Vichy and Saratoga mineral waters) may be used freely, while sour wines, lemonades, and tamarind-water are allowable. Systematic bathing (Turkish or Russian baths, under supervision) and regulated hours of sleep exert a beneficial effect. The free use of pure water often does good by increasing the flow of bile and by dislodging plugs of mucus.

Gerhardt and Kraus have recommended the faradic current, applied over the region of the gall-bladder; manipulation has also been tried with a view to removing the obstruction, but without success.

The first *therapeutic indication* is to keep the bowels freely soluble by the use of saline aperients. In obstinate constipation calomel or rhubarb may be employed.

Conspicuous among other remedies may be mentioned the alkalies, sodium bicarbonate, salicylate, and phosphate, which tend to increase the flow of bile and render it less thick; hydrochloric acid (which, according to Ewald, by aiding digestion prevents the formation and consequent absorption of toxic substances) in combination with the bitter tonics—gentian, quassia, and nux vomica; ammonium chlorid which sometimes proves beneficial; and silver nitrate (gr. $\frac{1}{8}$ to $\frac{1}{4}$ —0.008–0.016, thrice daily).

Injections of cold water (60° to 70° F.—15.5°–21.1° C.) daily, in quantities of 1 or 2 quarts (1–2 liters), are highly recommended as promoting the secretion of bile; while lavage, practiced daily and over a protracted period of time (one to two months), has proved highly beneficial, especially when gastro-duodenal catarrh has existed.

Itching.—This troublesome symptom may often be relieved by the external application of a solution of borax or sodium bicarbonate (3ss to Oj—15.0–500.0), or of menthol and alcohol (gr. x to ʒj—0.6–30.0). Internally, large

doses of the bromids or the continued use of pilocarpin, as recommended by Witkowski, are worthy of a trial.

Flatulence.—To this end it is important to regulate the diet, avoiding starches and sugars. Charcoal tablets, bismuth subnitrate or salicylate, and beta-naphthol are all useful. Irrigation of the colon with some efficient antiseptic in solution is often a factor of service.

Headache is caused by the circulation in the blood of some toxic principle. Of drugs, caffeine citrate, camphor monobromate, and acetphenetidin, either singly or in combination, may be recommended.

When the obstruction is due to mechanical causes (biliary calculi, tumors pressing on the duct) the treatment is surgical.

ACUTE INFECTIOUS CHOLECYSTITIS

Definition.—An acute inflammation (infective) of the gall-bladder.

Pathology.—Five pathologic varieties—catarrhal, suppurative, phlegmonous, gangrenous, and membranous—are recognized. The gall-bladder progressively enlarges and becomes filled with mucopurulent or purulent or (rarely) hemorrhagic material. The cystic duct is often occluded. In the suppurative form ulcers may coexist and perforation, followed by localized peritonitic abscess or acute diffuse peritonitis, may occur. The lesions of cholangitis, either catarrhal or suppurative, and also cholelithiasis, may be associated. Cholecystitis may exist without gall-stones.

Etiology.—The *bacterial* excitants include the streptococci, staphylococci, the pneumococcus, the colon bacillus, and the typhoid bacillus.

Among predisposing conditions are many of the acute infections, as typhoid, typhus, malaria, sepsis, pneumonia, puerperal fever, and cholera.

DaCosta has collected 58 cases of typhoid cholecystitis. His figures show that it may occur at almost any *age*, and of 48 cases in which the sex was stated, 26 were males and 22 females.

Symptoms.—The onset is abrupt, with pain (often paroxysmal) in right side of the abdomen or epigastrium. The region of the gall-bladder is acutely sensitive, and with the development of spreading peritonitis the tender area grows correspondingly. Rigidity of the right rectus may be observed. In many cases a *tumor* occupies the seat of the gall-bladder. It is detected on palpation as a firm, pear-shaped tumor or as a “mere resisting mass below the costal margin.” The latter is often due to peritonitic abscess following perforation.

Nausea and *vomiting*, which may be persistent, are usual symptoms at the onset. *Jaundice* occurred in 17 out of 58 cases (DaCosta). Among the *general symptoms* chills are conspicuously absent. *Fever* may be present, but by no means always; the pulse becomes rapid and feeble, the abdomen distended, and prostration profound. Bayard Holmes noted cardiac disturbance as the most characteristic symptom in 46 cases. In the suppurative form a blood examination generally shows leukocytosis. The writer¹ has reported 3 cases of cholecystitis complicating lobar pneumonia. Jaundice occurred in 2 of the cases. This serious affection may be entirely latent.

Differential Diagnosis.—*Appendicitis* may be mistaken for cholecystitis, particularly if the appendix be situated abnormally high up. The discrimination would here rest upon the history (following typhoid or other

¹ *Amer. Medicine*, March 18, 1905.

infection), the presence of a *tumor* and marked sensitiveness in the region of the gall-bladder, corroborated by jaundice.

Acute intestinal obstruction may be closely simulated in cases in which adhesions between the gut and gall-bladder are present. In such cases exploratory celiotomy is to be advised or at least considered with a view to clearing the diagnosis. *Recurrent cholecystitis*, a not uncommon complaint, gives the history of recurring attacks of pain simulating cholelithiasis. In one of my cases Laplace operated and found the gall-bladder somewhat enlarged and the seat of catarrhal cholecystitis. Osler suggests that in some of these cases gall-stones may have been present and have passed before the operation (*vide infra*).

Prognosis.—This is dependent upon the special variety, although it is among the most fatal of diseases. A fatal result is the rule in purulent and phlegmonous cholecystitis. In the catarrhal form recovery is not infrequent (DaCosta). Pneumococcal cholecystitis is more acute and severe than that due to colon or typhoid infection (Richardson). Gangrenous cholecystitis is rare and quite fatal.

Treatment.—This embraces absolute rest, rectal alimentation, the relief of pain by the judicious use of morphin, and of other symptoms as they arise. Stimulants are necessary as a rule. If the diagnosis of suppurative or phlegmonous cholecystitis can be established, surgical intervention is imperatively demanded as a rule.

Chronic Cholecystitis.—By this term is meant chronic inflammation of the gall-bladder, either secondary to an acute cholecystitis or a chronic low-grade infection from the beginning. It cannot be differentiated clinically from cholelithiasis, with which it is associated in the majority of cases.

CALCULOUS CHOLECYSTITIS

(*Biliary Calculi; Gall-stones; Cholelithiasis*)

Definition.—Concretions formed in the gall-bladder, usually due to infection of its walls; they set up characteristic disturbances.

Etiology.—Catarrhal inflammation of the gall-bladder excites pathologic production of cholesterin by perverting metabolism inside the mucus-secreting cells in its walls. Schürmayer believes that cholelithiasis is really an expression of a metabolic disease of the liver. Infective catarrh of the small intrahepatic ducts leads to an albuminous exudation, which precipitates bilirubin-calcium calculi in the bile. Scheel found gall-stones in 15 per cent. of 2753 cadavers. In 67 per cent. of those showing gall-stones the bile passages were apparently not pathologic. The *exciting* cause is an infective inflammation of the gall-bladder and bile-ducts due to various organisms—*e. g.*, the *colon bacillus* and the *typhoid bacillus*. Among **predisposing causes** are: (a) *Female sex*, especially between the ages of forty and sixty. Senac's statistics, out of a total of 311 individuals, give 227 women (Dujardin-Beaumetz). (b) *Stagnation of bile*, due to an *excessive diet of starches and of fats*, a sedentary life, *constipation, tight lacing, pregnancy, obesity, chronic obstruction* to the outflow of bile (tumors, visceroptosis). Kehr claims that stones can develop in sterile bile, when the flow is obstructed. (c) It may occur during childhood. (d) Disorder about the pancreas may be the cause of gall-stone formation (Croftan). (e) *Insanity*, particularly chronic melancholia. (f) *Incidence*. Brockbank found among 13,047 completed postmortem records 7.4 per cent. of gall-stones.

Composition and Appearance.—Gall-bladder calculi are formed principally from cholesterin mixed with some bilirubin-calcium from the earliest stage. Certain salts (lime, potash, soda, traces of iron, and copper) also enter into the composition. Those formed in the hepatic ducts are composed of bilirubin-calcium alone. In *size* they vary from the smallest particle of sand to that of a goose egg. Fagge reports a calculus weighing, in a dry state, 462 grains (30.0). The *color* varies from white or light yellow to that of a dark green (pigment-lime calculi), and may present any variation between these two extremes. The *nucleus* often consists of cholesterin, the outer layer being usually the harder, and made up, for the most part, of lime-salts. The cholesterin gall-stones cut like wax, are white, and the cut section presents a crystalline appearance. Other forms are apt to be brittle. The *surfaces* may be smooth, striated, or hollowed out, solitary calculi being usually round or ovoid, while multiple stones often present smooth facets due to the massing together of the calculi (Dujardin-Beaumetz). They are usually olive shaped, but may be pyramidal, cylindric, lenticular, pisiform, cubic, finger shaped, or olivary. Their *seat* is usually the gall-bladder, but they may be found anywhere along the biliary passages, or may be truly intrahepatic.

Symptoms.—The passage of a calculus through the duct, if it sets up a “perialienitis” or inflammation of the structures surrounding it (*cholecystitis*), will give rise to *hepatic colic*, whereas a permanent blocking of the duct will cause symptoms of chronic obstruction (*vide infra*).

Hepatic Colic.—When a gall-stone becomes impacted in a bile-duct the patient experiences *agonizing pain* (tearing, cutting, or lancinating in character) in the right hypochondriac region, radiating to the right shoulder, and accompanied often by profuse *sweating*, *vomiting*, and a *feeble, running pulse*. The most common *seat* of the pain is 2 to 3 inches to the right of the median line and about an equal distance below the ensiform cartilage. Less frequently it is in the region of the gall-bladder. This happens in cases in which the gall-stone is impacted in the cystic duct, and may be due either to distention of the gall-bladder or, more commonly, to associated cholecystitis. Hepatic colic, however, may occur independently of the passage of biliary calculi, as from non-calculous cholecystitis (Stockton, Riedel). If pain is severe without relation to meal-time, you should suspect cholelithiasis. On the other hand, large calculi have been found in the dejecta without having excited hepatic colic. I saw an instance in which the gall-stone was the size of an English walnut. A *rigor* or *chill* often precedes the attack, which is usually accompanied by moderate *fever* (Charcot’s intermittent fever), the temperature reaching 101° to 102° F. (38.3°–38.8° C.). If the stone passes through the common duct without becoming impacted, jaundice and pain may be absent. When, however, occlusion of the common duct occurs, the *jaundice* becomes intense. This symptom may be present, though less marked, before the gall-stones reach the *ductus communis*. Jaundice occurs in about 50 per cent. of the cases (Fitz), and it sets in within forty-eight hours after the onset of the attack. *Physical examination* reveals on inspection a slight prominence in the hepatic area, and on palpation the edge of the liver can often be distinctly felt below the costal margin—at times as low as the umbilical level; it is sensitive on pressure, and particularly the gall-bladder, which can often be palpated. If the latter viscus contains many calculi, and the abdominal wall is relaxed, crepitation may be noticeable to the palpating fingers (rarely). Tenderness in Boas’ area to the right of the spine between the tenth and twelfth rib is a valuable confirmatory sign. The swollen organ, after the cessation of the colic, quickly subsides. Tenderness over Mayo Robson’s point at the junction of the lower third with the upper two-thirds of a line drawn from the tip of the ninth

rib to the umbilicus is a characteristic feature. *Recurrences* of the attacks after varying intervals of time are common, and in the female especially at the menstrual period. Finally, the gall-stone may be expelled and the colic cease to return. Multiple stones, however, may be passed. Hyperchlorhydria is commonly present.

Rupture of the duct, followed by fatal peritonitis, has been known to occur. Localized peritonitis results from extension of inflammation through the walls of the gall-bladder. Biliary colic is of variable *duration*, lasting from a few hours to a few days or one or more weeks even. The blood cholestrin is usually increased, though not necessarily. Hypercholesteremia frequently occurs in many of the conditions often associated with gall-stones (pregnancy, obstructive jaundice, severe diabetes, etc.). Examination of the *urine* after the paroxysm reveals bile, uric acid, and urates. The *pulse* often becomes slowed. Exner found about 0.4 per cent. of sugar in the urine in 39 out of 40 cases of gall-stones. On the other hand, Kausch has found glycosuria in only 1 of 85 cases.

The **prognosis** as regards life is good, but as regards recovery only guardedly favorable. Cardiac distress with palpitation may occur during hepatic colic and form a serious complication. Fatal syncope has also been known to occur, and gall-stone ileus, especially near the ileocecal valve, may terminate life. If evidences of an infectious inflammation arise, the outlook is then more serious. The sequelæ will be discussed hereafter (*vide infra*).

The **diagnosis** of gall-stones is sometimes difficult on account of the obscure clinical symptoms and the absence of physical signs. When, however, the calculus becomes impacted in the duct, symptoms of biliary colic—intense pain in the epigastrium and right hypochondriac region, radiating to the back and right shoulder—usually appear. The attack is of brief duration, with abrupt cessation. There are also fever, vomiting, and in one-half the instances jaundice. The urine should be examined early, since bile may be present many hours before icterus occurs. Pfahler¹ claims that in 50 per cent. of the cases gall-stones are demonstrable by the roentgen rays. Biliary calculi are not often found in the dejecta.

Differential Diagnosis.—*Gastralgia* occurs in neurotic individuals, and is characterized by severe paroxysmal pains in the epigastrium, extending to the back and base of the chest. It occurs when the stomach is empty and is relieved by eating. Firm pressure over the epigastrium often alleviates the pain temporarily, and the absence of fever, jaundice, stones in the dejecta, and the negative urinalysis, together with the history of former attacks, would tend to differentiate it from hepatic colic.

Renal Colic.—The pain in this condition starts in the flank of the affected side and is transmitted down the ureter, and there is localized tenderness. The testicle and inner side of the thigh are very painful, the former being often retracted. Micturition is frequent and sometimes painful, and the urine is scanty in amount and often mixed with blood.

Intestinal Colic.—In this variety the pain is of a boring or twisting character, usually centering about the umbilicus. It is relieved by firm pressure. Abdominal distention is often present, and relief comes with the passing of flatus. Usually there is a history of an indiscretion in diet. When due to *lead-poisoning*, the history, the blue line on the gums, and the presence of wrist-drop would tend to confirm the diagnosis.

Reflex colic, due to uterine or ovarian disease, may also occur. The recurrence of the attacks, together with causes and symptoms pointing to pelvic disease, would establish the identity of the condition.

¹ *Jour. Amer. Med. Assoc.*, April 25, 1914, p. 1304.

CHRONIC OBSTRUCTION OF THE DUCTS BY GALL-STONES

The obstruction may exist either in the common or the cystic duct.

1. **Obstruction of the Common Duct.**—**Pathology.**—The result of the irritation produced by the presence of the stone is a catarrhal process (*cholangitis*) that may either remain chronic or terminate in suppuration (*suppurative cholangitis*). In a case of simple obstruction the gall-bladder is often moderately enlarged, though rarely extending below the lower border of the liver. The common duct is greatly distended, the stone being usually located near its termination. Occasionally two or more calculi are present, completely obliterating the canal. The hepatic duct and its branches are greatly dilated, and often contain thin, colorless mucus, the lining membrane being smooth and clear. The liver in these cases is firmer in consistency than normal, showing some increase in the connective-tissue element (biliary cirrhosis). Following moderate enlargement of the organ progressive atrophy may rarely occur. When *suppuration* has occurred the mucous membrane is greatly swollen and reddened, and in some instances shows erosion or ulceration (*ulcerative angiocholitis*). The process often ascends the hepatic ducts into the liver, with infection of this organ, and in the severer cases abscess formation. On the other hand, it may extend to the gall-bladder, giving rise to empyema of the latter. In some instances the gall-bladder has been perforated and abscesses have formed between the liver and stomach. *Diver-ticula* are sometimes found postmortem, containing biliary calculi.

While cholelithiasis is a common cause of catarrhal, suppurative, and ulcerative angiocholitis, it not rarely complicates hydatid disease, carcinoma of the bile-ducts, and the acute infections, particularly typhoid fever (*vide* Acute Infectious Cholecystitis, p. 837). Rarely foreign bodies (fish-bones, lumbricoids) operate as excitants.

Symptoms.—Chronic obstruction by gall-stones, with coexisting *catarrhal inflammation* (catarrhal angiocholitis), is characterized by a distinctive group of symptoms, among the most prominent of which are—

Jaundice.—This may be constant and very intense, or intermittent and slight, depending upon the amount of obstruction present. There are periodic elevations of temperature accompanied by a deepening of the jaundice, when this symptom already exists (ball-valve action of the stone). *Itching* is, as a rule, a most distressing feature. A stone low down produces obstruction also of the pancreatic ducts, in which case the stools will contain a great amount of fat and undigested muscle-fibers.

Pain, occurring in paroxysms and referred to the region of the liver. This is accompanied by fever that may reach a high degree (102° to 103° F.—38.8°–39.4° C.), also by chills and sweating, resembling the paroxysms of malaria. Painful points in the right side posteriorly may be annoying; these are either constant or paroxysmal.

The *chills* are often intense, and may present a quotidian, tertian, or quartan form. The temperature of the intervals is normal. The peculiar exacerbations of temperature were first described by Charcot, and to them has been given the name of *Charcot's intermittent fever*. Concerning their nature Murchison writes: "These paroxysms may be more or less periodic, and may extend over several months, without necessarily indicating pyemic hepatitis, the patient ultimately recovering." He adds that they are probably analogous to febrile paroxysms produced in passing a catheter along the urethra. Charcot believes the etiologic factor to be a septic poison, bacterial in origin and the result of chemical changes in the bile. Various micro-organisms have been detected in the bile in such cases (*Bacterium coli commune*, *Streptococcus pyogenes*, et al).

Gastric Disturbances.—These may excite alarm during the paroxysm. Intense pain is complained of in the epigastrium, accompanied often by nausea and vomiting, which, however, usually subsides at the close of the paroxysm, while the jaundice at this time deepens. Lichty found disturbance of the gastric secretion in 75 per cent. of the cases, of which two-thirds showed hyperchlorhydria. Gastric motility was disturbed in about the same proportion of cases.

The symptoms of *suppurative cholangitis* are intense. The *paroxysms* of fever occur more frequently, the temperature merging into the remittent type. Grave constitutional symptoms, indicating septicopyemia, are present, and the case rapidly tends to a fatal issue. The attacks of colicky pain occur with jaundice, but the latter symptom is less intense than in the catarrhal form. As to hepatic enlargement, the converse is true; this organ takes on progressive enlargement and "may descend as low as the umbilicus, the swelling being uniform and smooth and tender to pressure" (Robson). It should be borne in mind that pain may be absent when the disease is not dependent on gall-stones. Pneumonia and empyema are serious and not uncommon complications. In *ulcerative angiocholitis* severe hemorrhage may occur, resulting either in melena or hematemesis. Mayo Robson reports a case in which hematemesis was the only antemortem symptom and had been the cause of death. The process being a septic one, it leads to the constitutional disturbances of septicemia or septicopyemia. *Pancreatitis* may be caused by stones in the common duct.

2. Obstruction of the Cystic Duct.—This almost invariably causes distension of the gall-bladder (dropsy of the gall-bladder). If obstruction of the cystic duct alone occurs, *jaundice* may be entirely absent, the bile in the distended tissues being replaced by a thin, mucoid fluid. This is more apt to exist as the obstruction becomes more chronic. In some instances the distention is so great as to reach below the umbilicus, and the dilated viscus has has even been mistaken for an *ovarian tumor*. Osler records a case in which 18 oz. (540.0) of fluid were removed from the gall-bladder. The contents are neutral or alkaline in reaction, albumin often being present in abundance. Catarrhal inflammation of the gall-bladder may be associated, causing *pain*, at times being so severe as to simulate hepatic colic, and *sensitiveness* in the region of the organ, although, as a rule, few symptoms are presented. The examiner can *feel* an elastic, gourd-shaped tumor closely connected with the liver, movable in respiration in the vertical, and also, under the influence of the palpating fingers, in the lateral direction. Occasionally Riedel's tongue-like projection of the anterior margin of the right lobe is palpable. Given a gall-bladder well filled with stones and a relaxed abdominal wall, gall-stone crepitus may be detectable.

I have reported some cases giving a more or less characteristic clinical history of cholelithiasis, in which gall-stone crepitus on palpation furnished proof of stones in the gall-bladder. In one case I combined auscultation with palpation and detected a grating sound.

If the obstruction persist for a length of time, calcification or atrophy of the bladder are common sequelæ. Complete obliteration of the cavity of the gall-bladder may ensue.

Among rarer sequelæ of chronic obstruction may be mentioned: (a) *Empyema of the Gall-bladder.*—When this takes place the organ becomes greatly distended, and has been known to contain as much as 1 pint of purulent material. The *symptoms* of suppurative cholecystitis simulate and accompany those of purulent cholangitis; they are sometimes preceded by those of catarrh of the gall-bladder and ducts. Perforation may occur, giving rise to circum-

scribed periportal abscesses or to generalized peritonitis (see also Acute Infectious Cholecystitis, p. 837).

More Remote Effects of Gall-stones.—These will be spoken of under three headings:

1. Stricture of the duct, resulting from ulceration and cicatrization produced by the passage of a stone.
2. Intestinal obstruction, due to impaction of stones or volvulus.
3. Biliary fistulæ resulting from perforations.
4. Chronic pericholecystic adhesions.

1. **Stricture of the Duct.**—Obliteration of the common duct may result from the passage of a gall-stone, giving rise to ulceration and cicatrization, or the stone may become impacted and lead to adhesions and permanent closure of the duct below it (Murchison). When due to ulceration the seat of the stricture is usually low down in the common duct.

The *symptoms* are those of chronic obstructive jaundice (Osler). In many cases there will be an antecedent history of the passage of gall-stones. In all cases in which the symptoms of gall-stones are followed by permanent jaundice without pain it may be suspected either that the calculus has become firmly impacted or that it has produced organic stricture or closure of the duct.

2. **Intestinal Obstruction from Impaction of Gall-stones.**—The ileum is commonly the seat of obstruction by gall-stones that may give rise to intussusception or cause ulceration and gangrene of the bowel with perforation and fatal peritonitis. The latter event, however, occurs more frequently when the biliary concretions are situated in the cecum. Rarely they are found in the appendix, and may produce appendicitis. Cases of impaction in the rectum of biliary calculi have been recorded. I saw a case with the late Dr. R. Bruce Burns.

Symptoms.—If the impaction occurs in the small intestine, the abdomen becomes tympanitic and tender on pressure. The contents of the stomach are first vomited, followed by bile and stercoraceous matter. Symptoms of peritonitis develop and continue until either the impaction disappears or death ensues. Ileus, the result of biliary concretions, is common in females of advanced age, and adhesions about the gall-bladder region may obstruct the lumen of the bowel. The history of previous acute attacks would tend to confirm the diagnosis. The pain is intense. The duration of the last attack is often short.

3. *Perforation* may occur with the establishment of *fistulous communications* between the gall-bladder and stomach, intestinal canal, bladder, vagina, lungs, abdominal parietes, or portal vein. Fistulæ between the gall-bladder and stomach are rare, though cases are recorded by Oppolzer, Frerichs, Cruveilhier, Murchison, and others. Cruveilhier states that vomited gall-stones necessarily reach the stomach through fistulous tracts, as the passage through the pylorus would be impossible.

Fistulæ into the duodenum are of much more common occurrence, ulceration taking place usually in the fundus of the gall-bladder and in the descending or third portion of the duodenum: 39 cases are recorded of fistulous communication with the colon (Osler). I have reported a fortieth case.¹ In 6 of 9 cases reported by Murchison carcinoma of the gall-bladder was present. Fistulæ into the urinary passages may occur, 2 authenticated cases being reported. The distended gall-bladder may come in contact with the urinary viscus, or the stone may perforate into the pelvis of the kidney and pass through the ureter into the bladder.

¹ *Clinical Lecture, International Clinics*, vol. ii, third series, p. 27.

Fistulous openings through the abdominal parietes are the most common, the place of exit of the biliary concretions being usually in the region of the gall-bladder or at the umbilicus, to which it may be directed by the suspensory ligament of the liver. As many as 600 stones have been removed from the gall-bladder in this manner. Advanced life and female sex are said to be predisposing causes. Courvoisier's statistics show 184 cases, in 78 of which recovery took place.

Fistulæ into the pleura, bronchi, and vagina have been recorded, but are extremely rare. Courvoisier records 24 cases of fistulæ into the lungs, only 7 of which terminated in recovery. Fauconneau, Dufoesne, Frerichs, Bristowe, and Murchison mention cases of fistulæ into the portal vein, with the presence of biliary concretions in the latter.

4. Chronic Pericholecystic Adhesions.—Adhesions which are due to previous infectious inflammation, either acute or chronic, of the biliary tract are of frequent occurrence. Their pathogenesis is analogous to that seen elsewhere in the body (*e. g.*, appendix).

Symptoms.—The clinical recognition of the adhesions offers formidable difficulty. More or less periodic attacks of biliousness and indigestion without apparent cause, and accompanied by pain and tenderness to deep pressure over the region of the gall-bladder or pylorus, with rigidity of the overlying muscles, form a grouping of significant diagnostic points. A roentgen-ray examination should be undertaken. Either the pylorus or duodenum may become obstructed, with ensuing gastrectasis.

Diagnosis.—I would strongly urge an exploratory celiotomy as an accurate means of diagnosis in obscure cases.

Treatment of Foregoing Conditions.—The indications for treatment in *cholclithiasis* are: (*a*) to remove the cause; (*b*) to relieve the paroxysms of hepatic colic, and (*c*) to adopt palliative or radical measures for the removal of the stones.

Preventive Treatment.—This has reference to the removal or mitigation of the predisposition. The diet should be as simple as possible, consisting largely of skimmed milk, lean meat, eggs, fruit, and green vegetables. Fatty foods, sugars, starches, and pastries are to be strongly interdicted. All foods should be thoroughly masticated, so as to digest easily, and meals should be taken at regular intervals. Systematic exercise in the open air is of signal value, as it stimulates the flow of bile. Punkhauer strongly recommends horseback-riding for obstructions in the common duct. Drugs that have supposedly an influence upon hepatic function are chiefly the salicylates and ox-gall. In my own experience 1 dram (4.0) of sodium phosphate dissolved in a glass of hot water in the morning on rising has yielded excellent results. The same dose may be repeated before the noon and evening meals, if required. Constipation should be carefully avoided.

To prevent recurrences a course of alkaline treatment at some of the more noted mineral springs (Bedford, Vichy, Carlsbad) is often attended with good results. The efficacy of the Carlsbad treatment lies in reducing inflammatory processes, and not in the expulsion or solution of the gall-stones. "As the result of Carlsbad treatment, Fink, in 375 cases, had good results in 291 = 72.8 per cent., of which 20 cases, or 4.95 per cent., had relapse" (Forcheimer).

Treatment of the Paroxysm of Biliary Colic.—At the very onset of an attack of hepatic colic the prompt exhibition of morphin or of codein may greatly mitigate an attack. The former may be given hypodermically in $\frac{1}{8}$ - to $\frac{1}{4}$ -gr. (0.008–0.016) doses every hour until relief follows; the latter is exhibited by the mouth in doses of 1 gr. (0.065) every hour. Inhalations of chloroform, with morphin hypodermically, the former being continued until the latter

has taken effect, is the typical treatment of an attack. Gilman Thompson recommends chloroform (℥xx—1.3) by mouth for the relief of pain.

Hot baths and hot applications (with counterirritation) over the liver are valuable aids in the treatment of hepatic colic, being given at a temperature of 98° to 100° F. (36.6°–37.7° C.), and continued for twenty minutes, if endurable, so as to effect relaxation. If cardiac depression results and the pulse becomes weak, the baths should be discontinued. Hot flaxseed-poultices, cloths wrung out of hot water, hot hop-bags, or turpentine stupes may be applied over the hepatic region until the attack subsides. Ice-poultices have been advised by Buchetan.

If shock or syncope should develop, the body-temperature must be maintained by hot bottles or bricks placed in contact with the surface of the body, together with strychnin (gr. $\frac{1}{80}$ —0.0021), atropin (gr. $\frac{1}{150}$ —0.00042), and brandy (1 dram—4.0) hypodermically.

Nausea and vomiting may be reduced by 15-drop doses of spirits of chloroform every half-hour; also by brandy or champagne.

In mild cases sodium salicylate (gr. viij to xv—0.5–1.0 in twenty-four hours), recommended by Prevost and Binet, or codein (gr. j—0.06), with phenacetin (gr. x—0.6), every few hours gives relief. Purgation and remedies presumed to act as cholagogues, given during an acute seizure, are harmful in their effects. The aim should be to reduce the inflammatory process in the gall-bladder. D. D. Stewart well says: "The treatment of recent cases of stone in the common duct belongs to the physician but a short time only." If the gall-bladder is palpable after an attack of hepatic colic, the cystic duct is probably obstructed and the treatment is surgical.

Treatment for Removal of Gall-stones.—Solvents for the stones have been tried at various times, among them being *Durande's method* (turpentine and ether), but so far all such methods of treatment have been unsuccessful.

Of the various surgical measures for the removal of gall-stones the following are the chief: (a) Removal of the stone from the common duct (choledochotomy); (b) removal of the stone from the cystic duct (cholecystotomy); (c) establishing a fistulous opening between the gall-bladder and the bowel (cholecystenterostomy); (d) extirpation of the gall-bladder (cholecystectomy), the latter operation giving a mortality of 17 per cent., according to Murphy's statistics. And operative procedure is indicated in infectious (suppurative) cholecystitis as well as in infectious (suppurative) cholangitis; *e. g.*, evacuation and drainage. W. Mayo has operated on 510 cases of cholelithiasis with a death-rate of only 3 per cent. Of 326 cases of gall-stones complicated with biliary infection and malignant disease, 16, or 5 per cent., proved fatal. Kehr has never had a recurrence in 900 operations for cholelithiasis; Toeplitz has had recurrence in 14.2 per cent.

CARCINOMA OF THE BILE-DUCTS

Carcinoma of the gall-bladder and bile-ducts may occur as a primary disease and exist over a long period of time without being recognized.

Pathology.—The gall-bladder, as the result of obstruction of the duct, is often greatly distended, measuring as much as 7 inches (17.7 cm.) in length (in a case reported by Harley) from the entrance of the duct to the fundus, and being filled with a cloudy liquid, somewhat resembling barley-water, that contains flakes of epithelium, granular matter, and particles of inspissated bile. If the growth be near the duodenal orifice, the common and cystic ducts are often greatly distended, and the dilatation may extend into the he-

patic ducts and their branches. The liver may be enlarged, and in more than one-half of the instances presents the secondary nodules that are characteristic of the disease. Microscopically, carcinoma of the gall-bladder exhibits marked variations in different cases; "it may be either columnar or spheroidal celled" (Rolleston).

Etiology.—The causes of carcinoma of the bile-ducts are the same here as elsewhere, and among these the mechanical or inflammatory theory of Virchow might be accepted. Tight lacing and mechanical irritation by gall-stones are followed in many instances by cancerous degeneration; Osler states that "biliary calculi are present in at least seven-eighths of all cases." Among other factors, heredity and age (after forty) play an important part. Although carcinoma of the *liver* undoubtedly occurs more frequently in males, Musser found that out of 100 cases of carcinoma of the *ducts*, 75 occurred in the female; and Ames found the ratio to be 4 to 1 in favor of females.

Symptoms.—The signs and symptoms, according to Harley, present nothing characteristic to distinguish them from other causes of obstruction in the duct. On *palpation* in the early stages the gall-bladder is found moderately enlarged, but later it rapidly undergoes diminution in size. *Jaundice* becomes very intense, and remains permanent. Throughout the course of the disease all the symptoms referable to chronic obstruction of the duct by gall-stones (paroxysmal pain, gastric disturbance, rise of temperature, Charcot's fever) may develop.

Examination of the urine and feces reveals the presence of *bile-pigment* in the former and its absence in the latter. The urine often shows the presence of bile-stained casts (*vide* Fig. 58).

Ascites not rarely occurs during the later stages, with the involvement of surrounding organs by contiguity, as well as with the appearance of secondary nodules in the liver and the development of cachexia.

Diagnosis.—Carcinoma of the biliary ducts cannot always be detected by physical examination. Distinct evidence of chronic obstruction of the duct, as persistent and intense jaundice (which occurs in three-fourths of the cases), the development of cachexia and the absence of cancerous involvement of other organs, however, will tend to characterize it. Often a hard tumor mass is present in the region of the gall-bladder, projecting in the direction of the umbilicus. It should be recollected that the bile-ducts are oftener the seat of the primary affection than the liver. Cholelithiasis may simulate carcinoma in all its symptoms except those due to metastasis.

The **prognosis** of carcinoma of the bile-ducts is, like that of other organs, absolutely fatal, though the course of the disease is not so rapid as that of carcinoma elsewhere until secondary involvement of the liver occurs.

The **treatment** is merely palliative. Operative measures are rarely justifiable, since the disease is rarely recognized before the liver becomes involved. As seven-eighths of the cases follow obstruction of the duct by gall-stones, the preventive treatment of the latter should be carefully observed whenever symptoms of disordered liver function manifest themselves.

The treatment of the pain, anemia, and emaciation will be described in the discussion of Carcinoma of the Liver.

STENOSIS OF THE BILE-DUCTS

Stenosis may result from any of the following causes: (a) *Round-worms* in the duct (rarely); (b) foreign bodies, as seeds; (b) ulceration and cicatrization

following the passage of gall-stones (most commonly); (d) pressure from without, as from tumors (carcinoma chiefly) of the head of the pancreas and pylorus (rare); (e) abdominal tumors; (f) aneurysm of the abdominal aorta or of the celiac axis (rare); (g) secondary enlargement of the lymphatics of the liver (common); (h) more rarely in man than in the lower animals *Distoma hepaticum*, or liver-flukes and echinococci; (i) adhesions due to chronic peritonitis.

Pathology.—If the stenosis is of recent origin the liver is enlarged and shows more or less congestion, with some increase of the connective-tissue elements. The substance is firmer than normal, the color varying from an olive green to a deep bronze. If, however, the obstruction be of long standing, the presence of the dilated intrahepatic ducts and the increase of connective tissue cause secondary atrophy of the hepatic cells, with a diminution in the size of the organ.

The **symptoms** vary greatly according to the cause of the stenosis, but in the main they are those of chronic obstruction of the duct—viz., paroxysmal pain in the region of the liver, referred to the right shoulder; jaundice of varying intensity, but gradually deepening after each attack; and gastric disturbance, with ague-like paroxysms (fever and sweating), the latter being most frequently met with in occlusion from gall-stones.

Diagnosis.—The pathognomonic symptoms determining the nature of the stenosis are very often wanting, and the diagnosis is rendered correspondingly difficult. On the other hand, stenosis or complete occlusion of the bile-passages calls for diagnosis principally on account of the special cause or causes of the given case.

When the condition is due to *lumbricoid* worms reflex symptoms usually appear, as pruritus of the nose and anus, grinding of the teeth during sleep, and convulsions.

In *carcinoma of the head of the pancreas or the pylorus* pressing on the ducts the growth may be detected by palpation, together with a recognition of more or less characteristic features (*vide* Carcinoma of Pancreas), and the rapid course of the disease.

Abdominal aneurysm may give rise to obstruction of the duct without being evidenced by physical signs. Usually, however, when the sacculaton presses against the bile-duct, the throbbing in the epigastrium, the tumor (which can often be grasped), and the expansile pulsation on palpation will tend to establish the cause of the obstruction.

When due to *cancerous nodules in the liver* there is usually a history of primary carcinoma of the stomach, mammary gland, rectum, or of one of the pelvic viscera. Osler records a case in which jaundice (thought to have been catarrhal in origin) developed seven weeks previously. On careful examination "a small nodule was detected at the umbilicus, which on removal proved to be scirrhus."

When the stenosis is due to *ulceration* following the passage of gall-stones, the history of biliary colic, and of paroxysmal pain with jaundice and intermittent fever, will serve to establish the cause.

If the fever be of the continued type and the liver uniformly enlarged, with the development of jaundice, the case is probably one of *hypertrophic cirrhosis*; whereas if the enlargement be progressive and nodules can be detected on palpation in addition to the appearance of cachexia and jaundice, *carcinoma* is undoubtedly present.

Physical signs aid but little in the diagnosis, as obstruction of the common duct is usually unattended by any great enlargement of the gall-bladder.

In many cases only by remembering the various causes and eliminating them carefully, one by one, can a diagnosis be rendered.

The **prognosis** varies according to the cause of the stenosis. Generally speaking, the outlook is rather grave, since many of the causative conditions are fatal. If the obstruction is due to cicatricial contraction, the prognosis is guardedly favorable as to life, but hopeless as to recovery. If the obstruction is permanent, the case ends fatally.

The **treatment** of occlusion of the bile-ducts varies according as it is due to cicatricial contraction following ulceration or to foreign bodies (seeds or lumbricoid worms), or to gall-stones or tumors pressing upon or involving the ducts or adjacent organs (pancreas, pylorus). If the stenosis follows ulceration in the duct, and is sufficient to cause almost complete occlusion with biliary retention, the operation of cholecystenterostomy may become necessary in order to prevent dilatation of the gall-bladder with resorption of bile.

Foreign bodies in the duct may be removed by free purging, aided by the liberal use of alkaline mineral waters. In critical cases the operation of cholecystotomy is recommended.

Gall-stones form the most frequent causes of stenosis, and the treatment, both for the prevention and removal of calculi, has already been described in the discussion of Biliary Calculi (*vide* p. 838).

ICTERUS NEONATORUM

Definition.—By the term “icterus neonatorum” is meant jaundice occurring in the newborn. It is seen in about two-thirds of all newborn infants, is unaccompanied by any other lesions, and pursues a favorable course. Icterus neonatorum must not be confounded with jaundice occurring in the newborn and dependent upon various pathologic causes—*e. g.*, congenital stricture or absence of the duct, syphilitic disease of the liver, duodenal catarrh, and septicemia, as a result of infection through the umbilical vein. In this form the skin and conjunctivæ are more or less icteroid, the urine is loaded with bile-pigment, while the feces are of a pipe-clay variety. Hence it differs in its symptomatology from true icterus neonatorum.

The secretion of bile begins before birth, and Zweifel found bile-pigment and bile-acids in the contents of the intestines of a three-month fetus. Hence well-marked jaundice may be a congenital condition.

Etiology.—The following are the main causes: 1. The ductus venosus may remain patulous, allowing some of the portal blood, containing bile, to flow into the systemic circulation (Quinke). 2. Diminished pressure in the portal vessels from ligation of the umbilical vein causes increased tension in the hepatic capillaries and absorption of bile. 3. It is probable that the external conditions are in some way concerned in the appearance of the disease (Osler). 4. The destruction of red corpuscles may be followed by an increased amount of bile-pigment in the liver.

Symptoms.—The skin is tinted greenish yellow, resembling somewhat that of chlorosis. The mucous membranes are pale and the conjunctivæ pearly white except in the severer cases, when they show a slight discoloration. The icterus usually appears on the second or third day of life. The pulse is feeble and sometimes rapid. Auscultation over the base of the heart often reveals a soft systolic murmur, associated with a venous hum in the neck. According to Murchison, icterus neonatorum differs from the pathologic form in that—(1) The conjunctivæ are of a natural color; (2) the urine is free from bile-pigment; (3) the yellow color gradually fades from the skin after a few days; (4) the child is quite well and the bowels are acting properly.

Prognosis.—The jaundice gradually disappears spontaneously at the end of three or four days.

Treatment.—As a rule, nothing beyond hygienic measures are required. The diet need not be restricted.

VASCULAR (CIRCULATORY) AFFECTIONS OF THE LIVER

ANEMIA

The physical symptoms of this condition are absolutely *nil*, and its existence only discoverable *postmortem*. Its most common causes are those of general anemia, fatty and amyloid degeneration.

HYPEREMIA

Definition.—An excess of blood in the liver. This may be of two varieties: (a) *active* and (b) *passive*, the latter being the more common.

ACUTE HYPEREMIA

(Active Congestion)

Definition.—An excess of arterial blood in the liver.

Etiology.—Among the common causes are luxurious living, sedentary habits, alcoholism, traumatism, acute infectious diseases (typhus, typhoid), and pernicious malaria. The condition may also be vicarious, due to a sudden cessation of menstruation or of hemorrhage in other parts of the body. A *physiologic* condition is the temporary hyperemia that occurs during the ingestion of a full meal.

Symptoms.—There are no symptoms characteristic of this condition; those present in the different cases are varied and referable to disturbances of other viscera, as in coexisting cardiac hypertrophy or gastro-intestinal catarrh. There is a sense of *fullness* and *distress* in the right hypochondrium, most marked during the height of the digestive process, with *tenderness* on palpation over the margin of the organ.

Prognosis and Course.—It is impossible to make any definite statement as to the course and prognosis of active hyperemia, these depending wholly upon the cause of the affection. When due to errors of diet and hygiene the condition is easily remedied; the prognosis of hyperemia accompanying hepatic cirrhosis, however, is decidedly grave.

PASSIVE HYPEREMIA

(Passive Congestion)

Definition.—An increase of venous blood in the liver.

Pathology.—The organ is enlarged and changed into a deep-red color, while its substance is firmer than normal. The center of the lobule (the area of the hepatic vein) becomes deeply pigmented, the periphery (occupied by the portal vein) being lighter in color, sometimes owing to fatty infiltration. Because of its mottled appearance this has received the name of "nutmeg liver."

In long-standing passive congestion there is an increase of connective tissue, due to a proliferation of round-cells, causing atrophy of the parenchyma. The blood in the central capillaries becomes altered, the capillaries themselves are distended, and brown pigment is deposited about the center of the lobules.

The organ becomes very much darker in color, and to this condition the name "cyanotic induration" or "cardiac liver" has been given. Later, contraction of the connective tissue occurs, causing a diminution in the size of the organ and forming the so-called "atrophic nutmeg liver."

Etiology.—The causes that lead to passive hyperemia are both *local* and *general*. Among *local* causes may be mentioned the following:

1. Pressure over the portal area from without, as from a tumor or cyst.
2. Disease of the walls of the veins, as in syphilitic phlebitis.
3. Coagulation of the blood in the veins (thrombosis).

Among the *general* causes are—

1. Chronic valvular disease affecting the right side. Passive hyperemia also occurs in mitral disease.

2. Pulmonary emphysema and cirrhosis of the lung.

3. Intrathoracic tumors, which by their mechanical action cause an increased pressure in the efferent branches of the hepatic veins.

Symptoms.—Often the patient experiences a sensation of *fullness* and *weight* in the region of the liver amounting at times to *pain*. *Jaundice* is usually present, but varies in intensity, and is due to obstruction of the smaller ducts from distention of the hepatic venules. *Hematemesis* and also *hemorrhoids* (bleeding) may occur, and symptoms of gastro-intestinal disturbance are usually present. In marked cases the *stools* are *clay colored*, showing the absence of bile; the *urine* is loaded with bile-pigment; and jaundice deepens with the development of *ascites* or *anasarca* from portal obstruction. On *palpation* the organ is tender and increased in size, extending sometimes fully a hand-breadth below the costal margin. In pronounced cases the whole organ pulsates, owing to the regurgitation of blood into the hepatic veins (see also p. 615).

The **diagnosis** of passive congestion, *per se*, is difficult, but when secondary to heart and lung diseases it is more plain.

The **prognosis** and **treatment** depend upon the causal factors.

DISEASES OF THE PORTAL VEIN

THROMBOSIS AND EMBOLISM

Pathology.—In the early stages the clot presents a grayish-red or yellowish appearance, and on loosening it is found to adhere more or less closely to the inner coat of the vein. Later it becomes a mass of small white fibrin tightly adherent to the sides of the blood-vessel, which itself undergoes fibroid change (adhesive pylephlebitis). Organized thrombi are rarely found except in the smaller branches of the portal area. If the thrombus obstruct the vessel, collateral circulation may be established for years. Septic softening, however, is a very common result, and pylephlebitis even more so. If a parietal or channeled thrombus be formed, partial or complete circulation may be re-established and recovery take place. Hemorrhagic infarction may occur, but it is rare.

Etiology.—*Thrombi* are rare occurrences in the portal vein. Among the *causes* that lead to their formation, however, may be mentioned: (a) Traumatism; (b) cirrhosis; (c) carcinoma of the liver, stomach, and pancreas; (d) pressure from without, as in proliferative peritonitis involving the gastro-hepatic omentum, abscesses, enlarged glands, or impacted calculi pressing on the veins; (e) it may be occasioned by ulcerative affections of the bowels and

appendicitis, and pylephlebitis may precede its occurrence; (f) slowing of the circulation due to splenic diseases, such as marasmus. It is more common in males than females, and occurs at all ages.

Symptoms may be almost lacking in portal obstruction, or the condition may simulate cirrhosis of the liver. In ordinary cases the symptoms are very slight, the hepatic circulation, as shown by Cohnheim and Litton, being "sufficient for the nourishment of the liver and secretion of the bile" (Henry).

If the occlusion be *complete*, *edema* followed by the rapid development of *ascites* may occur. In such cases loss of strength is persistent and progressive, and death may result from exhaustion. *Hemorrhages* due to venous stasis may occur from the nose, stomach, and intestines. *Jaundice* and *diarrhea* occur frequently, the former being the result of obstruction to the biliary passages from the same causes that produce the thrombosis or of the diminished pressure in the portal area. On *palpation* the liver is found slightly enlarged and tender on pressure, and projecting below the lower margin of the ribs; the *spleen* is also enlarged. *Percussion* also reveals enlargement of the splenic area. If ascites is present, percussion will reveal dulness in the flanks, changing with the position of the patient; and on gently tapping one side of the belly wall, with the hand on the opposite side, a wave of fluctuation will be felt.

The **diagnosis** of portal thrombosis is often extremely difficult. "A suggestive symptom, however, is sudden onset of the most intense engorgement of the branches of the portal system" (Osler).

"Pylethrombosis may be regarded as probable if no other possible cause of the portal obstruction seems likely, and if we are able to discover a cause for thrombosis, like a former attack of circumscribed peritonitis" (Strümpell).

Sequelæ.—If the emboli are septic in origin, an abscess, with all its accompanying symptoms, will be the result. Hemorrhagic infarction may occur, but is very rare, since a free anastomosis exists between the lobular plexuses and the hepatic artery.

The **prognosis** is always unfavorable, although certain cases have been demonstrated by autopsy to have improved temporarily.

Course and Duration.—Nothing definite can be stated in regard to the course and duration, since these depend entirely upon the cause.

Treatment.—The symptoms resulting from portal congestion, due to thrombi in the portal vein, are those described under Cirrhosis of the Liver, and the treatment is identical with that of interstitial hepatitis. Septic emboli rarely give rise to abscesses; the treatment is symptomatic. It has been recommended to take the coagulation period of the blood, and if found to be abnormally brief, citric acid should be employed.

SUPPURATIVE PYLEPHLEBITIS

Definition.—A purulent inflammation of the portal vein or its branches.

Pathology.—If noted in the early stages, the coats of the portal vein are distended and thickened, and the connective tissue surrounding the portal area is infiltrated and the seat of minute ecchymoses. The inflammation usually originates in the smaller veins of the portal system or in the hepatic branches of the vein itself; the main trunk is attacked least often. Numerous thrombi are found obstructing the vein and its branches, which finally undergo suppuration. From these, emboli enter the circulation and are carried to all parts of the liver, forming metastatic abscesses. In advanced cases the whole organ (especially the peripheral parts) becomes infiltrated with pockets of pus, that communicate with the portal vein or its branches, and extend in some instances into the mesenteric or gastric veins. A single large abscess may be present, but multiple abscesses are the rule. The contents may be very fetid and bile

stained. From this focus of suppuration metastatic embolic abscesses may occur in the lungs, brain, kidneys, and joints.

The liver may present a uniform enlargement, the surface being of normal color and the capsule non-adherent. More commonly, however, the cortex presents a mottled appearance, and numerous yellowish-white spots are seen beneath the capsule.

Etiology.—The most frequent source of purulent pylephlebitis is appendicitis with abscess. Rarely the disease arises idiopathically.

Among other causes are: (a) A secondary (becoming a general) pyemia. (b) Ulceration of the intestines, occurring in dysentery and, more rarely, in typhoid fever. (c) Gastric ulcer. (d) Pelvic abscess; abscess of the spleen. (e) Specific infection through the umbilicus, occurring in the newborn. (f) The condition is more frequent in males.

The **symptoms** vary according as to whether the case remains one of suppurative pylephlebitis or terminates in hepatic abscess. If the condition is part of a general *pyemia*, the symptoms referable to the liver may be almost negative. The *liver* is usually enlarged and tender on pressure; this enlargement is most marked when a hepatic abscess coexists. Though *pain* is present, it is not always severe; it is frequently referred to the epigastrium, and may radiate laterally or downward. *Percussion* in the left axillary line shows splenic enlargement, and the organ can in some instances be felt below the costal margin, constituting the *acute splenic tumor* of septicopyemia.

The *fever* is of septic type; the elevation in temperature is accompanied by rigors or chills and followed by profuse sweating. Polynuclear leukocytosis is present. *Jaundice* of varying intensity is present, although usually it is not pronounced, the complexion being merely doughy or muddy. *Diarrhea* is not an infrequent symptom of this condition. Nausea and vomiting are often marked. As the case advances the pulse becomes rapid and small, and delirium develops, followed by stupor, coma, and death.

Duration and Prognosis.—The duration of suppurative pylephlebitis is usually from one to four weeks. The prognosis is absolutely fatal.

The **diagnosis** of suppurative pylephlebitis is sometimes extremely difficult unless the case is complicated by hepatic abscess, as enlargement of the liver is not constant in the former condition. The etiology, septic temperature, enlargement of the spleen, jaundice, and pain in the region of the liver would all, however, point to this affection.

The *differential diagnosis* of hepatic abscess will be spoken of later. Typhoid fever and the typhoid form of ulcerative endocarditis (without murmurs), as well as malaria, must be excluded.

Treatment.—Unfortunately, the treatment of suppurative pylephlebitis can only be palliative. Surgical measures are rarely curative unless the abscess is single and localized and shows signs of pointing. The circulation is to be supported by free stimulation. The leading symptoms should be met as they arise.

STENOSIS

Obstruction of the portal vein may be due, as before mentioned, to (a) thrombosis; (b) cicatricial contraction from cirrhosis or syphilis of the liver, and (c) tumors pressing on the portal area. The first cause is the more common, chiefly because mechanical obstruction, by causing a stasis of the blood-current, induces the formation of a thrombus.

The **symptoms** of portal stenosis may be *nil*; if the stenosis occurs slowly, the hepatic artery furnishes sufficient blood to carry on the functions of the liver, and the compensatory circulation is established by means of the systemic vessels. If due to thrombosis, the symptoms of portal engorgement appear

suddenly with the development of edema and ascites. The liver is rarely enlarged.

Prognosis.—This depends wholly upon the cause of the affection. Thrombi in the portal vein often give rise to a suppurative pyelephlebitis, terminating in hepatic abscess; tumors are rarely accessible; whereas fibroid conditions of the liver causing cicatricial contraction are incurable. As a rule, the prognosis may be said to be guardedly unfavorable.

AFFECTIONS OF THE HEPATIC BLOOD-VESSELS

Osler records a case of *stenosis of the hepatic veins* that was associated with fibroid obliteration of the inferior vena cava, with a greatly enlarged and cirrhotic liver. Among other affections of the hepatic veins are: (a) Emboli, originating from a thrombus in the right auricle, and (b) dilatation, from stasis of the blood-current flowing to the right heart, due to enlargement of the latter.

Affections of the *hepatic arteries* are exceedingly rare, but may occur in one of the following forms: (a) *Aneurysm*.—Only 10 or 12 cases of aneurysm have been reported. (b) *Hypertrophy and Dilatation*.—These may occur in connection with general hepatic cirrhosis, the cicatricial bands obstructing the lumen of the artery, and causing thickening in some places, and ampullæ, or sac-like dilatations, in others. (c) *Sclerosis*.—This may form a part of a general arteriosclerosis, though it occurs oftener in connection with cirrhosis or syphilitic hepatitis.

ATROPHY AND HYPERTROPHY OF THE LIVER

(a) *Atrophy*.—Simple atrophy of the liver may result from pressure (corset-liver), syphilis, advanced cirrhosis, senility, and from the toxic action of phosphorus, arsenic, or chloroform—all factors that induce rapid fatty degeneration with cell destruction.

(b) *Hypertrophy* is of two kinds: (1) *true* and (2) *false*. (1) *True hypertrophy* may be subdivided into *simple* and *numerical*, the latter referring to an increase in the number of the parenchymatous cells, and not necessarily implying an increase in the size of the organ.

The two causes of simple hypertrophy are active and passive congestion. The principal causes of numerical hypertrophy are as follows: Leukemia, hypertrophic cirrhosis, atrophic cirrhosis (hyperplasia), syphilis, diabetes, and malaria.

(2) *Pseudo- or false hypertrophy* occurs in amyloid and fatty infiltration, carcinoma, and abscess, and consists in an increase in the tissues least concerned in the function of the organ.

HEPATIC INFILTRATIONS AND DEGENERATIONS

AMYLOID INFILTRATION

(*Waxy, Lardaceous, Bacony, or Albuminoid Infiltration; Amyloid Disease*)

Definition.—A deposit in the hepatic connective tissues of a peculiar substance, which was formerly held to resemble starch, but has recently been

shown to be related to coagulated albumin. Recklinghausen, who is also supported by other investigators, contends that at first there is hyaline change only, and that later amyloid transformation occurs. Amyloid material contains nitrogen, hence is related to the proteins.

Pathology.—The organ is increased in all of its diameters and of firmer consistence than normal. The edges are rounded, ill-defined, and the surface is of a light color, presenting at times a mottled appearance. On section the surface presents a grayish-brown, glistening appearance, which when scraped fails to exude oil-droplets, as in the fatty liver.

On microscopic examination the connective-tissue trabeculæ and the intima and media of the capillary walls (the starting points) are chiefly affected, the lumen of the latter being lessened; this decreases the blood-supply to the liver, and often directly induces fatty degeneration. The hepatic cells may be atrophied.

Etiology.—Amyloid degeneration is most probably of microbic origin. Thus animals artificially infected with bacteria have shown amyloid change in the liver, spleen, etc.

Kawkow and, later, Davidsohn injected staphylococcus cultures, Gouget injected proteus cultures, and Carriere, the tubercle bacilli, and all obtained amyloid degeneration. Tuberculous foci that remain closed off are rarely attended with amyloid change, while ulcers of the intestines, the trachea, and the larynx show it with great frequency.

Predisposing Causes.—Amyloid infiltration may occur primarily in the liver, but it is often a part of a general infiltration, affecting especially the spleen (*sago spleen*) and kidneys. It is also found in some syphilitic scars and in certain tumors and old thrombi.

It is a frequent sequel to long-standing and exhausting suppurating and cachectic affections, as necrosis of the bones, hip-joint disease, and pyelitis; "especially is this the case when they occur in a hereditary tuberculous or syphilitic constitution" (Harley). Amyloid disease may also complicate chronic malaria, leukemia, and pseudoleukemia. In children tuberculosis and rachitis not uncommonly contribute to amyloid infiltration.

Tests and Characteristics of Amyloid Material.—Iodin frequently gives a blue color upon the addition of sulphuric acid. Lugol's solution (the aqueous solution of iodine and potassium iodide) gives a brown tint to amyloid liver substance and stains ordinary hepatic tissues a yellow color. Gentian-violet gives a reddish or pinkish hue to amyloid substance, while normal tissue is stained blue.

The following is taken from Harley's *Comparative Table of Amyloid Tests*:

	STARCH.	AMYLOID.	CHOLESTERIN.
Water.	Dissolves on boiling.	Dissolves on boiling.	Unchanged.
Ether.	Insoluble.	Insoluble.	Dissolves.
Heat.	Dries up.	Dries up.	Melts.
Sulphuric acid.	Chars.	Swells up, reddish brown.	Becomes green, blue, etc.
Iodin.	Becomes blue.	Blue color with H_2SO_4 , which is destroyed by excess.	Remains unchanged.
Sulphate of indigo.	Amyloid tissue soaked in it becomes a brilliant blue, while with ordinary liver tissues the blue fades to a pale green.	

Symptoms.—When amyloid disease occurs in *children* the subjects are poorly developed and puny, the complexion is, as a rule, muddy or sallow, and the abdomen usually prominent. Occasionally the *skin* is exceedingly transparent. At any age *gastro-intestinal symptoms* occur, prominent among which are marked constipation and a capricious appetite. *Mental phenomena*, as impairment of memory and inability to concentrate, are not unusual in this disease. *Pain* about the hepatic region is a rare symptom. The *spleen* is usually enlarged from coexistent amyloid infiltration. The *urine* often contains albumin (globulin is nearly always present), renal epithelium, and waxy tube-casts; it is of somewhat lowered specific gravity, but may be scanty and dark colored. Diarrhea, with slimy dejecta, is commonly present. The *physical signs* show an increase in the area of hepatic dullness; the edges of the organ extend below the costal margin and have a rounded outline. Sometimes, however, the edge, even in a very great enlargement, is sharp. Wilks speaks of an amyloid liver weighing 14 pounds—6.35 kgms. (Osler). In rare instances the liver is reduced in size.

Diagnosis.—The foregoing symptoms and physical signs, in conjunction with an ordinarily clear etiology (syphilis, tuberculosis, or other primary process in some other part of the body) and amyloid degeneration elsewhere, are sufficient to establish the diagnosis.

Treatment.—As amyloid disease is almost invariably a secondary condition, the treatment must be directed to the removal of the primary cause, whether syphilis, tuberculosis, or rickets. It has been shown recently that amyloid degeneration may disappear if the primary cause can be removed. The *diet* should consist of nitrogenous or animal substances, with a minimum amount of fat. French rolls and bran or gluten bread are allowable, together with lean meat, wholesome cereals, and green vegetables. Stimulants are to be strictly avoided. Moderate exercise, with the judicious use of Turkish (hot-air) and Russian (hot-vapor) baths, is also of great value.

Many drugs are mentioned in the treatment of this disease, among the more important being the ammonium salts (the chlorid, gr. v to x—0.3–0.6—three or four times a day) and other alkalies.

When syphilis has been clearly established as an etiologic factor of the disease, the tincture of iodine in 10- to 15-minim (0.6–1.0) doses, well diluted, has been recommended to be given three or four times daily. Cod-liver oil as a nutritive, if tuberculosis be associated, has been tried with good effect. Of tonics, the dilute mineral acids, given in moderate doses, have probably achieved the best results.

FATTY LIVER

The term “fatty liver” embraces (a) *fatty infiltration*, or a deposit of fat in the otherwise normal hepatic tissues, and (b) *fatty degeneration*, in which a conversion of the albuminates of the cells into fat occurs. It should be recollected, however, that the latter condition is invariably preceded and accompanied by the former, so that most instances of fatty liver partake of the nature of both processes.

FATTY INFILTRATION

Pathology.—The infiltration occurs often in localized areas, and may be so intense that the organ when cut presents a shiny, oily appearance. The liver is often evenly enlarged, and may weigh 12 to 15 pounds. The edges are rounded and the substance less firm than normally. Portions of the liver substance float in water. The color is light yellow or grayish. Microscopically, the protoplasm of the cell is seen to be pushed to one side by the

fat droplets, which tend to coalesce. Fatty infiltration may end in fatty degeneration.

Etiology.—(a) Fatty infiltration may form part of a general obesity or it may follow gastro-intestinal disorders even in childhood. (b) It often occurs in wasting diseases, as carcinoma, syphilis, chronic malaria, and tuberculosis.

Symptoms.—The subjective symptoms of fatty infiltration may be entirely wanting, since the function of the liver is not impaired to any extent. When they are present progressive *anemia* and *debility* are noted, and are accompanied by *nervous irritability* and *insomnia*. In marked cases the cardiac rhythm is disturbed, causing a *feeble* and *irregular impulse*.

The *physical signs* are well defined, and the area of hepatic dulness is uniformly increased, extending in some instances as low as the umbilicus. The enlargement, however, is not so great as in amyloid disease.

Differential Diagnosis.—Fatty infiltration of the liver is not apt to be mistaken for any other affection of this organ. The occurrence of general obesity, together with an entire absence of symptoms of obstruction to the portal vessels or bile-ducts or of other evidences of *fatty degeneration* (particularly feeble heart-sounds), will help to distinguish it from this latter condition. The etiologic factors above mentioned will also aid in the differentiation.

Prognosis.—This is decidedly favorable, as the function of the liver in many instances is not impaired in the slightest degree.

Treatment.—As the disease is of gradual development and long duration, a modification of the *diet* constitutes the first essential of the treatment. That prescribed under the Treatment of Amyloid Liver is admirably suited to this affection. Saccharine and farinaceous articles of food (potatoes, oatmeal, and sweetmeats) must be eschewed. Wheat bread must be partaken of sparingly, and in its place gluten and bran bread or crusts of French rolls should be used. Fish, lean meats, fresh vegetables, and fruits are also allowable. Alcoholic beverages must be interdicted. When fatty liver develops in tuberculous subjects the ingestion of fats and carbohydrates should be restricted.

Graduated daily exercise to stimulate metabolism and Turkish or Russian baths, judiciously used, are important factors in the treatment. Medicinally, the salts of the alkalies are highly recommended: sodium sulphate (in dram—4.0—doses, taken on an empty stomach) and ammonium carbonate (gr. xv to xxx—1.0–2.0—in twenty-four hours).

FATTY DEGENERATION OF THE LIVER

Pathology.—On examining a liver that is the seat of marked fatty degeneration the organ is found smaller than normally, and the substance is light yellow in color, soft, pliable, and easily torn. On section the relation between the interlobular connective tissue and the acini is lost, the latter being replaced by fat-cells and oil-droplets. Scattered areas of pigmentation may be observed throughout the organ.

Microscopically, the cells lose their shape and become globular; the nuclei tend to coalesce, and finally disappear, together with the cell wall, giving rise to compound globule-cells, which do not tend to coalesce and are stained black by osmic acid. Crystals, granular debris, Lener's spheres, cholesterin, tyrosin, and phosphatic crystals are also found in this form of granular change. His-

tologic differences are recognized at the present day between this disease and acute yellow atrophy.

Etiology.—The following are among the recognized causes of the affection: (a) The excessive use of beer or alcoholic liquors. (b) It may be a sequence of amyloid disease. (c) Diminution of the oxygen supply to the tissues, occurring in phosphorus-, chloroform-, or arsenic-poisoning, and in certain wasting diseases (carcinoma, phthisis, and chronic dysentery). (d) It may occur as a complication in the grave anemias, especially pernicious anemia, in acute infectious diseases, and the intoxications, as well as in pregnancy.

Symptoms.—I feel convinced that partial or *mild cases* of fatty degeneration of the liver present no morbid symptoms of diagnostic import. Pain, jaundice, and ascites may occur separately or conjointly, but form the exception rather than the rule. The *severe forms* are characterized by the symptoms seen in phosphorus-poisoning and acute yellow atrophy, to the discussion of which the reader is referred.

Complications.—The disease may be complicated with fatty change in the *kidneys*. Under these circumstances the *urine* is diminished in amount, of low specific gravity, and contains an abundance of albumin, fatty or oily casts, and crystals of cholesterin, leucin, and tyrosin. In marked cases there is a very feeble and *irregular cardiac impulse*, accompanied by attacks of *vertigo* and *syncope*, the latter symptoms indicating beginning degeneration of the cardiac muscle. *Edema* of the lower extremities and *anasarca* may occur as complications of this condition.

The **physical signs** elicited by *palpation* and *percussion* show increasing diminution in the size of the liver as the disease advances.

Diagnosis.—The chief diagnostic points of fatty degeneration may be summated thus: (a) A history of alcoholism, of poisoning by drugs (arsenic, phosphorus, or chloroform), or of an acute infectious disease (acute yellow atrophy); (b) grave general symptoms, as albuminuria, edema, ascites, cardiac failure, terminating often in acholia or cholemia; (c) progressive diminution in the size of the organ. When these occur conjointly the diagnosis is established beyond a doubt.

The **prognosis** is entirely dependent upon the curability of the cause. If due to an excessive use of stimulants, the process, if recognized early, may be arrested; if associated with an acute infectious disease, the outlook is unpromising.

Treatment.—The indications for treatment may be divided into the *dietetic*, *hygienic*, and *medicinal*. The same precautions regarding diet should be observed as in fatty infiltration. An open-air existence, short of injurious exposure, aided by hot salt-water, Turkish, or Russian baths, under restriction, is sure to improve the general condition of the patient.

The *medicinal* treatment varies according to the cause of the disease. If due to grave anemia, iron (tinct. ferri chlorid. or syrup. ferri iodid.) may be given in ascending doses. Poisoning by drugs that produce fatty degeneration of the liver is to be combated by their respective antidotes. Gastro-intestinal disturbances, if coexistent, demand appropriate treatment. For the latter Frerichs recommends highly the salts of the alkalies (sodium sulphate in dram—4.0—doses taken on an empty stomach and ammonium carbonate). Ascites and cardiac asthenia, when occurring as complications, must be met by suitable measures.

PERIHEPATITIS

ACUTE PERIHEPATITIS

(Pyopneumothorax Subphrenicus)

Definition.—An inflammation, either suppurative or fibrinous, of the peritoneal covering of the liver and the corresponding portion of the diaphragm.

Pathology.—The morbid changes may consist in a purely plastic inflammation, the serous layers being thickened, opaque, and covered with a fibrinous exudate leading to adhesion. In the majority of cases, however, the inflammatory product is chiefly purulent, and is ribboned by fibrous bands so as to form circumscribed areas, filled with pus, lying between the liver and the diaphragm; this constitutes the *subphrenic abscess*. The latter is found more commonly to the right than to the left of the suspensory ligament. It may contain much pus (1 quart—1 liter—or even more), which in most cases is mixed with air or gas derived from the gastro-intestinal canal. Rarely, bilirubin crystals are found, betraying the presence of bile. If the latter be present in large amount, the pus assumes an ochre-yellow hue.

Etiology.—The *fibrinous variety* may result from the direct extension of one or other of the acute forms of inflammation of the liver (abscess, hydatid cyst), from a pleurisy spreading along the lymphatics in the diaphragm, or from traumatism—particularly a blow. The *suppurative form* (*pyopneumothorax subphrenicus*, Leyden) may be caused in the same manner as the former but far oftener—in more than one-half of the instances—it follows perforation of a gastric ulcer, and far less commonly perforation of a duodenal or colonic ulcer. Appendicitis and penetrating wounds are not infrequent causes. Perihepatitis is a grave complicating event in carcinoma (of the stomach, esophagus, and intestines), in lobar pneumonia, and purulent pleuritis.

Symptoms.—Those of the *acute fibrinous variety* are either altogether missing or too vague to admit of correct interpretation. The co-appearance, however, of severe *pain*, increased on deep breathing, and *tenderness* over a circumscribed area either in the right hypochondrium or the epigastrium, after the action of some known cause or the occurrence of one of the causative affections, is suggestive of this form of the complaint. A *friction sound* may at times be heard below the seventh rib in the mammillary or over the epigastrium, as in 2 of my cases. It is of short duration, and is limited usually to the end of inspiration. Plastic pleurisy may, however, be associated.

In *suppurative perihepatitis* the symptoms are sometimes screened by those of the special causative complaint; but in my experience, in cases due to perforation, the *onset* is rapid and severe and is marked by *acute pain* referred to a circumscribed spot in the hepatic region, great *tenderness*, rapid, embarrassed, and *painful respiration* (owing to implication of the diaphragm), by *vomiting* (often bilious, though at times hemorrhagic) or *nausea*, and by faint *jaundice* in some cases. Shortly the *general features* of circumscribed peritoneal abscess also appear—rigors, irregular fever, sweats, and progressive prostration and emaciation.

Physical Signs.—*Inspection* discloses bulging of the right hypochondrium and often of the epigastrium. The same regions are immobile, but this is best appreciated by *palpation*. Palpable friction may at times be obtained. The anterior edge of the liver is felt even as low as the umbilical level. *Per-cussion* reveals a variable increase of hepatic dullness upward, sometimes touching the fourth rib. The upper level of the fluid is movable on change of posture, and this is particularly striking if gas be contained in the abscess; the presence of the latter also causes a zone of tympanitic resonance above the dull area, while overlying the latter there is the semitympanitic area of the

retracted lung. *Auscultation* reveals a *friction-sound* and an absence of breath sounds and of the vocal resonance over the dull and tympanitic areas, while the respiratory sounds over the displaced lung are bronchovesicular.

Differential Diagnosis.—Acute perihepatitis often remains unrecognized during life. It may be confounded with *empyema* of the right side, but the two conditions have different modes of development. Perihepatitis is preceded and accompanied by abdominal symptoms; empyema manifests thoracic symptoms—*e. g.*, cough and pleuritic pain. At a later stage the exaggerated respiratory murmur above the dull area, the slighter cardiac displacement toward the left, and the greater hepatic displacement downward in suppurative perihepatitis aid in the differentiation. The introduction of the trocar in the seventh or eighth intercostal space in the midaxillary line may also be helpful, especially if the exudate be found to contain bile-pigment. *Pfuhl's sign*—the more ready escape of the fluid during inspiration on aspiration of abscesses below the diaphragm—may not be without value. The points narrated above may likewise serve to separate pyopneumothorax from suppurative perihepatitis (see also Pneumothorax, p. 569). To differentiate from *acute plastic pleurisy*, Cantlie's sign, or grasping the liver between the hands and moving it backward and forward, thus causing pain running up into the supraclavicular fossa, may be employed.

Course and Prognosis.—In the milder or fibrinous variety the outlook is favorable and the course is brief. On the other hand, the suppurative type due to perforation, if not early brought under proper surgical treatment, often terminates unfavorably by gradual asthenia. Rarely the pus is resorbed, or it may find an outlet through the lungs, abdominal walls, or other avenue, followed by slow recovery.

The **treatment** is the same as for localized peritonitis. The first evidence of the presence of pus is the signal for surgical interference—evacuation and drainage, and Wakar¹ favors the transpleural method.

CHRONIC PERIHEPATITIS

(*Zuckergussleber*)

This affection is chronic inflammation of the perihepatic fibrous membrane, which becomes opaque and thickened. Contraction of this capsule ensues, with compression of the liver and atrophy to one-half the size of the normal organ (as in a case reported by Rumpf), and partial or total occlusion of the vessel and bile-ducts. These changes are most marked in cases that follow acute suppurative perihepatitis. Genuine instances show no hyperplasia of the interstitial connective tissue; hence the condition is closely related pathologically to "glissonian cirrhosis."

The main **causes** of chronic perihepatitis are great and protracted local pressure, as from a corset, and certain occupations. It may represent a portion of a more general chronic inflammation of the serosæ. I believe that syphilis is the leading single cause, and could discover no other factor present in 2 cases that yielded to antisiphilitic treatment. A circumscribed form (benign) may occur from local pressure.

The **diagnosis** is generally problematic. Of especial clinical worth are the etiology, pain in the right hypochondriac region—particularly in cases due to syphilis—absence of the signs of stasis of the gastro-intestinal tract, and the very protracted course.

The **treatment** is purely palliative, apart from the effort to remove the special cause, whether this be syphilis, occupation, or other influential factor.

¹ *Deutsch. Zeit. f. Chir.*, January, 1912.

ABSCESS OF THE LIVER

(Hepatic Abscess; Suppurative Hepatitis)

Definition.—A circumscribed collection of pus in the hepatic parenchyma.

Pathology.—If examined *in situ*, a liver that is the seat of abscess formation is usually found to be symmetrically enlarged, and on careful palpation one or more areas of fluctuation (either deep or superficial, according to the location of the abscess) may be detected. If single, its position is usually in the right lobe near the convexity of the organ (70 per cent. of cases). The tissue surrounding the abscess wall is usually deeply injected, the wall itself in acute cases being poorly defined, but grayish in color, irregular and shreddy, and composed of necrotic liver-cells, pus-corpuscles, and often amebæ. In chronic cases it becomes greatly thickened and often cartilaginous in appearance.

The amount of fluid contained in a liver abscess may exceed 2 or 3 quarts (2–3 liters), and its color varies from grayish white to a creamy, reddish brown. The collection in some instances resembles healthy pus. I have spoken of the methods of infection and of some of the different varieties of hepatic abscess in the discussion of Dysentery (see p. 67).

Various odors are described, depending largely on the extent of bacterial invasion and the degree of necrosis. Here it may be said that in amebic dysentery hepatic abscess is often single (involving more often the right lobe), whereas, in general pyemia, multiple abscesses are the rule. Multiple tropical abscess, however, is not uncommon and is indistinguishable from those that are met in temperate climates as the result of infection *via* the portal vein.

In these instances the surface of the organ presents many small yellow areas beneath the capsule, varying from 5 to 15 mm. ($\frac{1}{2}$ – $\frac{3}{8}$ inches) in diameter. Usually in such cases, too, the appearances of a suppurative pylephlebitis present themselves. If thrombi have formed in the portal tributaries, localized necrotic areas are the result, but more often the invasion affects the whole portal system, the liver being riddled with abscesses. If the abscess is secondary to obstruction by gall-stones or inspissated bile, the ducts and the gall-bladder are greatly distended, their walls and immediate vicinity infiltrated with round cells, leading to suppurative pericholangitis and invasion of the hepatic parenchyma.

Microscopically, the hepatic cells are altered in shape and devoid of nuclei; they undergo rapid degeneration. A round-celled infiltration occurs about the blood-vessels, their walls being filled with small emboli containing innumerable staphylococci and streptococci. As the suppurative process continues, liquefaction-necrosis occurs, resulting in complete destruction of the hepatic parenchyma.

Etiology.—Idiopathic abscess of the liver is rare even in tropical climates. The affection, when apparently excited by mechanical causes, as traumatism or obstruction by gall-stones, is invariably a micro-organismal affection, and the principal germs are streptococci, staphylococci, and the *Amæba histolytica*. Elliott¹ believes the latter to be the primal cause in at least 80 per cent of the cases.

Gastric ulcers, typhoid fever, or appendicitis may be followed by a purulent portal pylephlebitis, resulting in abscess formation. On analyzing 500 cases of suppurative hepatitis Kelsch found that in 85 cases in 100 the disease was associated with dysentery. Manson records a total of 3680 autopsies made on dysenteric patients in tropical countries, and of these, 21 per cent. showed abscess of the liver. Among Europeans in tropical climates the general aver-

¹ *Southern Med. Jour.*, Birmingham, Ala., December, 1915.

age is 12 per cent. In general pyemic processes or in bone suppurations of long standing infection of the liver occurs. Suppurating wounds of the head may be followed by abscess of the liver. Among other causes may be mentioned *foreign bodies* traveling up the ducts, as parasites, round-worms, liver-flukes; also, more rarely, suppuerperforation by mechanical irritants (needles, pins, fish-bones, and the like), and suppuration occurring in the course of a hydatid cyst. Leick has tabulated 19 cases of hepatic abscess caused by the *Ascaris lumbricoides*. Among other factors are: Age (adult life), male sex, alcoholism, and malaria.

The *manner of infection* is variable; it may be (a) through the portal vein (most commonly); (b) through the bile-ducts, and (c) the metastasis may take place through the blood (hepatic artery). (d) Exceptionally infection may occur *via* the lymph-channels.

Symptoms of Solitary Abscess.—In a typical case of hepatic abscess the most prominent symptoms are: *hectic temperature, pain, tenderness, and enlargement of the organ*, and often *slight jaundice*, although it must not be forgotten that any or all of these may be absent during its development. The multiple abscesses occurring in pyemic conditions, which are frequently diagnosed when in view upon the postmortem table, form an instance of this. The present description, however, has reference chiefly to the large, solitary abscess.

To facilitate the subject I shall consider the more important symptoms *seriatim*: *Pain* is circumscribed to the hepatic region, and radiates to the right shoulder in conjunction with the other symptoms and physical signs; it is very characteristic, although not pathognomonic of hepatic abscess. In the earlier stages this symptom is not pronounced unless the abscess or abscesses lie superficially. It is usually of a dull, boring character, differing in severity with the patient's position; it is usually aggravated by pressure over the costal margin and by lying on the left side, this tending to drag the liver by its own weight from its normal position. Luschka explains the radiation of pain to the right shoulder by stating that filaments of the phrenic nerves that distribute themselves in the suspensory ligament and Glisson's capsule are irritated. The phrenic arises from the third, fourth, and fifth cervical nerves, and as the fourth supplies sensation to the right shoulder, the impression is thus transmitted through the central nervous system.

In acute cases accompanied by rapid destruction of the hepatic tissues the *temperature* usually rises rapidly, reaching 103° or 104° F. (39.4°–40° C.) in the course of from twenty-four to thirty-six hours. Its course, however, is irregular and intermittent, and it may be hectic in character; just as often it resembles a tertian or quartan intermittent or a remittent malarial fever. *Rigors* or *decided chills* frequently accompany the rise of temperature, and during the decline profuse sweatings may take place. In chronic abscess of the liver pyrexia may be entirely absent. Less commonly the temperature may remain continuously high, with slight morning remissions. The *pulse* is usually rapid in proportion to the temperature.

The **physical signs** in a case of hepatic abscess are always present to a greater or less degree, and are often pathognomonic.

Inspection may reveal nothing during the entire course of the disease, although if there be intense congestion involving the anterior surface of the right lobe, bulging of the ribs on that side will occur, with a marked prominence in the hypochondriac region extending three or more fingerbreadths below the costal margin.

Palpation confirms inspection and reveals tenderness on pressure below the costal margin in the mammary line. The liver, if projecting below the edge of the ribs, is usually enlarged uniformly unless the abscess involves the sur-

face of the margin. As the upper right lobe is more often involved, the increase in diameter is upward, thus rendering palpation negative. In rare instances the abscess gives rise to fluctuation on palpation, and a friction fremitus if the peritoneum be inflamed.

Percussion.—The area of hepatic dulness may be increased uniformly, but it is usually most marked upward and to the right (fifth rib), and posteriorly to the level of the angle of the scapula. This high position of the upper boundary of dulness which starts about the nipple-line serves to differentiate abscess from other affections of the liver, in which the enlargement extends in a downward direction.

Other Symptoms.—The skin is pale and shows slight icterus, the *conjunctivæ* being often bile stained; intense *jaundice*, however, is rare. Progressive loss of flesh and strength, with *gastro-intestinal disturbance* (fulness in the epigastrium, flatulence, water-brash, nausea, and occasional vomiting), are common symptoms at the onset. The *bowels* are variable, and constipation usually alternates with diarrhea, the stools in some cases containing the *Amæba coli*. *Ascites* may develop from pressure on the inferior vena cavæ, but such cases are rare. The *spleen* may undergo active hyperplasia in acute abscess formation. *Pulmonary symptoms* (severe cough, characteristic reddish-brown sputum, resembling anchovy sauce, bronchovesicular breathing, râles) are commonly present; they are due to compression of the base of the lung by the abscess pressing upon the diaphragm. In fatal cases certain *nervous symptoms* (muttering delirium, cephalalgia, subsultus tendinum, stupor, coma) make their appearance. A marked *leukocytosis* is generally present.

Complications and Sequelæ.—The abscess may perforate into the pleural cavity (pyothorax), bronchi, lungs, intestinal tract, stomach, pericardium, peritoneal cavity, or externally through the abdominal wall, giving rise to various symptoms. If rupture occurs into the intestinal tract, sudden diarrhea, with the discharge of large quantities of pus, takes place. If the rupture is into the lung, the physical signs will reveal the sudden development of weak, tubular breathing over the base, with increased tactile fremitus and percussion dulness, together with the occurrence of profuse and typical expectoration. Reese, Lafleur, and Boston found the *Amæba coli* in the bronchial discharge. Rupture into the abdominal cavity gives rise to the development of a fatal peritonitis. Cerebral abscess may occur.

Diagnosis.—The clinical symptoms of hepatic abscess are of diagnostic importance only when taken in the aggregate, since the pain, fever, enlargement, and even hectic symptoms occur singly in other conditions unaccompanied by suppuration. The principal points in the establishment of the diagnosis of the affection may be summed up as follows: Residence in tropical countries, the previous existence of typhoid or dysenteric ulceration (or other gastro-intestinal inflammation), the characteristic expectoration, enlargement of the liver, with pain and tenderness on pressure, and in some instances fluctuation on palpation. Pain in the liver, often radiating to the shoulder if the patient be shaken, is a certain sign (Malbot). Roentgenography shows the right leaflet of the diaphragm to be displaced upward and unaffected by respiration. Lastly, exploratory aspiration with a medium-sized needle is to be resorted to in dubious cases; it may reveal pus-corpuscles, hepatic cells, staphylococci and streptococci, the amebæ, and bile-pigment, which when found are pathognomonic; if the abscess be secondary to an echinococcus cyst, the presence of hooklets will be detected. The patient should be anesthetized, since the puncture may have to be repeated.

Differential Diagnosis.—Hepatic abscess may be misdiagnosed for *emphyema*, *suppurative pylephlebitis*, *malarial fever*, and *hepatic calculi*.

In *empyema* there may be the history of a perforating wound of the chest, the rupture of a bronchiectatic or tuberculous cavity, or the pre-existence of a serofibrinous pleurisy; whereas hepatic abscess may be preceded by an attack of amebic dysentery, intestinal ulceration from other forms of infection, impacted gall-stones, traumatism, or a pyemic process. In both there may be the occurrence of hectic temperature, with chills and sweating; but in *empyema* cough and dyspnea are prominent, and, if the pleural cavity communicates with a bronchus, profuse mucopurulent expectoration containing pus-cells, staphylococci, streptococci, and tubercle bacilli may be observed. Rarely an abscess of the liver penetrates the diaphragm and is expectorated. The recognition of hepatic abscess under these circumstances is to be based mainly upon clear previous evidence of the affection, and copious, blood-tinted, purulent expectoration. The detection of the *Amœba coli* in the sputum alone would set the diagnosis at rest. The contents of hepatic abscess obtained by aspiration consist of the micro-organisms of suppuration, broken-down liver-cells, bile-pigment, and in some cases the *Amœba coli*. Inspection in *empyema* reveals bulging of the intercostal spaces on the side implicated, and there is movable percussion flatness over the base of the chest, rising posteriorly. On the other hand, in abscess of the liver, the lung is slightly displaced upward, being often bound to the diaphragm by adhesions; and the upper boundary of dulness is lower, particularly in front, and is immovable.

Suppurative Pylephlebitis.—In hepatic abscess there are present certain physical signs (swelling, fluctuation), and a history of amebic dysentery rather than of appendicitis, as in suppurative pylephlebitis.

HEPATIC ABSCESS

History of traumatism, dysentery, intestinal ulceration, or residence in tropical countries.

Hectic character of the temperature—high every evening and low every morning; irregular chills, followed by fevers and sweatings.

An irregular, fluctuating tumor or multiple nodules in the liver; no splenic enlargement; rapid emaciation, with or without jaundice, but no cachexia.

Blood shows simple anemia and leukocytosis, and in marked cases disintegration of red blood-cells.

Abscess contents show the staphylococci, streptococci, amebæ, or *Bacillus coli communis*, and pus.

Quinin is resisted.

MALARIA

History of previous attacks. Residence in warm, damp climates among the lowlands.

Regularly recurrent rise of the temperature (intermittent or remittent, quotidian, tertian, quartan, or septinarian), followed by profuse sweating; chills more often in morning.

The spleen is enlarged; also there is a yellowish-brown coloration of the skin, more or less marked; and, in long-standing cases, the occurrence of *cachexia*.

The presence of the hematozoa of Laveran and free pigment in the blood; usually a leukopenia.

Absent.

Quinin acts as a specific.

Impacted Calculi.—In this condition attacks of *hepatic colic* are often first noticed, followed by jaundice, and, if impaction be not absolute, by the occurrence of stones in the feces. In abscess the pain is not paroxysmal, but dull and boring in character, increasing in severity as the disease progresses. In *chronic impaction*, jaundice, dull pain over the hepatic area, distention of the gall-bladder (which in some instances may be palpated), and clay-colored feces constitute the principal symptoms. There occurs also an intermittent fever as in hepatic abscess, but it is occasional—*i. e.*, the febrile paroxysms recur at longer intervals. Again, the course of intermittent hepatic fever associated with biliary calculi is much more chronic than the fever-stage of suppurative hepatitis. On the other hand, in abscess of the liver jaundice

is comparatively rare, and, unless the abscess rupture into the gastro-intestinal tract, the stools show nothing abnormal. In some instances biliary abscesses may follow impacted calculi, and it is always a secondary affection.

Among the other liver conditions that are liable to be mistaken for hepatic abscess may be mentioned *carcinoma*, *hypertrophic cirrhosis*, *hydatid cyst*, and *pancreatic cyst*, the differential diagnosis of which will be spoken of under these diseases.

The **prognosis** of hepatic abscess is unfavorable, the disease generally progressing to a rapidly fatal termination. Prompt evacuation of the abscess when its location can be detected, however, may be successfully performed. The mortality ranges from 50 to 60 per cent. In rare cases the walls of the abscess become calcified and the disease remains latent. The single large abscess that most often follows dysentery offers the best opportunity for surgical measures.

Treatment.—Barring operation, the treatment of abscess of the liver is purely symptomatic. The temperature often responds to repeated spongings with cool water (65° F.—18.3° C.). For pain, mustard-poultices, the turpentine stupe, or hot fomentations over the hepatic area, in conjunction with full internal doses of opium, prove beneficial. Full and free stimulation and the free exhibition of quinin as soon as the condition is detected proves supportive and controls, in a measure, the pyemic process. L. Rodgers holds that 90 per cent. of amebic abscesses of the liver can be prevented by large doses of ipecac (gr. xxx to lx—2.0–4.0—daily, in freshly made pills). If the abscess be single and localized, prompt evacuation should be resorted to. Emetin should be used as a regular postoperative measure (Elliott). Patients who have been thus cured should not return to a climate in which tropical dysentery occurs, since, as in a case reported by Marshall, recurrence may take place.

ACUTE YELLOW ATROPHY

(*Malignant Jaundice; Icterus Gravis*)

Definition.—An acute and probably infectious disease (rare), characterized by a rapid destruction of the parenchyma of the liver and by a diminution in the size of the organ; also by jaundice, hemorrhage, and grave cerebral phenomena.

Pathology.—*Macroscopically*, in a case of acute yellow atrophy the liver is seen to be much reduced in size, weighing but 15 or 20 ounces (450.0–600.0), instead of its normal weight (50 oz.—1.6 kgms.). The capsule is shriveled and the organ is of a pulpy consistence, and changed in appearance from a mahogany-brown to a grayish-yellow hue. Sometimes the liver is primarily enlarged. The cut section often presents areas of red and yellow discoloration, the so-called “red atrophy” and “yellow atrophy,” the former being a later stage of the latter. The red appearance is due to an excess of blood in the capillaries, with free pigment that has been liberated by destruction of the red blood-cells. *Microscopic examination* reveals destruction or necrosis of the hepatic cells, the primary change being a “necrosis of the terminal hepatic veins” (Fraser). The nuclei have disappeared, and the cell wall contains a number of fat-globules of various sizes containing free pigment. In advanced cases, accompanied by total disintegration of the cells, fat-droplets, granular debris, cholesterin plates, leucin spheres, tyrosin needles (first discovered by Frerichs, both in the cells and in the blood-vessels), and crystals of bilirubin

may be found. Findlay¹ found the fibrous tissue to be increased and in the periphery of the lobules attempts at regeneration (proliferation of the hepatic cells). The common duct is patulous.

In well-marked cases both the *heart* and *kidneys* show evidences of fatty degeneration. The *spleen* is greatly enlarged from active congestion, giving rise to the so-called "acute splenic tumor." The splenic substance is soft and easily torn. The *skin* and *mucous membranes* may be the seat of numerous ecchymoses, and dropsy of the serous cavities is frequently noted. The *blood* is dark and fluid (disintegrated).

Etiology.—The causes of acute yellow atrophy are both primary and secondary. *Primary* or idiopathic acute yellow atrophy is rare and its etiology as yet unsettled. Among the *secondary* predisposing causes are age (being most common from fifteen to thirty-five years), female sex, mental worry, nervous shock, syphilis, chloroform anesthesia, trauma, and certain acute fevers (puerperal fever, typhoid, septicemia, malaria). The influence of pregnancy is noteworthy (30 per cent. of all cases). Acute phosphorus-poisoning sometimes presents changes resembling those of acute yellow atrophy. The disease rarely accompanies cirrhosis of the liver and may follow a debauch. Rarely an endemic form is assumed, but the exciting cause is thus far unknown. The disease is probably micro-organismal or toxic in nature, and although various germs have been discovered, their claim to specificity has not been established.

Symptoms.—The clinical history of acute yellow atrophy varies considerably in the early stages of the disease, the graver symptoms of the later stage alone being pathognomonic. The attack is usually ushered in by *headache*, *malaise*, *anorexia*, *nausea*, and *vomiting*, moderate *fever*, and after a few days *jaundice* appears. *Physical examination* at this time shows the area of hepatic dulness to be normal or only slightly increased. After a period varying from a few days to two or three weeks (during which the typical features of catarrhal jaundice have been present) grave *nervous* and *cerebral* symptoms present themselves, as restlessness and violent headache, followed by delirium, which often becomes maniacal. *Convulsions* then appear, and are succeeded by stupor and coma, the latter occurring usually within forty-eight hours from the onset of the period of cerebral excitement. Often *coarse tremors* are noticed in the voluntary muscles, and with the onset of the second stage the jaundice usually deepens.

The *temperature* often remains normal until just before death, when it may rise 1 or 2 degrees. The *pulse* is much diminished both in volume and tension, and is rapid in proportion to the temperature. The *tongue* at the onset is covered with a light coating, most marked on the dorsum and tip. Later it changes to a thick yellow color and becomes dry and fissured, with the development of a typhoid state. Vomiting appears usually during the premonitory stage and often becomes intense; the *vomit* consists at first simply of the gastric contents, which later in the disease becomes mixed with blood (hematemesis). *Hemorrhages* also occur into the skin (ecchymoses) and from the mucous membranes, giving rise to epistaxis, hematuria, melena, hemoptysis, and menorrhagia. *Constipation* with clay-colored stools is common.

The *urine* in acute yellow atrophy is often scanty in amount, high colored, and shows an increase in specific gravity (1028 to 1032). The urea is greatly diminished, but bile-pigments and albumin, tube-casts, *leucin* and *tyrosin* are found both on chemical and microscopic examination. The latter can be easily demonstrated by allowing a drop of the urine to evaporate on a cover-glass and examining under the microscope. Tyrosin crystals are deposited

¹ *Brit. Med. Jour.*, June 2, 1900.

in the form of sheaves and rosettes, leucin as globular masses. These bodies are not constantly present. Thus, out of 34 cases collected by Thierfelder, in which the urine was examined in this relation, "in 7 the result was negative; in 17 both were found; in 3 tyrosin only; in 7 leucin only." Among other products found in the urine worthy of mention are creatinin, lactic and sarcolactic acids, and other bodies belonging to the fatty acid series.

The **physical signs** reveal tenderness over the hepatic region, often amounting to actual pain. During the second stage, in extreme cases, the edges of the organ cannot be palpated under the costal margin. Percussion, moreover, shows a great diminution in the size of the liver, the area of dulness in a case recorded by Harley extending over but 1 inch (2.5 cm.) in the mammary line and $1\frac{1}{4}$ inches (3.1 cm.), measured perpendicularly, in the midaxillary line.

The left lobe is often the first to show physical signs of atrophy, percussion giving tympany instead of flatness in the upper epigastric region. As the atrophy continues the tympany extends below the seventh rib from above and advances upward from the costal margin, leaving but a small circumscribed area of hepatic dulness. The atrophy is usually progressive until death occurs, although favorable cases have been recorded in which the liver increased in size perceptibly during recovery.

Diagnosis.—The symptoms occurring during the second stage of the disease are usually so characteristic as to leave little doubt concerning the diagnosis. The occurrence of gradually increasing jaundice with vomiting, grave delirium, hemorrhages, the presence of an immense amount of bile, with leucin and tyrosin, in the urine, and greatly diminished size of the liver, all combine to form a typical symptom-complex. Unfortunately, leucin and tyrosin are also found in the urine in acute phosphorus-poisoning and rarely in severe acute infections.

Differential Diagnosis.—*Catarrhal jaundice* may be confused with the early stages, but a small, tender liver and pregnancy, together with careful studies of the urine (acid intoxication), should awaken strong suspicion. In *hypertrophic cirrhosis* the onset is gradual. There is generally a negative history; and an examination of the urine fails to reveal leucin and tyrosin; fever is rarely present in cirrhosis, and there is a considerable increase in the area of hepatic dulness.

The differential diagnosis between this disease and phosphorus-poisoning is given under the latter condition (*vide infra*, p. 868).

The **prognosis** is almost invariably fatal, since every case of true yellow atrophy is associated with a destruction of liver cells that is accompanied by acute toxemia.

Treatment.—As yet no specific treatment has been discovered, all remedies used being directed to the relief of symptomatic indications. The gastro-intestinal system should be relieved at the onset by divided doses of calomel. For the vomiting, cracked ice, with 1-minim (0.065) doses of the wine of ipecac repeated every half-hour, or divided doses of opium, may be given. Marked nervous phenomena with delirium I have seen controlled by cool baths and the ice-cap, together with camphor, chloral, or other antispasmodics used internally. The pregnant woman who develops acid intoxication and jaundice demands appropriate treatment for these conditions. Free stimulation should be begun early and persisted in throughout the course of the disease.

THE LIVER IN PHOSPHORUS-POISONING

Following the ingestion of a dose of phosphorus varying from gr. $\frac{1}{8}$ to gr. 1 (0.0008–0.065) symptoms of poisoning manifest themselves (Taylor, Wormley) as follows:

After a period of time varying from three to twelve hours a sense of wretchedness, nausea, abdominal pain (not intense), and, often, vomiting occur. The vomitus consists of the gastric contents, with bile, and during the first few hours it may contain phosphorus, which gives it a luminous appearance in the dark.

After the second or third day the vomiting usually ceases with the appearance of *jaundice*, which may become intense as the process continues. Later in the course of the case emesis recommences, the vomita consisting of altered blood, giving rise to the so-called "black vomit." At this stage *nervous symptoms* usually manifest themselves (headache, insomnia, vertigo, and delirium, with convulsions and coma in fatal cases), death closing the scene usually in from thirty-six to forty-eight hours.

The bowels are constipated, although attacks of diarrhea may supervene, and the evacuations are in some instances phosphorescent.

Fever is irregular and usually is not marked, the temperature swinging from 99° to 101° F. (37.2°–38.3° C.). In fatal cases the temperature may become subnormal just before death.

The *urine* is scanty, of high specific gravity, and contains bile, bile-acids, albumin, sarcolactic acid, and in rare cases leucin and tyrosin (Wood). Renal epithelium and free fat-globules have also been found. When occurring in pregnant women, abortion or miscarriage invariably follows.

Physical examination reveals a liver uniformly enlarged and tender on pressure. In protracted cases atrophy of the organ may rarely occur.

Etiology.—The most common causes are: (a) Occupation, workers in match factories being the most frequent sufferers; (b) the accidental swallowing of phosphorus (*e. g.*, rat-poison, friction-match heads).

Pathology.—On opening the abdominal cavity in a case of phosphorus-poisoning the liver is seen to extend below the costal margin, its surface being lighter in color than normal and mottled in appearance, and its substance softer in consistence and friable.

The cut section presents marked evidences of fatty degeneration, the acini being lighter in color than the interlobular tissue. Portions of the hepatic parenchyma are deeply bile-stained, and on scraping the cut surface bile- and fat-globules will be found on the edge of the knife. The gall-bladder may be either full or empty. *Microscopically*, disintegrated liver-cells, fat-globules, granular debris, biliary coloring-matter, leucin spheres, cholesterin plates, and tyrosin needles are noted.

The *gastric mucosa* is found thickened, opaque, and yellowish-white in appearance, due, as pointed out by Virchow, to a universal gastro-adenitis, and not to the local action of the poison. Ulcerative or erosive gastritis is very rare in phosphorus-poisoning.

The *kidneys* may show beginning atrophy, the epithelium in the cortices undergoing granular and fatty degeneration, with final destruction of the cells.

The *blood* is dark, fluid, and not easily coagulable. Concato found that during life the white corpuscles are increased in number, and that the red are changed in shape and smaller than normal (Wood). Petechiæ and ecchymoses frequently appear in all parts of the body.

The **diagnosis** of acute phosphorus-poisoning is always extremely difficult and often impossible. The disease with which it is most apt to become

confounded is *acute yellow atrophy of the liver*. The differential points may be summated as follows:

ACUTE PHOSPHORUS-POISONING

There is a history of accidental ingestion of poison (friction-match heads, rat-poison) or occupation.

The onset is sudden; violent nausea, vomiting, and pain over the region of the liver. Jaundice appears on the second or third day.

Nervous symptoms appear late in the disease—always preceded by jaundice.

The vomit and stools are phosphorescent. Black vomit precedes death.

Temporary arrest of symptoms between the occurrence of jaundice and black vomit.

Sarcolactic acid is present in the urine, and rarely leucin and tyrosin.

ACUTE YELLOW ATROPHY

There may be an endemic history.

A slow onset—malaise, slight fever, with nausea and vomiting; jaundice is a beginning symptom.

Nervous symptoms may appear early, even before the occurrence of jaundice.

Black vomit occurs early and persists throughout.

Progressive march of symptoms with no remission.

Leucin and tyrosin are common in the urine.

Prognosis and Duration.—The prognosis in phosphorus-poisoning is bad, as small a dose as gr. $\frac{1}{8}$ (0.008) of white phosphorus having caused death (Wormley). The duration is usually from one to six days, although the symptoms have been known to persist for twelve days before death. In violent cases the end may come within twenty-four hours.

Treatment.—The initial plan of treatment is by causing emesis to free the system of the poison that still remains undigested. For this purpose copper sulphate (gr. x—0.6) in divided doses (gr. ij or iij—0.13–0.2—every five minutes) should be given until free vomiting occurs. As copper sulphate is a chemical antidote, forming with phosphorus black copper phosphid, it should be continued in less frequently repeated doses (gr. ij—0.13—every half-hour) and guarded by morphin to prevent vomiting. If emetics by the mouth fail to afford relief, apomorphin muriate (gr. $\frac{1}{5}$ —0.013), hypodermically, may be resorted to. The free evacuation of the stomach should be followed by the administration of the French oil of turpentine. Wood recommends that 1 part be given to every $\frac{1}{16}$ part of the poison ingested. Ordinary turpentine is useless, but combined with mucilage of acacia, 2 fluidrams (8.0) of French oil of turpentine may be given every fifteen minutes until 1 ounce (30.0) has been taken.

Alkalies (magnesia) have been given, but are practically valueless. Free purgation should be effected if possible by Rochelle salts or magnesium citrate. Demulcent oils are never allowable, as they dissolve the phosphorus and hold it in solution. After absorption of the poison and degeneration of the tissues have taken place all known remedies are futile.

CIRRHOSIS OF THE LIVER

(*Sclerosis of the Liver; Nutmeg Liver; Gin-drinker's Liver; Interstitial Hepatitis*)

Definition.—A chronic disease of the liver, characterized, pathologically, by an excess of connective tissue. It presents various biliary, gastro-intestinal, circulatory, and cerebral symptoms.

Pathology.—There are three pathologic varieties: (a) Portal cirrhosis, or “gin-drinker's liver”; (b) hypertrophic cirrhosis, and (c) biliary cirrhosis.

(a) **Portal Cirrhosis** (*Laennec's, atrophic, or alcoholic cirrhosis*) is the most common form, at least in the earliest stages, as Foxwell's studies teach; the alcoholic (indurative) liver is more commonly enlarged than decreased in size. Morse examined the records of 37 cases of cirrhosis, and found that among these there were 13 instances of enlarged liver, 11 of normal size, and 12 smaller than normal. In typical examples the capsule is thickened, the organ greatly reduced in size, hard, granular, and much altered in shape. On section (which resists the cutting-knife) the surface presents grayish-white bands of connective tissue surrounding yellowish areas (acini) that project above the surface from compression (hob-nails); hence the term "hob-nailed liver."

Microscopically, the process is seen to commence as an increase in the connective-tissue element surrounding the terminal branches of the portal vein. Compression of the liver cells and of the portal veins, with consequent obstruction of the circulation, constantly increases with the progress of the proliferation of the connective tissue and its secondary contraction. Atrophic changes in the hepatic cells, however, are often comparatively slight. The biliary canaliculi may be increased in number. Weigert and his disciple contend that atrophy or degeneration of the acini is often the primary change, and the connective-tissue production the secondary—filling the gap, so to speak.

In alcoholic cirrhosis the liver is sometimes large, smooth, or slightly granular, soft rather than hard, as ordinarily the case, and presents a light yellow color (*fatty cirrhosis*). Histologically, this is a form of true cirrhosis, as shown by the presence of an increase in the connective tissue, with which, however, fatty infiltration of the acini is associated.

(b) **Hypertrophic Cirrhosis** (Hanot).—On examining the liver *in situ* during hypertrophic cirrhosis the various diameters of the organ are increased (the left sometimes more than the right), the lower border projecting several fingerbreadths below the ribs. The margin of the liver is well defined, the substance firmer than normal, and it cuts with difficulty. The organ is lighter in color than in health, and presents a yellow or mottled green appearance. On treating a section with compound iodine solution (Lugol's) the color changes to that of a deep mahogany red. The acini are darker in hue than the interstitial tissue.

Microscopically, the peripheral zones of the acini are seen to be the seat of a round-cell infiltration, with the formation of embryonal tissue; later, the interlobular connective tissue undergoes hyperplasia, causing obstruction of the biliary ducts with retention of bile, but the parenchyma is unchanged. New-formed bile-ducts are proliferated.

(c) **Biliary Cirrhosis**.—French writers have described "biliary cirrhosis" as opposed to a "portal cirrhosis" (atrophic). It results from obstruction of the bile-ducts; this causes retention of bile with swelling of the organ as a consequence. The action of the chemical irritants that are the result of stasis of bile starts a cirrhotic process around the small bile-ducts (reactive inflammation). The *microscopic appearances* of the organ simulate those of hypertrophic cirrhosis; but the hepatic cells are more deeply bile-stained. *Microscopically*, the first discoverable changes are spots of insular necrosis in the peripheral zones of the acini (Stengel). These are shortly replaced by proliferation of the interlobular connective tissues. The formation of new ducts and liver cells is common.

There is also a so-called glissonian cirrhosis (perihepatitis) in which the capsule of the organ is surrounded by a dense white fibrinous membrane, which contracts, reducing the size of the liver and altering its shape. This I have described elsewhere (*vide* Chronic Hepatitis, p. 859). Syphilitic cirrhosis of the organ receives special consideration (p. 374).

Etiology.—(a) **Portal Cirrhosis.**—1. *Alcoholism.*—Freyhan, Osler, and the writer have found this causal factor operative in nearly all cases. Clinical history tends to prove that the stronger the alcoholic beverage (*e. g.*, raw spirits) and the larger the amount consumed, the sooner cirrhosis develops, although the quantity necessary to produce the disease varies greatly in different individuals. The influence of alcohol is undoubtedly exaggerated. Experimentally it is impossible to reproduce the picture of cirrhosis by feeding animals with alcohol in large amounts over long periods of time.

2. *Spicy foods* are, according to some, classed as predisposing agents. Tiraboschi records a case that had been induced by the long use of spicy foods and by overeating. Longcope, by repeated anaphylactic shock, has produced experimentally lesions in the liver resembling those of cirrhosis.

3. *Male Sex and Middle Life.*—The cases produced by alcohol occur chiefly in males. According to my experience, females who misuse potable alcohols, particularly the more concentrated liquors, are less susceptible to the poison than males. Two-thirds of the fatal cases occur between the ages of thirty-five and fifty (Hawkins), although cases have been known to occur at both extremes of life. Toxins of bacterial origin may cause liver cirrhosis. Micro-organisms have also been found in cirrhotic livers, especially the colon bacillus, but no specific causative action can be ascribed to it, though Opie and others have been able to produce experimentally the anatomic changes of cirrhosis more consistently than by any other method by combining bacterial infection with certain liver poisons, such as chloroform.

4. It may follow the acute infectious diseases, notably scarlet fever.

5. Certain *chronic diseases* (rickets, diabetes, gout, malaria, carcinoma, tuberculosis) that favor the formation of connective tissue are apt to be complicated by cirrhosis, usually partial. Syphilis produces a liver which has many of the characteristic features of cirrhosis.

6. *Passive congestion*, secondary to chronic cardiac lesions or to obstructive lung disease, not infrequently gives rise to hepatic cirrhosis.

7. Fatty cirrhosis results from the abuse of malt liquors in some cases, and is often associated with more or less obesity.

(b) **Hypertrophic Cirrhosis** (Hanot).—In most cases there is an absence of recognizable causes. Sex is a strongly predisposing cause, males being the most frequent victims, in the proportion of 6 to 1. It is not uncommon in young adults. In catarrhal jaundice the morbid processes may rarely extend to the liver and there persist, giving rise to hypertrophic cirrhosis. Cases are met with in children, in whom it may follow the acute infectious diseases. Alcohol plays an unimportant rôle in the causation of Hanot's cirrhosis. The disease is most common among the inhabitants of warm climates, and is also hereditary.

(c) **Biliary Cirrhosis.**—This form is produced by chronic obstruction of the bile-ducts (see also Obstruction of the Common Duct, p. 841).

Symptoms.—**Portal Cirrhosis.**—The symptoms of this variety of cirrhosis may present nothing characteristic as long as the sclerotic process does not interfere with the portal circulation. In some cases the collateral (compensatory) circulation is maintained throughout the long course and symptoms fail to arise. Among the *prodromal symptoms*, a gradual loss of flesh, anorexia, constipation, a coated tongue, slight jaundice, dyspepsia, and occasionally hematemesis are to be mentioned.

As the obstruction of the portal circulation becomes marked the mucosa of the gastro-intestinal tract is congested, and gives rise to augmenting *nausea* and *vomiting* (most marked in the morning), and *hemorrhages* from the stomach (hematemesis, visible and occult) and intestines (melena), which may be

frequent and profuse, but are rarely fatal. Severe hemorrhages may also occur from enlarged varicose esophageal veins. The *tongue* is coated. Uneasiness and even pain may be experienced in the hepatic area. Owing to the establishment of a compensatory circulation the superficial epigastric and internal mammary veins enlarge and form about the umbilicus ("caput medusæ").

Hemorrhoids are common and are due to passive congestion of the hemorrhoidal veins. As the disease progresses the *general emaciation* becomes more marked. The face assumes a pinched expression, the tip of the nose has a purple tinge from distended veins; the eyes are sunken, the cheeks hollow, and the skin presents a sallow tint (*hepatic facies*). The failure of the compensatory circulation gives rise to *ascites*, or hydroperitoneum. The *spleen* becomes enlarged. At any stage, although generally in advanced cases, *toxemic symptoms* may develop due to some poisonous product in the blood of unknown nature: these are violent headache, followed by wild, noisy delirium, convulsions, stupor, and coma. They may occur without jaundice, and have been mistaken for uremia. With or without hemorrhages secondary anemia, more or less profound, is observed. Rogers states that leukocytosis is common.

Fever may be absent throughout the course of the disease, but is often present, and may reach 100° to 102° F. (37.7°–38.8° C.).

Examination of the *urine* shows it to be of increased specific gravity and frequently containing bile. It may be slightly albuminous, and contains casts, though out of 28 urinalyses in cases of cirrhosis Henry discovered the presence of albumin in but one. The urea elimination varies from health, probably owing to the disturbance of the urea-forming function of the liver.

The *physical examination* in a typical case of atrophic cirrhosis reveals a distention of the abdomen; there may be also an extreme enlargement of the superficial veins over the surface of the body. An icteroid tint of the skin is present in about 25 per cent. of the cases.

Palpation of the liver and spleen may be greatly interfered with by the large amount of peritoneal fluid present. On withdrawal of the latter, however, the spleen is found greatly enlarged. Palpation commonly detects hardened arteries, and W. W. Ford,¹ in an analysis of 500 autopsies, finds that practically all the cases of beginning cirrhosis of the liver are associated with renal disease and cardiac affections.

The liver may show slight enlargement in the beginning of the disease; but it soon atrophies, and in emaciated subjects with lax abdominal walls its finely granular or nodular edge can be *felt* above the margin of the ribs. *Percussion* shows its vertical diameter, which normally extends from the sixth interspace to the costal margin, and averages about 4 inches (10 cm.), diminished, especially toward the median line. Posterior dullness begins lower than normally. It must be recollected that the liver is often enlarged in otherwise typical cases. An alcoholic hypertrophic cirrhosis without ascites (Gilbert, 1899), in which there is a marked collateral circulation in the abdominal wall, occurs, and all its symptoms are those of a bivenous hypertrophic cirrhosis.

Fatty cirrhosis, in which the organ is sometimes enlarged, may be latent and remain unrecognized or be discovered on the postmortem table. In 5 of my 6 cases the symptoms resembled those of the ordinary form. Among *complications* of this variety may be mentioned tuberculosis, pleurisy with effusion, and chronic nephritis.

(b) **Hypertrophic Cirrhosis.**—In this variety of the disease there is usually an absence of any alcoholic history, and it is apt to be met in young adults and even children (*vide* Etiology). *Moderate enlargement* of the liver may be present before any *digestive disorders* are observed. The latter may be absent,

¹ *Univ. of Penna. Med. Bull.*, Philadelphia, February, 1904.

except the presence of slight jaundice and an occasional disturbance of digestion, until late in the course of the disease. Intense jaundice, fever, and hepatic enlargement may then appear, with the rapid development of a grave general condition. The *urine* contains bile-pigment, but the stools are not typical (pale drab or slate colored). Paroxysms of *pain*, resembling mild hepatic colic, may occur at irregular intervals. *Hemorrhages* into the skin from the mucous surfaces (due to passive congestion) are also common. In long-standing cases albumin and tube-casts may be present in the urine. Leucin and tyrosin have also been found, but are not constant. These symptoms are probably due to recent inflammatory infiltration arising in the course of an old cirrhosis. Splenic enlargement occurs, but ascites is exceedingly rare. The cases run an extremely chronic course, and in a patient of mine, a lad of fourteen years, the grave symptoms mentioned above suddenly developed and terminated life after four years of slight, though decisive, attacks of jaundice, with moderate hepatic enlargement. The stools were bilious looking, and hemorrhages from the mucous surfaces frequently occurred. There was a leukocytosis.

Physical examination shows a uniform and progressive enlargement of the organ; the lower border is felt distinctly outlined below the costal margin, its edges being rounded and at times granular.

Percussion shows an increased area of hepatic and splenic dulness.

Late in the disease, in addition to the grave symptoms described above—icterus gravis, high fever, hemorrhages, and the like—serious nervous symptoms, as delirium, convulsions, stupor, and coma, may supervene. The temperature now usually ranges from 102° to 104° F.—38.8°–40° C. (*febrile jaundice*)—although fever may sometimes be absent throughout the course of the disease. Death results either from an intercurrent disease or progressive asthenia.

Hemochromatosis (Opie).—Recklinghausen first called attention to hemochromatosis in connection with cirrhosis. Its association with diabetes mellitus and bronzing of the skin I have previously referred to (p. 394). There are cases, an illustration of which was reported by Opie, in which bronzing of the skin, cirrhosis of the liver, and chronic interstitial pancreatitis occur without diabetes. Opie's conclusions may be cited: (1) "There exists a distinct morbid entity, hemochromatosis, characterized by the wide-spread deposition of an iron-containing pigment in certain cells and an associated formation of iron-free pigments in a variety of localities in which pigment is found in moderate amount under physiologic conditions. (2) With the pigment accumulation there are degeneration and death of the containing cells, and consequent interstitial inflammation of the liver and pancreas, which become the seat of inflammatory changes accompanied by hypertrophy. (3) When chronic interstitial pancreatitis has reached a certain grade of intensity, diabetes ensues, and is the terminal event in the disease."

(c) **Biliary Cirrhosis**.—*Symptoms and Diagnosis*.—The clinical interest of this form centers principally around the symptoms of the causative condition—chronic obstruction of the bile-ducts—which have been given in detail elsewhere (*vide* p. 841). With the latter may be associated the features of either catarrhal or suppurative cholangitis. *Jaundice* is usually more intense than in the hypertrophic form, particularly during the earlier stages. *Intermittent hepatic fever* is commonly observed. The *physical signs* are similar to those of Hanot's cirrhosis.

The *diagnosis* of biliary cirrhosis rests on the presence of the characteristic features of prolonged obstruction of the bile-ducts, from impaction by gall-stones, a tumor or stricture of the duct, and the like, with slow and gradual, smooth, or slightly granular, hepatic enlargement. It is to be recollected that

when obstruction of the gall-ducts becomes complete, or "acute fermentative changes" are set up in the retained bile, the cases may terminate acutely (*e. g.*, in acute atrophy).

General Diagnosis.—(a) **Of Portal Cirrhosis.**—An assured diagnosis may be based on the following points: 1. A clear history of the most common causes (inebriety, male sex and middle life, rickets, diabetes, gout, malaria). 2. The combined presence of ascites, with hippocratic facies, and diminution in the size of the liver, as shown by the physical signs. 3. Absence of the characteristic features of acute disease, and the negative character of results from an examination of the heart, lungs, and kidneys. It is to be recollected that the volume of the liver is not invariably decreased, and even may be increased.

With the atrophic form of cirrhosis, *chronic peritonitis with effusion* is most liable to be confounded. In the latter disease there are characteristic abdominal tenderness, fever, and usually associated tuberculous lesions of other organs (lungs, kidneys, intestines); but the hepatic facies and clearly indicative history of atrophic cirrhosis are absent. A large peritoneal effusion is in favor of cirrhosis. Cheney recommends that the blood be examined for *sypilis*, since there may be nothing noted on physical examination or in connection with the symptoms to determine the luetic etiology.

(b) **Of Hypertrophic Cirrhosis.**—The principal diagnostic points are an absence of the usual alcoholic history, slight icterus, extending over a variable and oftentimes long period, paroxysms of pain, mucous and cutaneous hemorrhages, moderate enlargement of the liver and spleen (without ascites), and the development of grave symptoms at any stage—intense jaundice, fever, sometimes marked nervous phenomena.

Functional Tests of Hepatic Insufficiency.—In many cases of suspected liver disease, particularly the cirrheses, the symptoms and physical signs may be suggestive of the disorder, but not sufficiently definite to make a diagnosis. Furthermore, it is often of value in prognosis to attempt to determine the functional power of the liver cells. Unfortunately, no functional test of marked clinical value has been elaborated comparable to the phthalein-test of kidney function. The liver has many functions, so that disturbance of one function does not necessarily imply disturbance of all functions. The functions of the liver are necessarily dependent upon the proper efficiency of other organs through the collaboration of which the end-results are attained; the liver has no single function that is peculiar to the organ alone or which, rather, does not depend upon many extraneous factors; furthermore, obvious disease of the liver may be associated with undisturbed function so great is the factor of safety in this large organ. It follows, then, that tests of liver sufficiency depend upon so many factors that no single test is specific, and that the estimation of hepatic insufficiency must depend upon a careful correlation of symptoms, physical findings, and laboratory tests.

Probably the most efficient test of hepatic function is that which shows the presence or absence of *urobilin* when evidence of increased blood destruction is not demonstrable. Urobilinuria is extremely common in hepatic cirrhosis and in advanced passive congestion of the liver. Acute yellow atrophy and phosphorus- and chloroform-poisoning all show it. In febrile conditions, probably as a result of cloudy swelling of the liver parenchyma, it is also present.

Alimentary levulosuria (Strauss's test) is often present in liver disease, particularly cirrhosis and catarrhal jaundice. According to Chajes, it is found in 86.9 per cent. of cases of cirrhosis of the liver. The test depends upon the fact that the action of liver is apparently necessary for properly metabolizing levulose and also galactose. To perform the test 100 grams of levulose dissolved in weak

tea or hot water are given when the stomach is empty. The urine is collected for five hours afterward. As a rule, a normal individual will not show the presence of the sugar in the urine, while one with cirrhosis will; 40 grams of galactose may be given instead of levulose. The appearance of more than 2 grams of the sugar is supposedly indicative of hepatic insufficiency. Either of these tests may be used, but it is better to use both at different times. If the same results are achieved each time, then considerable dependence may be placed upon the tests.

Other tests of the urine that may show hepatic disturbance include the excretion in excess of ammonium and amino-acids, the former probably showing only an acidosis in the course of the liver disease. A test that is supposedly specific is the phenoltetrachlorophthalein test of Able and Rowntree. This dye is eliminated through the liver, so that its recovery in the stool is possible in amounts varying with the degree of hepatic injury. Unfortunately, the test is not clinically practical. The same statement applies to the estimation of blood fibrinogen and blood lipase as recommended by Whipple for tests of liver function.

Differential diagnosis of hypertrophic cirrhosis may be confounded with *carcinoma of the liver*, *hydatid cyst*, *hepatic abscess*, and *fatty cirrhosis*.

HYPERTROPHIC CIRRHOSIS

Absence of recognizable causes.
Occurs in young adults and in childhood.
Usually a primary affection.
Jaundice is slight unless grave symptoms develop; there is no cachexia.
Paroxysms of pain. The case runs a slow course, usually lasting many years.
Enlargement is uniform.

HYPERTROPHIC CIRRHOSIS

History negative as to alcohol. More common in warm climates.
Occurs idiopathically.
Fever, jaundice, and ascites may be present singly or together.
Anemia and emaciation slowly progressive. There is a leukocytosis.
Regular enlargement of the liver. No fluctuation nor thrill.
Aspiration is negative.

HYPERTROPHIC CIRRHOSIS

Etiology usually negative. May rarely follow acute infectious diseases.
There are tenderness on deep pressure and paroxysmal pain.
Hectic symptoms absent although a continued fever may develop usually late.
Slow course, lasting months or years.
Slow enlargement, regular, or slightly nodulated. No fluctuation.
Aspiration gives negative results.

CARCINOMA OF THE LIVER

Hereditary history.
Usually occurs after forty years of age.
Often occurs as a secondary growth.
Anemia is present, and also the development of a typical cachexia.
Pain more constant with rapid emaciation. The case terminates usually within one year.
The liver is irregularly enlarged, and contains umbilicated nodules.

MULTILOCLAR HYDATID CYST

History of ingestion of the embryo of *Tenia echinococcus* with the food.
Simultaneous occurrence in colonies or in others in the vicinity.
No fever, pain, jaundice, or ascites.
Emaciation not marked; no leukocytosis.
On palpation an irregular, fluctuating tumor is felt over the hepatic area, giving a "hydatid thrill."
Aspiration gives a clear, serous fluid, rich in chlorids, and containing hooklets.

ABSCESS OF THE LIVER

History of dysentery, traumatism, or pyemia.
Severe and constant pain; marked tenderness.
Hectic symptoms appear early (fever, chills, and sweating).
Acute course, lasting a few weeks.
Rapid development of a fluctuating tumor in the hepatic area.
The aspirating-needle reveals pus.

So-called *fatty cirrhosis* may be distinguished from hypertrophic cirrhosis by the history of alcoholism and the absence of jaundice.

(c) *Biliary cirrhosis* causes enlargement of the liver, but to a much more moderate extent than hypertrophic cirrhosis. In the former the symptoms of obstruction of the bile-ducts—jaundice and loss of color on the part of the stools (unlike the hypertrophic form) are in evidence. The duration of biliary cirrhosis is, on the whole, shorter than that of hypertrophic, and terminal diminution in size (atrophy) more common.

The **prognosis** of the atrophic form of cirrhosis is decidedly unfavorable, the function of the liver cells having been impaired, although the principal source of danger is probably the ascites; and death usually takes place within a few months or a year after symptoms of portal obstruction appear. In

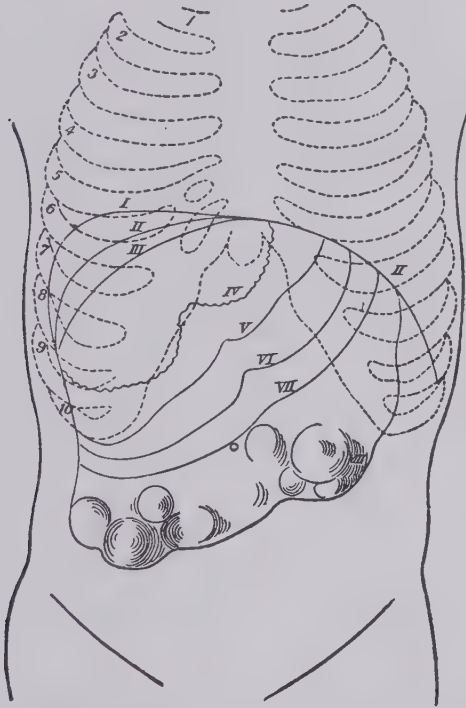

Fig. 55.—Showing approximate enlargement of the liver corresponding to the different diseases described in the text (after Rindfleisch): I, Position of the diaphragm to the maximum enlargement (carcinoma); II, II, normal situation of the diaphragm; III, III, relative dullness; IV, border of the liver in cirrhosis; V, border in health; VI, lower border of the fatty liver; VII, of the amyloid liver; VIII, of carcinoma, leukemia, and adenoma.

rare cases the symptoms abate, owing to the establishment of a compensatory circulation, and may remain in abeyance for months or years.

The prospect of life is much enhanced by an early recognition and removal of the overshadowing cause—alcoholism. I have seen a few cures made in this manner. Even after the occurrence of jaundice, hematemesis, and toxic symptoms, under appropriate treatment patients have been known to enjoy comparative health for years.

Treatment.—The *prophylactic* treatment, which is of first importance, consists in improving the general health of the patient and in removing, if possible, the cause of the affection. Rest, graduated exercise, systematic bathing, and regular hours for eating and sleeping should be inaugurated and strictly adhered to. Alcohol, strong coffee, spices, and gastro-intestinal

irritants of every nature must be interdicted. H. C. Wood states that tavern-keepers and bartenders who are unable or will not cease using alcohol may greatly prolong life by substituting hard cider for all other drinks. The diet should be simple and easily digestible. An exclusive milk-diet has been highly recommended (Semmola). Einhorn claims that duodenal alimentation often causes the liver to become markedly smaller.

The medicinal treatment is largely symptomatic, no remedy having been discovered to prevent the formation of or remove the new-formed connective tissue. The chief object is to deplete the portal system and prevent, if possible, the occurrence of ascites. The bowels should be kept freely open by the use of saline purgatives (concentrated solution of Epsom salts), elaterium, or compound jalap powder. The skin is to be kept active by means of Turkish or Russian baths (under supervision), and in extreme cases by the steam bath or hot pack, employed just short of the point of exhaustion. The kidneys should also be kept active by the hydragogue diuretics, as potassium acetate, squills, calomel, digitalis in the form of the infusion, or Niemeyer's pill. Klemperer and others have also recently recommended urea as an efficient diuretic, and from 20 to 30 grains (1.3–2.0) may be given in solution. If the case be syphilitic in origin, salvarsan and potassium iodid should be exhibited.

Ascites calls for free diuresis, diaphoresis, and catharsis; and if not relieved in the course of a few days, tapping should be resorted to.

The operation of *paracentesis abdominis* is relatively free from danger. The bladder having been emptied, a spot over the linea alba about 3 inches (7.5 cm.) above the symphysis pubis is anesthetized preferably by means of the hypodermic use of cocain (2 per cent. solution) and a trocar is quickly thrust through the abdominal wall for a distance of about 1 inch (2.5 c.). The distance is determined by the forefinger, which is placed at the desired distance from the point of the canula before its insertion. The patient must be in a sitting or semireclining position, so as to allow the ascitic fluid to collect by gravity in the lower part of the abdominal cavity. A tube having been attached to the canula to convey the liquid to a receptacle, the trocar is withdrawn, the fluid allowed to run out, the canula removed, and the wound closed by antiseptic gauze or a pledget of cotton. A collodion dressing is then applied to the site of puncture, and the abdominal binder, previously applied, is tightened.

Epiplasty (Roberts' operation), or suturing the great omentum to the anterior abdominal wall for the purpose of establishing a collateral venous circulation, for the relief of the ascites in cirrhosis is useful in advanced cases. The Talma-Drummond operation should be undertaken earlier, but its precise value has not as yet been determined. In Hanot's cirrhosis, splenectomy has been practised with undoubted benefit and possible cure (Mayo).

Complications, as cardiac hypertrophy, tuberculous peritonitis, or chronic meningitis, demand appropriate treatment.

CARCINOMA OF THE LIVER

Definition.—A malignant growth of the liver, occurring usually after the age of forty, and characterized by pain, progressive emaciation, cachexia, and the appearance of a nodular mass in the hepatic parenchyma. It may be primary or secondary, though the former is rare.

Pathology.—Histologically, the cells are not distinctive, being identical with those of carcinoma elsewhere; they are epithelial in character, having a small vesicular nucleus and much protoplasm. They are altered greatly by

pressure and vary in shape, being hexagonal, polyhedral, or amorphous. Large giant-cells and spots of pigment known as "brownish granules" are not uncommonly found in the cancerous mass. The so-called colloid cancers are nearly always mucoid, and the cells have undergone a mucoid change; the stroma of connective tissue surrounding the cancer-nests in some instances undergoes hyaline or myxomatous degeneration. In other instances the interstitial trabeculæ completely surround the epithelial nests, which are separated by a basement membrane; this variety is termed *adenocarcinoma*.

When examined microscopically, *medullary cancer*, either in a large mass (primary) or in secondary nodules scattered throughout the organ, is the most common variety found in the liver. On examining a liver that is the seat of carcinoma, one of two conditions usually presents itself: *First*, the organ may be apparently normal with the exception of one lobe (usually the right), which contains a dense whitish growth of firm consistence, being distinct and sharply defined from the surrounding liver tissue. On section the tumor is often of uniform density, bluish-white in appearance, and exudes a milk-white fluid known as "cancer-juice," which, when examined microscopically, is found to contain large, nucleated, and irregularly shaped cells containing free granular matter. The center of the tumor may have undergone liquefaction-necrosis, with the formation of a cyst, or it may be the seat of an abscess. Various smaller nodules may be scattered throughout the organ by metastasis from the primary growth. The *second* and most common condition is secondary carcinoma of the liver, the primary lesion being situated in the mammary glands, pylorus, or the cervix uteri. The organ is greatly enlarged, as a rule. Numerous nodules are scattered throughout, and can usually be seen projecting beneath the capsule, those superficially situated having received the name of "Farre's tubercles." In the center of these nodules characteristic pits or umbilications are often present, caused sometimes by contraction of the interstitial trabeculæ and sometimes by a central softening. On section they are usually grayish-white in color and of firm consistence, although cysts, hemorrhages, pus cavities, or areas of hyaline and fatty degeneration are often found. The cells are identical with those of the primary growth, and are composed for the most part of cylindric epithelium.

In rare instances carcinoma occurs simultaneously with *cirrhosis* in the same liver, the organ presenting an uneven, nodular appearance, and being slightly increased in size and of firmer consistence than normal. When examined *in situ* the external appearance does not differ materially from that of cirrhotic liver, but on section the whole organ is found to be infiltrated with various sized cancer-nodules surrounded by bands of cicatricial tissue. In some cases the excess of connective tissue and the amount of contraction are extreme, and the size and weight are reduced below the normal. Eggels¹ has collected 163 cases of primary hepatic carcinoma, and calls attention to the frequent association of atrophic cirrhosis and carcinoma; he regards the cirrhosis as the primary process.

Etiology.—Among the more important predisposing factors are—

(a) *Age*.—The disease is most common after thirty-five or forty years of age, although cases are not rare between twenty and thirty-five years. Descroizilles reports the case of a child eleven years old who died with a tumor in the right hypochondriac and iliac region, the autopsy revealing a liver studded with numerous nodules, as was demonstrated microscopically.

(b) *Sex*.—Men are more often the victims of carcinoma of the liver (primary form) than women. The secondary variety, however, is slightly more frequent in women, following carcinoma of the uterus or mammary gland.

¹ Ziegler's *Beiträge*, 1901, xxx, 506.

(c) *Heredity*.—Lichtenstein found a hereditary predisposition in 192 out of 1137 cases (17 per cent.).

(d) *Traumatism* may contribute.

(e) *Mechanical Obstruction*.—Primary carcinoma of the gall-bladder and bile-ducts commonly follows chronic obstruction by gall-stones.

Symptoms.—There may either be almost no symptoms of carcinoma involving the liver, or its manifestations may be intense and varied according to the extent and location of the growth or growths. Associated gastric symptoms, often due to a primary growth at or near the pylorus, which increase as the disease advances, usually attend. A more or less marked cachexia may be the first noticeable feature. The chief symptoms may be considered in detail, as follows:

(a) *Jaundice*.—Discoloration of the skin is often by no means intense, and may be entirely absent. Harley states that true icterus was present in only 6 out of 100 cases seen by him, though few observers agree with his view as to the rarity of this symptom. The reason given for its lack of intensity is that in most cases the growth is situated in the right lobe and does not compress the bile-ducts.

(b) *Pain* is usually present to a marked degree. It is dull and boring in character, and localized generally in the right hypochondriac region. In some instances (as in the case of impacted biliary calculi) it may radiate to the right shoulder and the scapular region. It usually increases as the hepatic enlargement progresses, although cases of enormous sized cancerous tumors of the liver have been known to occur without pain. The character and location of the pain are of diagnostic importance, and will be spoken of under the differential diagnosis.

(c) *Ascites*.—When the cancerous growth compresses the portal vessels, and also in cases of cirrhosis with carcinoma, obstruction to the portal circulation occurs, and results in the development of ascites. This may cause distention of the abdominal cavity to such an extent as to occlude the physical signs of hepatic enlargement. The cancerous growth may also invade the peritoneum and cause an effusion. This symptom, however, is not frequent, at least two-thirds of all cases terminating without the appearance of ascites.

(d) *Fever* is usually absent until the later stages of the disease. It may then appear and rise to hyperpyrexia (105° F.— 40.5° C.), but it is usually moderate in degree, irregular, and intermittent in type.

(e) *Cachexia*.—In every case of carcinoma, at some stage of the disease, cachexia develops; when pronounced, it is almost pathognomonic. The destructive effect of the neoplasm, or the toxic substances produced by it may play a rôle in the causation of the cachexia. At all events there is a distinct increase in the excretion of nitrogen.

(f) *Cerebral Symptoms*.—These may be absent throughout. In the advanced stages, however, such striking symptoms as violent headache, mental hebetude, or delirium (less frequently), which may be maniacal in character, appear. These symptoms resemble those of cholemia (*vide* Hepatic Cirrhosis, p. 868). The patient may die in sudden coma.

(g) The development of *metastases* (*e. g.*, in the peritoneum).

(h) *The Blood*.—There is a decrease in the erythrocytes and the hemoglobin. *Per contra*, the leukocytes are both relatively and absolutely increased.

Physical Signs.—*Inspection* often reveals enlargement of the superficial veins over the abdomen, and a prominence in the upper epigastric and hepatic regions, varying with the degree of enlargement, may also be seen. In the nodular form and late in the disease, when emaciation has become extreme, elevations that are movable with respiration can be noticed beneath the skin.

On *palpation* the organ can be distinctly felt projecting below the costal margin and extending in some instances to a point below the level of the umbilicus. During respiration (forced) the liver can be felt to move downward and upward, the organ being under the influence of the diaphragmatic excursions. In emaciated subjects the cancer-nodules are readily appreciable, and in some instances the central pits or depressions are palpable, forming a characteristic sign. Cancerous infiltration of the anterior margin is most easily felt, and in enormous enlargements of the organ I have detected them on the posterior surface as well. Rarely the liver is found to be uniformly large. Palpation may also show splenic enlargement due to passive congestion.

Percussion.—In primary carcinoma (usually found in the right lobe) the percussion dulness is increased irregularly downward and generally to the right. On the other hand, in secondary growths (usually massive) the nodules are oftener distributed equally throughout the liver. In such cases the area of dulness may extend across the epigastrium to the left hypochondriac region, the heart and other viscera being now displaced. Posteriorly, dulness may extend upward on a level with the fourth rib, and anteriorly downward to the iliac fossa. The organ may now weigh from 15 to 20 pounds (6.5–9 kgms.), while in the average case the carcinomatous liver weighs from 3 to 6 pounds (1.3–2.6 kgms.).

Diagnosis.—In forming a diagnosis the family tendency, the history of primary carcinoma elsewhere in the body (stomach, colon, esophagus, pancreas, gall-bladder, uterus, mamma—Rolleston), the age, the localization of the pain in the right hypochondrium, the blood findings, the metastases, the cachexia, and the progressive enlargement of the liver, presenting umbilicated nodules, are the reliable points. The appearance of jaundice or ascites, or both, is confirmatory.

Differential Diagnosis.—Among affections of other organs that are likely to be mistaken for carcinoma of the liver may be mentioned (1) carcinoma of the *pylorus*, and (2) carcinoma of the *colon and omentum*. The chief diseases of the liver itself apt to be diagnosed as carcinoma are: (a) *Abscess*, (b) *syphilis*, (c) *benign growths* (adenomata, angiomatica), (d) *hydatid cysts*, and (e) *hyper-trophic cirrhosis*.

(1) *Carcinoma of the Pylorus.*—In carcinoma of the pylorus the physical examination frequently shows a hard nodular tumor that is most plainly outlined in the epigastric region. In a typical case, on deep inspiration, the tumor is pressed downward by the liver, but is not pulled upward by forced expiration, as in hepatic carcinoma. In many instances, however, adhesions bind the stomach firmly to the liver, which may be the seat of secondary involvement. The presence of jaundice, as well as the negative results from an examination of the gastric contents, would tend to eliminate pyloric carcinoma.

(2) *Carcinoma of the Colon and Omentum.*—Secondary carcinoma of the intestines affects most frequently the sigmoid flexure. The symptoms of intestinal obstruction arise, constipation being followed by attacks of serous diarrhea due to irritation, and later by the presence of blood in the stools. In carcinoma of the liver, on the other hand, the bile-ducts may be obstructed, causing clay-colored stools, but otherwise the dejecta are normal; the seat of the nodular enlargement and pain is located in the right hypochondrium. Jaundice and ascites are absent in carcinoma of the colon. The tumor, if palpable, in the latter condition is more movable and is less under the influence of the diaphragm. It does not give an absolutely flat percussion-note, as does hepatic carcinoma. Carcinoma of the omentum is usually secondary. The absence of small movable tumors in the umbilical, lumbar, or hypogastric regions, ranging in size from that of a pea to a walnut, aids in the elimination

of carcinoma of the omentum. As the latter affection advances the abdomen becomes distended and painful to the touch, the bowels are obstinately constipated, and the physical signs reveal the presence of an effusion which, when aspirated, is generally serous, but sometimes bloody. Microscopic examination may possibly reveal the presence of cancer-cells, though their recognition is difficult. The liver, unless primarily involved, is not enlarged, and cachexia does not usually appear until late.

From *hepatic abscess* the points of differentiation are—

CARCINOMA OF THE LIVER

There is often a history of a primary growth or chronic irritation.
Occurs usually after the age of forty.
Jaundice is rare.
Fever is absent or slight.
Cachexia is present and almost pathognomonic.
Pain is dull and boring in character, and more constant.
A nodular, umbilicated tumor or tumors may be detected.
The enlargement is downward.
The duration is a few months to one year.
Microscopic examination reveals disintegrated liver-cells, cancer-nests, and in some cases the micro-organisms of supuration.

HEPATIC ABSCESS

There is a history of traumatism or of intestinal ulceration, as in dysentery.
Occurs at any age.
Jaundice is sometimes present.
Hectic temperature, chills, and sweating.
Anemia may be present, but never cachexia.
Pain is sharp, lancinating, and paroxysmal.
A fluctuating tumor may sometimes be detected below the costal margin.
The enlargement usually upward.
The duration is usually a few weeks.
The microscope reveals pus, liver-cells, staphylococci and streptococci, the *Bacillus coli communis* or the *Amœba coli*.

Benign Growths (Adenomata, Angiomata).—Occasionally growths are detected in the liver, and may occur at any age; when these are present at or about the age of forty they may be mistaken for carcinoma. The absence, however, of a primary growth in some one of the other viscera, together with the duration of the growth and the absence of cancerous cachexia, would tend to differentiate them from cancerous involvement. An examination of the blood may be of service, leukocytosis being more common in carcinoma.

The **prognosis** is invariably fatal, the disease terminating rapidly in from a few months to a year. The most rapid course is run by secondary carcinoma of the organ. In exceptional cases growths favorably situated have been removed without recurrence.

The **treatment** is, with rare exceptions, purely symptomatic. An easily digested, nutritious diet should be given, together with active stimulation to support the system. The pain may be relieved by the free use of morphin, given by the mouth or hypodermically. For the nausea and vomiting that are apt to supervene the carbonated waters, cracked ice with champagne, or repeated doses of creasote, dilute hydrocyanic acid, or wine of ipecac (2 minims—0.13—every hour until relieved) may be given. If violent delirium should occur during the later stages of the disease, cold compresses to the forehead or vertex, and bromids and chloral hydrate given in rectal enemata, may prove efficient.

OTHER NEW GROWTHS IN THE LIVER

(a) Angioma, Adenoma, and Cyst.

Occasionally benign growths occur in the liver, and often with an absence of symptoms unless their increase in size gives rise to mechanical obstruction.

One of the most common of these is angioma, which is often found in the livers of old people. Angiomata consist of tortuous and dilated capillaries in the hepatic connective tissue; they rarely attain a size larger than a crab-apple, and usually cause no symptoms. Although most common in adults, they have been known to occur in children.

Adenomata and cystomata may also occur in the liver. They are both benign growths. The former is of the tubular variety, consisting of connective-tissue nests lined with cylindric epithelial cells. Von Bergman removed a portion of a tuberous adenoma of the liver with perfect recovery and non-recurrence of the growth. Cysts are quite rare. Lippmann,¹ who searched the literature, found reported 3 retention cysts, 9 cystic adenomas, 1 lymph-cyst, and 3 cases that could not be classified.

(b) **Sarcoma.**

Of the many varieties of sarcomata, those occurring most commonly in the liver are the small and large round-celled and the melanotic variety, the latter often being secondary to sarcoma of the choroid coat of the eye. These grow rapidly, causing a wide-spread destruction of the liver structure, with a change in the size and shape of the organ that is often demonstrable by palpation. E. R. Axtell reports a case in which at the *postmortem* the upper two-thirds of the liver revealed an entire absence of hepatic structure, and consisted of three tumor masses. On section the tumor is seen to be of firmer consistence than the surrounding liver tissue, and presents a dark, grayish-white, striated appearance. If the growth be of the pigmented variety, patches of a deep black or of different shades of pigment may be scattered throughout the mass. Metastasis is rapid and wide-spread (lungs, kidneys, heart, skin), as is shown by the fact that other organs are invariably found involved at the time of the growth and development of the sarcoma in the liver. Melanosarcoma may, in rare instances, appear as a primary growth, and attain a considerable size, as shown by a case reported by Bramwell and Leith.

The *symptoms* are those of mechanical obstruction, and consist of gastrointestinal disturbances due to passive congestion, edema, and ascites. Anemia and emaciation may become marked late in the disease, but cachexia does not develop. The passage of an intensely dark colored urine (melanuria) has been noted in some cases. Secondary nodules may appear on the skin surface.

The *diagnosis* can often be made from the primary growth (melanosarcoma of the choroid or sarcomata of the lymphatic glands) and from the rapid development of the tumor. From *carcinoma* of the liver melanosarcoma may be distinguished by the presence of ocular symptoms, particularly blindness of one eye, by the rapid wide-spread metastasis, the melanuria, perhaps, and by the absence of a true cancerous cachexia.

The *prognosis* is absolutely fatal and the *treatment* merely palliative.

X. DISEASES OF THE SPLEEN

Diseases of the spleen are mostly secondary to other diseases, the consideration of which embraces an appropriate description of the associated splenic disorders. The intimate relation between the spleen and blood accounts for the frequency with which this organ is involved in many of the blood diseases.

¹ *Deutsch. Ztschr. f. Chir.*, February, 1900.

DISLOCATION OF THE SPLEEN

(Floating Spleen)

Etiology.—This may be either congenital or due to the increased weight of an enlarged spleen, to tight lacing, to relaxation of the ligaments, or to traumatism, and is often met in splanchnoptosis. Carcinomatous enlargement of the left lobe of the liver caused it in my case.

The **symptoms** are vague and are the result of pressure. Distinct symptoms of gastro-enteritis and neurasthenia may result from a wandering spleen. By *physical examination* we discover with the touch the spleen as a mobile tumor pendant from the left hypochondrium; the tumor is superficial, blunt edged, and notched on its anterior border, and may be replaced by the hand in its normal position. On percussion over the splenic area the normal dullness is found to be absent.

Diagnosis.—It is important to distinguish between *floating spleen* and simple enlargement; also between the former and *movable kidney*.

The **prognosis** is guarded as to cure, though favorable as to life. Twisting of the pedicle has been followed by strangulation, with the development of intense pain and other alarming symptoms (necrosis). Intestinal obstruction, due to pressure, may appear.

The **treatment** must be mechanically supportive, consisting of pads and bands. Splenectomy has given excellent results.

SPLENIC HYPEREMIA

Acute or active hyperemia may be found as the result of the acute infectious diseases, giving rise to the *acute splenic tumor*, or as the result of amenorrhea, or of injuries and inflammation (*circumscribed hyperemia*). The organ is uniformly enlarged (except in the last-named cases), and is darker in color and softer in consistence; the capsule also is tense. This condition merges insensibly into *acute splenitis*.

Chronic or passive hyperemia is due to some mechanical obstruction of the portal circulation caused by tumors, cardiac, hepatic, and pulmonary disease, and pylephlebitis. The spleen is enlarged, firm, dark red in color, and the capsule is somewhat thickened.

The *symptoms* are vague, and may consist of simply a sense of weight, fullness, and pressure, and some tenderness in the left hypochondrium. In cases of extravasation of blood and rupture of the spleen the symptoms of intestinal perforation, hemorrhage, and collapse may supervene.

On *physical examination* the edge of the spleen may be palpated below the margin of the ribs. The percussion dullness is increased in area, especially downward and forward, and may encroach upon the slightly curved umbilico-axillary "resonant line."

The detection of acute or chronic splenic hyperemia (enlargement) is often of invaluable aid in the diagnosis of the causative disease.

The *prognosis* and *treatment* are embraced in those of the disease causing the congestion.

SPLENITIS

Definition.—This term comprises acute and chronic (hypertrophic) proliferative splenitis and suppurative inflammation.

Pathology.—Next to the kidneys, the spleen is the favorite seat of metastatic inflammation and *embolic infarction*. Splenitis, due to a benign embolus originating in the left side of the heart or from the aorta above the splenic arteries, is usually circumscribed to a zone of serohemorrhagic infiltration about the resultant infarct. The latter is hemorrhagic at first, and later becomes particolored or *mixed*, and is of a yellow color, owing to partial fatty degeneration; still later it may become whitish and remain as a wedge-shaped (the base being peripheral), cheesy (necrotic softening), or even calcareous mass, or as a fibrous cicatrix. Infection of the infarcts by pus micrococci leads to the development of *small abscesses*, and the trabeculae surrounding the latter may give way until finally one large pus-sac may be formed. Embolism may follow primary splenic arterial or venous thrombosis.

Perisplenitis generally follows, and sometimes with adhesions attached to adjacent hollow organs, as the stomach and colon, through which the perforating abscess may discharge its purulent contents. An unfortunate termination is the bursting of the abscess into the peritoneal cavity; a more fortunate ending results in an external opening. In acute splenic tumor there is an active congestion, with round-cell infiltration and some proliferation of the splenic cells. The spleen is moderately enlarged, dark, soft, pulpy, and friable.

In cases of intense vascular engorgement, as in the acute splenic tumor of severe typhoid fever, intermittent fever, and epilepsy (during the paroxysm), *hemorrhagic extravasation* may occur, and there may finally be even a rupture of the capsule and a passage of the blood into the peritoneal cavity. In chronic splenic tumor there is a persistent hyperplasia of the splenic cells. *Cirrhosis of the spleen* (chronic interstitial splenitis) differs characteristically from that of other organs (liver, kidneys) in that there is *enlargement instead of contraction*. Added to the increase in the size of the spleen, there are in both forms of chronic splenitis thickening of the capsule, patches often of old perisplenitis, and a slaty color of the tissues, with more or less pigmentation.

Etiology.—The disease probably never starts primarily in the spleen itself. *Acute proliferative or hyperplastic splenitis (acute splenic tumor)* is seen as the result of the acute infectious diseases (typhoid, typhus, relapsing, malarial fevers). *Chronic proliferative splenitis (chronic splenic tumor)* is due to chronic malarial infection or repeated acute attacks, to Banti's disease, chronic passive congestion of the spleen, and leukocythemia. The leukemic spleen represents a somewhat different form of chronic proliferative splenitis from the ordinary forms. *Acute suppurative splenitis (abscess)*, either diffuse or circumscribed, is usually secondary to infectious (pyogenic) emboli, as in ulcerative endocarditis and pyemia. Again, as the result of simple valvulitis of aortic thrombosis, *embolic infarction* of the spleen may be found, which may soften and break down in abscess formation from subsequent infection. Abscess of the spleen may also follow traumatism, perforation of a gastric ulcer, and the extension of adjacent inflammation.

Symptoms.—These are indefinite or absent in most cases. Usually there is no pain or tenderness unless perisplenitis exists. Considerable enlargement of the spleen may be attended with a *sense of weight, tension, or distress* in the left hypochondrium, and perhaps by slight *dyspnea*. Any *suppurative fever* present will most probably be dissociated from the idea of abscess of the spleen provided the local signs of pus be absent. *Sudden pain* appearing in the gastric region, followed by the *vomiting of pus and blood*, in the course of an infectious disease with *splenic enlargement*, may be due to the rupture of an abscess of the spleen. *Ascites* may also be present.

The **physical examination** may reveal some bulging on inspection, and a fluctuating tumor may be palpated. The enlargement may be sufficient to

enable one to feel the notch in the spleen. The percussion dulness is correspondingly increased.

Diagnosis.—This may be made from a consideration of the physical signs in conjunction with a study of the primary disease. In cases in which pus is suspected an exploratory puncture may clear the diagnosis. The splenic inflammation is rather an aid to diagnosis than a condition essentially needful of recognition in itself.

Differential Diagnosis.—Acute suppurative splenitis might be mistaken for *gastric or pancreatic disease*; but the previous history in the former, as contrasted with that of the latter affection, conjoined with the local symptoms that are more or less characteristic of the organ involved, will generally furnish an accurate means of differentiation.

The huge enlargements of chronic splenitis may be confounded with *hepatic, renal, omental, or ovarian growths*. Here a careful, discriminating observation of the constitutional state and of the physical signs is requisite for a diagnosis. Splenic enlargement must not be assumed when a *large pleural effusion* on the left side is causing the depressed lower border of the organ to be felt. Finally, *fecal accumulation in the splenic flexure* of the colon may be mistaken for moderate enlargement of the spleen. The former gives an irregular, doughy tumor, tympanites, vomiting, and a history of constipation alternating sometimes with diarrhea; there is no increase in the splenic area of dulness.

Prognosis.—This will depend upon the primary systemic condition. Abscess is a grave complication, the danger consisting of rupture and fatal peritonitis. Even in acute splenic tumor of a violent type there may be a hemorrhagic extravasation so severe as to burst the capsule. Chronic splenitides are not in themselves grave disorders.

Treatment.—This is to be directed mainly at the causative condition. Quinin and arsenic are often useful in the malarial form, and the chalybeates, iodids, and ergot have been recommended for the various chronic splenic enlargements. Strapping the affected side affords comfort. Abscess must be treated by splenotomy and drainage. Splenectomy may be useful in certain cases of simple hypertrophy. The state of the patient must be well considered.

AMYLOID DEGENERATION OF THE SPLEEN

(*Sago Spleen*)

This occurs as a part of the cachectic condition attending amyloid degeneration of other organs (liver, kidneys). The condition develops in the course of cases of prolonged and wasting discharges (phthisis, empyema, suppurative otitis, syphilis, chronic peritonitis, chronic enterocolitis). The spleen is, as a rule, greatly enlarged, putty-like, and rotund. The capsule is tense and glistening. There are two forms of waxy degeneration, namely, the so-called *sago spleen* and the *diffuse waxy or lardaceous spleen*. In the former the Malpighian bodies are chiefly affected and appear on section like sago granules; in the latter the whole splenic pulp, and even the trabeculæ, are degenerated, and on section the spleen appears pale, smooth, and homogeneous (boiled-ham appearance). This may be but a late stage of the "sago" spleen. The spleen gives a characteristic reaction with iodine.

The *symptoms* are those of general cachexia, and the *diagnosis* rests upon the detection of an enlargement of the organ associated with evidences of amyloid disease in other organs.

The *prognosis* is unfavorable, and the *treatment* does not differ from that indicated for the underlying and causative disease.

MORBID GROWTHS OF THE SPLEEN

The principal new growths are the granulomata, as tubercles and syphilitic gummata; also secondary carcinoma, melanotic sarcoma, and hydatid and other cysts. Lymphadenoma (*e. g.*, in leukemia), angioma, and fibroma may be included among tumors of the spleen.

These affections of the spleen are all of rare occurrence, and are not readily, if at all, discoverable during life. *Carcinoma* of the spleen is always secondary; it may be diagnosticated by a physical examination, showing the organ to be enlarged, with the signs of the primary carcinoma, as of the stomach. Secondary sarcoma is more common, and is recognized by an irregular enlargement and the presence of a primary tumor.

Syphilitic gummata of the spleen are often associated with amyloid degeneration and enlargement.

Gaucher's disease¹ is a type of splenomegaly due to a peculiar cell hyperplasia which is familial in character, begins in early childhood, runs an extremely chronic course, with gradual enlargement of the spleen until it reaches an enormous size, and is not associated with jaundice, ascites, nor lymphadenopathy. The blood may show changes similar to those of the early stages of Banti's disease, while the spleen after operation shows the presence of very large multinuclear phagocytic vesiculated cells.

RUPTURE OF THE SPLEEN

This may occur as the result of an intense hyperemic engorgement, both in splenitis from the rupture of an abscess and from traumatism. In the acute splenic tumor of typhoid fever, in malaria, and during an epileptic paroxysm rupture of the capsule has been known to occur on account of the extravasation of blood. The *symptoms* are usually mistaken for those of intestinal perforation with internal hemorrhage. The *treatment* is surgical, though palliative pending the surgeon's arrival.

XI. DISEASES OF THE PANCREAS

ACUTE PANCREATITIS

Three varieties of acute pancreatitis—hemorrhagic, gangrenous, suppurative—will be described, following the usual classification, but it is to be recollected that, in the majority of instances, these are indistinguishable clinically, and represent but different stages of a single disease.

HEMORRHAGIC PANCREATITIS

Pathology.—The pancreas is enlarged, usually firm, and somewhat chocolate colored. Irregular areas show the circumscribed as well as the diffused form of hemorrhagic infiltration of the interstitial fat tissue, with thrombosis of the pancreatic veins in some cases (Day). There is also an infiltra-

¹ See Brill and Mandelbaum, *Amer. Jour. Med. Sci.*, 1913, cxlvi, 863.

tion with round-cells of the interlobular tissues. Some cases are examples of degeneration (non-inflammatory). The gastro-intestinal mucosa may be hyperemic, ecchymotic, or in a slightly catarrhal state. Evidences of a localized peritonitis (*peripancreatitis*) are not frequent. Hemorrhage with inflammation is to be distinguished from true hemorrhagic pancreatitis. Opie and Meakins consider hemorrhagic pancreatitis to be primarily a necrosis, the inflammatory changes being secondary.

Disseminated fat-necrosis is quite commonly associated with hemorrhagic pancreatitis. Small areas of a peculiar (tallow-like) substance, ranging from the size of a miliary tubercle to that of a pea or even larger, are found scattered in the fatty interlobular pancreatic tissue in the omentum, mesentery, and sometimes in the abdominal fat. H. U. Williams and Kätz and Winkler, from experimental researches, conclude that probably the fat-splitting ferment is capable of causing changes similar to fat-necrosis. H. Coenen believes that the necrosis is the result of autolysis from activation of the pancreatic secretion by bacterial action, the bacteria penetrating into the pancreas in infected bile or intestinal juice, and also, rarely, *via* the blood- or lymph-stream.

In infectious fevers the pancreas may show diffuse, parenchymatous, and granular degenerative changes. Chiari has pointed out that *postmortem* digestion is frequent in the pancreas.

Etiology.—Most of the cases reported have occurred in *men*, and in persons past *fifty years* of age. An especial *predisposition* to the disease seems to be the result of cases of severe and obstinate dyspepsia (gastroduodenal), alcoholism, obesity, glycosuria, and traumatism. Hemorrhage into the pancreas may cause the disease. Opie emphasizes the etiologic importance of gall-stone and gall-duct disease (42 per cent.—Egdahl), and suggests that pancreatitis may be the result of the entrance of bile into the pancreatic duct. It is seen occasionally *postmortem*, *e. g.*, in acute tuberculosis and the specific fevers (metastatic infection.) The *direct cause* is an infection through the ducts of the gland, although when due to impaction of a calculus bacterial infection may be absent. Flexner¹ injected acids, alkalies, and bacterial cultures into the duct of Wirsung and the interstitial tissue, and produced acute pancreatitis.

Symptoms.—Eve states that of 40 cases, over one-half had premonitory symptoms, particularly attacks of pain referred to the right side of the upper abdomen, resembling cholelithiasis or duodenal ulcer. The *onset* is sudden and violent as a rule. It is characterized by *excruciating, deep-seated pain*, usually in the epigastrium, not radiating, with pain-free intervals at first, later becoming continuous. There are also *nausea* and *severe retching* and *vomiting, constipation*, and *speedy collapse*, ending fatally within a few days (second to the fourth—Fitz). The vomitus may consist at last of slimy mucus or dark blood. *Fever* is generally slight at first, though it may touch 103° or 104° F. (39.4°–40° C.) later. *Dyspnea* and a rapid, feeble *pulse*, with *jactitation* and *marked anxiousness* or an *afebrile delirium*, may perhaps be present. In some cases there may be *diarrhea*, with thin and watery stools containing free fat. Instances may be repeated in which, owing to the coincident presence of gallstones, there may be *jaundice* and *colicky pains* over the right hypochondrium. The jaundice, however, may sometimes be due to swelling of the head of the pancreas, which presses upon the bile-duct. *Tympanites* occurs in a majority of the cases. *Hiccup* and *albuminuria* have also been noted. The pain and collapse may be due either to a circumscribed peritonitis or to pressure upon the solar plexus. Cyanosis of the face and abdominal walls is common (Halsted). Localized *tenderness* and moderate *rigidity* above and to the right of the umbilicus are important signs.

¹ "Experimental Pancreatitis," Festschrift in honor of William Henry Welch.

Diagnosis.—This is at all times difficult, since many or all of the symptoms enumerated may be present in other affections. A careful inquiry into the previous history is important. The sudden development of an intense, deep-seated pain in the epigastrium, followed by vomiting, collapse, abdominal distention, with circumscribed resistance in the epigastrium, and the presence of constipation and slight fever, point to hemorrhagic pancreatitis. The detection of free fat in the dejections and the discovery of scattered points of tenderness are significant. Cammidge's reaction is valueless where a pancreatic disorder is suspected. Other affections may give a positive response (pneumonia, appendicitis with diffuse peritonitis). Cammidge¹ advises that the urine examination be controlled by an examination of the feces.

Differential Diagnosis.—The temperature is apt to be higher and the pain and tenderness less localized and more constant in *peritonitis*. Fecal vomiting would indicate *obstruction of the bowel*. Here also we may determine the patency of the bowel by injection or inflation. Intestinal obstruction is of comparatively rare occurrence in the epigastrium, where the pain and distention of acute pancreatitis are localized; there are likely to be present more marked and general tympany, including the flanks, and a circumscribed distention of the intestinal coils.

In *perforating gastric or duodenal ulcer* there is a history of pain after eating, hemorrhages from the digestive tract, and anemia.

Corrosive poisons may be excluded by the history of the case and by an examination of the mouth and vomitus. *Hepatic colic* must be excluded; the pain is intermittent, and referred more to the right side than in pancreatitis. There is in pancreatitis also an early collapse.

Acute gastroduodenitis is characterized by fever, by a history of injudicious eating, followed by mild inflammatory symptoms within a few hours, and by an absence of the sudden prostration and collapse so common to hemorrhagic inflammation of the pancreas.

Prognosis.—Acute hemorrhagic pancreatitis in most cases ends in death. In view of the ease with which the disease may be overlooked it is quite possible that certain cases of milder type may recover; in these the recovery has been said to follow a different affection. Osler reports a case diagnosed as one of intestinal obstruction in which abdominal section was performed and recovery followed. Thayer and Korte have also reported cases of cure in which a celiotomy decided the diagnosis.

The **treatment** as for shock by the use of external heat and of warm saline injections, hypodermics of morphin, atropin, strychnin, and of diffusible stimulants may probably be of some avail. Early operation with a view to establishing free drainage is the important factor in the treatment (Ochsner).

SUPPURATIVE PANCREATITIS

Pathology.—The suppuration may be diffuse, with numerous small abscesses; more commonly a single abscess exists in the head or body of the pancreas, which may be enlarged and its structure extensively destroyed. The abscess may communicate with peripancreatic areas of suppuration, or it may evacuate either into various organs (duodenum, peritoneal cavity) or externally. Pylephlebitis and hepatic abscess or pyemia may follow. A disseminated fat-necrosis is sometimes found.

Etiology.—Most of the cases occur in adult males *prior* to fifty years of age. Intemperance, trauma, and dietetic errors are among the *predisposing* causes. Infection takes place through the ducts, or from extension of neigh-

¹ *Brit. Med. Jour.*, May 19, 1906.

boring septic foci. Cholangitis, due to gall-stones, may extend to the pancreatic duct, producing suppurative pancreatitis.

Symptoms.—These may be *acute*, *subacute*, or *chronic*. Acute cases occur less frequently than the latter. **Acute suppurative pancreatitis** usually begins *suddenly*, with *severe epigastric pain*, *vomiting*, *hiccup*, *chills*, and an *irregular pyemic temperature*, *progressive tympanites* (at times limited to the left half of the abdomen), and perhaps acute splenic enlargement. *Constipation* may be followed later by *diarrhea* (sometimes fatty), and slight jaundice or glycosuria may appear. Brusch and Koenig¹ report a case in which the feces showed a decided diminution in the absorption of fats. *Prostration* is generally great, and death may set in within one week from the onset.

Not seldom, however, the *course* is prolonged to three or four weeks, the symptoms persisting with progressive emaciation and final exhaustion. *Rupture* of the circumscribed peritoneal abscess, evidenced by copious dejections in which the sloughing pancreas has been found, and rapid diminution in the size of the abdomen, may take place.

Again, the onset may be less severe, and yet the case progresses steadily downward with little pain, slight suppurative fever, anorexia, anemia, and gradually increasing debility, lasting for months or even a year, and ending in anasarca and death. A tender swelling is often *palpable*.

Diagnosis.—A limitation of the pain and a tender mass to the epigastrium, irregular fever, and the evidences of sepsis (leukocytosis, suppurative type of fever) are probably all that can be relied upon in arriving at a diagnosis. In fact, the diagnosis is hardly made *antemortem*.

For the differentiation from *circumscribed peritonitis*, *perforative gastric ulcer*, and *obstruction of the bowel*, *vide* p. 887.

The **prognosis** is unfavorable and the **treatment** surgical.

GANGRENOUS PANCREATITIS

Pathology.—The pancreas may be found in various stages of necrosis, depending upon the duration of the disease. It may be a dark brown, soft, friable, shreddy, and putrid mass, with areas of hemorrhagic infiltration and yellow softening, and surrounded by a dirty greenish, thin, purulent, and ichorous fluid. In cases lasting for from three to seven weeks the gland may be found completely sequestered, lying in the omental cavity as a small, thin, brownish-black, shreddy, and foul-smelling detritus, soaked in a purulent fluid. The peri- and parapancreatic tissues are usually involved with acute peritonitis. Splenic thrombophlebitis is commonly associated, and disseminated fat-necrosis is frequently seen.

Etiology.—Males and females are equally liable, and persons past thirty years of age are most commonly affected. Hemorrhagic pancreatitis is the most frequent antecedent of the gangrenous form. The disease may result also from perforative ulceration of the gastro-intestinal or biliary tract, or from the extension of a catarrhal inflammation of those tracts into the pancreatic duct (Fitz). Traumatism is a cause.

Symptoms.—These are essentially the same as those of hemorrhagic pancreatitis. The *course* may last longer, however, so that death may not occur until the second or fourth week, preceded by symptoms of collapse. The necrotized pancreas may be discharged per rectum, followed at times by recovery. An epigastric tumor usually appears. Mariño states that an excessively large amount of diastase is eliminated in the urine in necrosis of the pancreas.

¹ *Berlin. klin. Woch.*, December 25, 1905.

CHRONIC PANCREATITIS

Pathology.—The pancreas is indurated from an increased development of interstitial fibrous tissue. The glandular substance may be nearly obliterated, and, owing to pressure upon the duct of Wirsung, pancreatic cysts may be formed. Interstitial hemorrhages and peripancreatic adhesions may be present. In *chronic suppurative pancreatitis* there may either be small circumscribed abscesses or one large pyogenic cyst.

Etiology.—Chronic pancreatitis may be due to several attacks of the acute disease or to chronic inflammation of the pancreatic duct, often secondary to gastroduodenal catarrh. Since the distribution of inflammation often corresponds to that of the lymphatics the infection may be lymphatic rather than duct-borne. Persistent inflammation of contiguous structures may excite it. The majority of cases, however, arise from *disease of the biliary passages*, especially cholelithiasis as a result of obstruction of the ducts. The Mayos found 81 per cent. of their cases accompanied by gall-stones. Chronic alcoholism, syphilis, tuberculosis, and trauma probably lead to this disease. The condition may be limited to a part of the organ.

Symptoms and Diagnosis.—The symptoms are hardly indicative of the disease. The symptoms of *chronic gastric catarrh*, frequently attended by *diarrhea* and *large stools*, may compose the early clinical picture. Later there may be *paroxysms of deep epigastric pain, slight fever, marked anemia, with great anxiety and faintness*, occurring at irregular intervals. Some *ascites* and *jaundice*, due to pressure, may be observed. The detection of *free fat* in the dejections (*steatorrhea*) and undigested muscle-fibers (*azotorrhea*) in the absence of diarrhea are of great semiotic importance in the interlobular form. This may best be studied after a pancreatic test-meal consisting of scraped beef 100 gm., milk 1 liter, butter 100 gm. It has been suggested that the effect of the administration of the pancreatic ferments may be taken as a valuable diagnostic aid. On the other hand, the occurrence of *glycosuria* without pancreatic disturbance of digestion in the intestines (*e. g.*, *interacinar pancreatitis*) and *lipuria* would be of distinct diagnostic value. The presence of glycosuria probably indicates an extreme degree of destruction of this gland (Fitz). Walko regards the muscle-nucleus test as being of diagnostic value. Stadtmüller advises Sahli's glutoid capsule test. Klieneberger¹ advocates the casein test for trypsin.² Matko³ has described a test which will give exact information as to which of two conditions, namely, hyper- or hyposecretion of pancreatic juice, obtains. The most elaborate tests of the pancreatic secretions may be performed by means of the Einhorn method of extracting the duodenal contents and by means of the agar-tube method he has devised⁴ for studying the ferments in the duodenal contents.

Achylia pancreatica, absence of the pancreatic external secretions, usually arises in association with *achylia gastrica*, but frequently is an end-result of chronic pancreatitis. It may be recognized by the accompanying *creatorrhea* and *steatorrhea*.

Pancreatic infantilism, a term suggested by Bramwell,⁵ is characterized by arrested bodily and sexual development, chronic diarrhea, and flatulent distention of the abdomen, depending upon cessation of pancreatic secretion in the young, the result of chronic pancreatitis.

¹ *Medizinische Klinik*, Berlin, January-16, 1910.

² For the methods of obtaining the pancreatic secretion from the duodenum, see special works on diagnosis.

³ *Archiv. f. Verdauungs-Krankheiten*, Berlin, xix, No. 6.

⁴ *Jour. Amer. Med. Assoc.*, May 19, 1915, p. 1872.

⁵ *Edinburgh Med. Jour.*, May, 1915.

A *cachectic* appearance may be associated. *Circumscribed resistance* on palpation in the pancreatic area has been noted. Evidences of hepatic cirrhosis or of chronic renal and arterial disease may be present.

Differential Diagnosis.—

CHRONIC PANCREATITIS

History of acute onset in some cases.
Absence of, or gradual and incomplete, obstruction to flow of bile.
Distention of gall-bladder, gradual and of moderate degree.
Azotorrhea less common.
Enlarged cervical glands absent.
Emaciation and weakness less marked and of slow development.

PANCREATIC CARCINOMA

More gradual onset of symptoms.
Evidence of complete obstruction of rapid development.
Gall-bladder distention more rapid and often marked.
More common.
Present in certain proportion of cases.
Rapid, becoming pronounced, and characteristic of the disease.

The **prognosis** is grave. The greater portion of the gland may become functionless, however, as the result of progressive fibrous change, without much impairment of the health.

The major **treatment** is *dietetic*. Fats, since they demand the pancreatic ferment for their conversion, are to be interdicted, or, if permitted, are to be, so far as may be, artificially digested by the administration of salol-coated tablets of pancreatin and soda (gr. v to x—0.3–0.6) fifteen or twenty minutes after meals. Carbohydrates tend to stimulate pancreatic secretion. Minced raw pancreas promotes the digestion of fat and protein. Pankreon, a proprietary preparation of pancreas extract, enjoys a wide popularity. Bickel has shown that salt, alcohol, pilocarpin, and hydrochloric acid stimulate pancreatic secretion. The surgical treatment consists in the relief of tension by opening and draining the gall-bladder (Deaver).

PANCREATIC HEMORRHAGE

(Pancreatic Apoplexy)

It is only in recent years that this fatal affection has been isolated and defined, and mainly through the observations of Fitz, Zenker, and Draper.

Pathology.—The pancreas may or may not be enlarged; it may also be soft and friable. The hemorrhage is apt to occur into circumscribed areas of the gland—*e. g.*, its head, the interstitial and subperitoneal tissues. Extensive hemorrhage may be found in the omentum, transverse mesocolon, in the retroperitoneal fat tissue, and adjacent mucous surfaces. Secondary reactive inflammations and necrosis are commonly noted.

Etiology.—*Slight hemorrhages* into the pancreas may be found secondary to excessive chronic passive congestion, to hemophilic or purpuric cases, and acute infective diseases. These have, however, no clinical import. The etiology of *marked hemorrhage* into the pancreas is not known. Most cases have occurred in males (in 25 of 34 instances collected by the writer), and in adult or advanced middle life (the age in 13 of 30 cases having been over forty-five years). In the majority of cases the previous health was apparently good. Traumatism may be a direct cause. Again, some local vascular lesion (*e. g.*, necrosis), superinduced by alcoholic habits or a rich diet in an atheromatous person; or some corrosive action of the pancreatic secretion may operate as causes. It has been ascribed to the action of the glycerin set free during the fat-splitting process in the production of fat-necrosis. There was a history of chronic alcoholism in 12 of 18 cases (66.6 per cent.). Severe *symptomatic*

pancreatic hemorrhage is dependent on a variety of primary affections of the gland—*e. g.*, acute pancreatitis and carcinoma (Anders¹).

Symptoms.—The patient may have been in apparently robust health when the attack comes on with *sudden* and *startling* gravity. The most prominent early symptom is *intense epigastric pain*, together with a sense of *constriction*. *Nausea* and *vomiting* may be associated, and the latter is usually obstinate and gives only temporary relief. *Tympanites* may also occur. There are early and constant *general evidences of internal bleeding*—an anxious countenance, restlessness, depression, yawning, pallor, cold sweat, a lowered surface temperature, and a small, rapid, and weak pulse. *Prostration* and *syncope* follow, and death ends the case in from half an hour to twenty-four hours. Death is caused by reflex paralysis of the heart, due either to some coincident vascular affection, or to pressure, perhaps upon the solar plexus and semilunar ganglion (Zenker).

My table includes 24 cases, exclusive of 16 reported by Fitz, in which the condition led to speedy death from shock or from compression of the solar plexus. Owing to its "idiopathic" character in many cases, and quick destruction of life, pancreatic hemorrhage assumes intense medicolegal importance. A few cases reach death more gradually.

Diagnosis.—Given the suddenly developed signs of a concealed internal hemorrhage, with pain referred distinctly to the epigastrium, and vomiting and rapid collapse, a *probable* diagnosis may be made.

Treatment.—This consists in relieving the pain and in overcoming the collapse by free stimulation. An exploratory operation is advisable.

CARCINOMA OF THE PANCREAS

Pathology.—Primary carcinoma is the more frequent variety. It is of the scirrhus form in most cases, and usually involves the head of the gland, which may attain the size of a child's head. Not rarely the adjacent organs are found affected, either by direct or metastatic extension of the disease, or by the pressure of the growth; the liver, peritoneum, stomach, portal vessels, bile-ducts, and aorta may thus be involved. The pancreatic duct may be occluded, so as to form retention-cysts. In 1000 autopsies at the Johns Hopkins Hospital there were 5 cases of secondary carcinoma of the pancreas. Simple extension of carcinoma of the stomach or of the duodenum may involve the pancreas.

Etiology.—*Men* from forty to sixty years of age are most liable to carcinoma of the pancreas, though it has been met with in the *newborn*. Mirallié has collected 113 cases of primary carcinoma of this viscus (Fitz).

Symptoms.—These are scarcely ever sufficient to indicate the disease with certainty. There are usually a *stubborn dyspepsia*, a *progressive loss of flesh*, *anemia*, and a *dull*, or sometimes *neuralgic*, *epigastric pain*. *Nocturnal paroxysms* of pain are common, and are often accompanied by signs of *collapse*. In some cases *vomiting* and *diarrhea* are present. The *stools* may be light in color and greasy, and may contain blood. There may also be found an abundance of *undigested muscular fibers* in the stools in the absence of diarrhea; this is an incontestable proof of faulty pancreatic digestion. *Steatorrhea* is not commonly present. Among the *pressure-effects* due to carcinoma of the head of the pancreas there may be *jaundice* (pressure upon the common duct), which persists and "is associated with an enlargement of the liver and

¹ "Pancreatic Hemorrhage," *Jour. Amer. Med. Assoc.*, December 2, 1899.

gall-bladder." *Ascites* may appear from pressure on the portal vein. Chylous ascites, from pressure upon the thoracic duct, has been observed. The inferior vena cava may be compressed, causing *dropsy* of the lower half of the body; also the duodenum, followed by *gastrectasis* or by signs of *intestinal obstruction*. Carcinoma of the tail of the pancreas may be a cause of *hydronephrosis* of the left kidney, from pressure upon the ureter (Fitz). *Marasmus* and the *cachexia* develop rapidly in pancreatic carcinoma, and emaciation may become so extreme as to permit of a satisfactory *palpation* of the *tumor*, which occupies a position near the median line above the umbilicus. The growth, however, is palpable in about one-third of the cases only. *Glycosuria* may be associated.

Diagnosis.—Carcinoma of the pancreas is probably present in a given case in which there are rapid and progressive emaciation, deep-seated epigastric pain, muscular fibers in the stools without diarrhea, persistent jaundice, enlargement of the gall-bladder, and the detection of a deep-situated, fixed, and firm tumor in the region of the gland. In the majority of cases the duodenal tube allows of early and absolute diagnosis (Crolin).

Aortic abdominal aneurysm may be mistaken for carcinoma of the pancreas because of the transmitted aortic pulsation. But in aneurysm the impulse is expansile instead of two and fro, while the cancerous cachexia is absent. *Chronic pancreatitis* is distinguished by the history of gall-stone attacks, greater tenderness, and the less marked cachexia.

It is sometimes difficult to differentiate a malignant tumor of the pancreas from carcinoma of the *pylorus*, of the *stomach*, or of the *transverse colon* or *omentum*; the following points will help in the differentiation of the former two:

CARCINOMA OF THE PANCREAS

The tumor is deep seated and fixed; later it becomes slightly movable. It is not associated with gastric dilatation.

Symptoms of chronic dyspepsia appear.

The vomitus is bilious; rarely contains blood.

HCl is present, while there is an absence of lactic acid.

The stools contain undigested muscle-fibers and sometimes fat. There is an absence of pancreatic secretions. The urine may contain sugar.

There is usually jaundice; sometimes ascites is present.

Inflation of the stomach shows the absence of a pyloric growth.

The course is more acute. Death may occur within a few weeks or months.

CARCINOMA OF THE PYLORUS

The tumor is more freely movable, and is usually associated with dilatation of the stomach.

There are more marked gastric symptoms. There is "coffee-ground" vomitus; it is seldom bilious.

HCl is absent from the gastric contents; lactic acid is present.

Usually the bowels are constipated, with occasional diarrhea. The stools are black after a hemorrhage. The urine does not contain sugar.

Usually there is no jaundice or ascites.

Inflation shows the presence of a pyloric tumor.

The course is more chronic, and secondary growths often appear in the liver.

Neoplastic growths of the transverse colon are also more often superficial, and are movable and definable with the palpating fingers. There are symptoms of intestinal obstruction here, and inflation of the colon will show the relation of the tumor to the gut. In carcinoma of the colon the urine generally contains an increased amount of indican.

A discussion of the **prognosis** and **treatment** is unnecessary. Robson records 14 cases in which the portion of the gland affected was removed, with 10 deaths.

Other Tumors of the Pancreas.—Exceptionally, sarcoma, adenoma, and lymphoma occur. Sarcoma is rarely primary. Secondary nodules are more common. According to Körte, of 10 cases of tumor of the pancreas operated upon of late years, 6 recovered.

PANCREATIC CYST

Pathology.—Pancreatic cysts may be single or multiple, and large or small. When large they develop chiefly to the left of the median line. Single cysts may grow to an enormous size, containing as much as several gallons of fluid. The contents may at first consist simply of retained pancreatic juice, and usually the liquid is dark gray or dark brown, alkaline, and hemorrhagic or albuminous. A hematoma may be converted into a serous cyst. The specific gravity is from 1010 to 1024. Atrophy of the pancreas may ensue. Examined *microscopically*, the contents reveal leukocytes, red blood-corpuscles, oil-drops, fatty degeneration of the epithelium, and crystals of fatty acids and cholesterin.

Etiology.—Cysts of the pancreas may be due to occlusion of the pancreatic duct or its branches by compression from within or without the gland. They may also be due to tumors, to impaction of biliary or pancreatic calculi, to cirrhosis or angular displacements of the gland, or to the obstructive swelling from extension of catarrh of the bowel (Krecke). Of 121 cases collected by Körte, 33 were traced to traumatism. Lloyd suggests that the cysts that follow local injury are instances of encysted peritonitis involving the lesser omentum or that portion covering the pancreas (*pseudocysts*). Cysts of the pancreas usually occur in adults—in 66 of 116 cases in the third and fourth decades of life (Körte). Railton, however, met a case at six months of age.

Symptoms.—*Pain* may be absent, or it may occur as colicky paroxysms, referred either to the epigastrium, the left hypochondrium, or even the left shoulder. *Jaundice* and *ascites* are present in large tumors. *Vomiting*, *constipation*, or *fatty diarrhea* (rarely), with undigested proteins in the dejecta, or clay-colored, pasty, and offensive stools, may be present. *Albumin* and *sugar* may be found in the urine. *Emaciation* is not infrequent. *Intestinal hemorrhage* may occur and recur. A late and constant symptom is a *feeling of pressure* in the epigastrium. Rarely there is increased salivary secretion (pancreatic salivation). Occasionally all subjective symptoms are absent.

On **physical examination** a smooth, elastic, lobulated *tumor* is discovered in the region of the pancreas if the growth is moderate in size. Sometimes a very large cyst develops in a remarkably short space of time—*i. e.*, in a few weeks. When very large in size fluctuation is easily elicited. It may be slightly movable in the grasp and during inspiration. It usually presents between the stomach and transverse colon an area of dullness, and unless the tumor be of large size it is surrounded by tympanitic resonance of deeper timbre above than below. Auscultation may reveal a murmur caused by compression of the aorta. When the cyst attains enormous dimensions the usual *mechanical pressure effects* are produced. Körte points out that cysts without any inflammatory or traumatic etiology may exist for many years or even decades.

The **diagnosis** rests on the typical physical signs—the discovery on palpation of a smooth, elastic, lobulated, or rounded tumor that is slightly movable, and on percussion of a dull area that is not continuous above with the spleen and liver dullness. Resort has been had to filling the stomach with air and the colon with water (after purging), and thus proving by *palpation* the deep-seated situation (behind the stomach and omentum) of the tumor. If a fluid be obtained from the supposed cysts containing an alkaline liquid with proteolytic powers, it is almost certainly connected with the pancreas. A pancreatic cyst may be mistaken for an *ovarian cyst*, for *hydatid cyst* of the left lobe of the liver, of the mesentery, *renal tumors (cysts)*, *dropsy of the gall-bladder*,

and *retroperitoneal sarcoma* (*Lobstein's cancer*). The differentiation must be made by a careful study of all the points in the case.

The **prognosis** is good under proper treatment—incision and drainage. Of 31 reported cases thus treated, only 2 proved fatal.

PANCREATIC CALCULI

Pathology.—These are grayish-white, rounded concretions, consisting principally of calcium carbonate. The calculi may be as fine as dust or as large as an almond. Among their pathologic effects are fistulous communications with the colon, peritoneal cavity, and stomach; also cystic dilatation of the duct and abscess formation. Atrophy of the organ and carcinoma due to irritation of the stones may be associated.

Etiology.—Pancreatic calculi presuppose a catarrhal condition of the pancreatic duct, with retention or anomalies of the pancreatic secretion, or some form of obstruction of the duct. The condition is rare, and, unlike gall-stones, more common in males.

The **symptoms** are developed when, during the passage of the stones along the duct to the duodenum, the latter excite inflammation. In consequence, paroxysms of *pain* occur (*pancreatic colic*) that are usually attributed to gall-stones, and we are often unable to differentiate the two conditions. The *radiation* of pain along the lower left costal border to the back rather than to the right side, and possibly the *detection of free fat in the stools* or *glycosuria*, may aid markedly in the diagnosis.

The finding of characteristic *calculi* in the stools is entirely confirmatory. Minnich has reported a case in which the calculi were found in the stools. Jaundice rarely appears in pancreatic lithiasis.

The **prognosis** is mainly dependent upon the associated lesions and upon certain sequelæ—pancreatic cysts and chronic pancreatitis.

The indications for **treatment** do not differ materially from those of hepatic colic. Surgical intervention should be considered.

XII. DISEASES OF THE PERITONEUM

ACUTE PERITONITIS

Definition.—An acute inflammation of the peritoneum. The condition may be primary or secondary. Clinically, two varieties—general and circumscribed—are recognized, while, pathologically, the disease is classified according to the nature of the exudate.

Anatomic and Physiologic Peculiarities.—The surface area of the peritoneum is quite extensive, being almost equal to that of the skin. Fluids of all sorts are rapidly absorbed by the peritoneum, and thus, if they be poisonous, constitutional manifestations are speedily propagated.

Pathology.—Upon opening the abdomen in **acute generalized peritonitis** vascular injection both of the serous covering of the intestines and of the parietal layer is observed. Even in the most recent cases the coils of intestines may be feebly glued together by lymph, while in those of longer duration the adhesions are quite firm. As in the analogous inflammation of the pleuræ

or pericardium, we distinguish the following forms pathologically: (a) A *plastic* or *fibrinous*, in which there may be also a small amount of serum present. (b) *Serofibrinous* (inflammatory ascites), chiefly characterized by considerable serofibrinous fluid; additionally, the coagulated fibrin forms a covering for the parietal and visceral layers of the peritoneum. (c) *Purulent* (most frequent). The amount of inflammatory exudate varies greatly, and is frequently enormous, exceeding 30 liters (quarts). Putrefactive decomposition of the pus may occur, especially in cases due to gangrene of the gut or to puerperal peritonitis (violent forms), giving rise to a thin fluid that is grayish-green in color, is sometimes distinctly sanious, and ill-smelling. Offensive gases are present with relative frequency. These may come from the intestinal canal, following the track of perforations; or they may be due to decomposition of the purulent exudate. (d) *Hemorrhagic*.—This form is common in cases that are of a carcinomatous or tuberculous nature, and in subjects whose vitality has been lowered by various primary affections. It may also be of traumatic origin.

Changes in the Intestines.—The effect of acute peritonitis is to thicken the coats by inflammatory edema; soon the musculature is paralyzed. An associated catarrh of the mucosa of the intestines is sometimes observed.

The different pathologic varieties above described may be limited to definite portions of the peritoneal sac, when they are termed "encapsulated" or **localized acute peritonitis** (*vide supra*). In localized purulent peritonitis further extension of the process is arrested by the rapid formation of circumscribed adhesions due to the exudation of lymph; there are also undoubted instances of circumscribed, aplastic peritoneal abscesses. The milder forms of limited plastic and serofibrinous peritonitis pursue a slower course than the purulent variety, and commonly lead to the development of firm adhesions (*adhesive peritonitis*). Since the histologic changes in acute peritonitis do not differ from those observed in other inflammations of serous membranes, the reader is referred to the section on Pleurisy (p. 545) for their consideration.

Etiology.—The irritants causing acute peritonitis may be: (a) **Bacteriologic Irritants**.—These may be *specific* or *non-specific*. Among the non-specific agents are the pyogenic bacteria. Grawitz has shown that the latter can only cause peritonitis under certain conditions: they excite the disease when injected into the peritoneal cavity or when poured out from the diseased or injured membrane more rapidly than the peritoneal tissue can dispose of them; also when the epithelial layer has from any cause been removed. Absorption may be interfered with, while the pyogenic micrococci continue to enter from the bowel or other viscera in great numbers. Unfortunately, the clinical practitioner often meets with cases of peritonitis in which these pyogenic organisms are the only positive agents. These essential conditions obtain when the membrane is wounded by the perforation of gastric and intestinal ulcers, and also in perforation of the gall-bladder, in rupture of the liver, kidneys, and spleen, when the latter are the seat of abscesses, and, with uncommon frequency, in appendicitides, in purulent inflammation of the ovaries and of the fallopian tubes. "There are instances in which peritonitis has followed rupture of an apparently normal graafian follicle" (Osler). These perforative forms of peritonitis are at the same time the most serious and the most important. "Death may result from the injection into the peritoneal sac of putrid liquid if the dose be large enough; but it is practically the same whether the fluid is injected into the blood-stream at once or allowed to find its way into the peritoneal cavity, and the result follows nearly as quickly in the one case as in the other" (Moullin). The rapid absorption of liquid substances gives full opportunity for the phagocytic action of the white blood-corpuscles.

Among specific organic irritants the *tubercle bacillus* deserves special men-

tion, though, as before intimated, a discussion of its characteristics is not in place here. The *Streptococcus pyogenes* is probably responsible for the most violent forms of peritonitis (e. g., those occurring in puerperal sepsis and post-operative varieties). The *Staphylococcus pyogenes aureus* (or *albus*) has also been found in such instances.

The *Bacterium coli commune* (always present in the intestinal tract) is frequently the leading factor in peritonitis of intestinal origin, and usually in association. The streptococcus is often present also in these cases. In 12 cases of primary peritonitis, 11 were instances of mono-infection; and in operations upon the peritoneum (not involving the intestine), 25 of 33 cases were mono-infections, the *Staphylococcus aureus* being present alone in 12 and the streptococcus in 5 (Flexner). Occasionally other organisms, as the *pneumococcus*, the bacillus of Friedländer, or the *Bacillus pyocyaneus*, *typhosus*, and *proteus*, the *gonococcus*, the *Bacillus aerogenes capsulatus*, and the *anthrax bacillus*, have been found. Multi-infection is quite common. The bacteriologic classification of peritonitis would be desirable from the standpoint of treatment (*vide infra*), but it cannot be applied clinically.

(b) **Chemical Irritants.**—These are rather numerous and varied, though all produce their effects in one of two ways. First, the irritant acts upon the membrane, exciting an exudation of lymph. Here constitutional intoxication is secondary. Second, the chemical irritant may be quickly absorbed, and produce systemic intoxication immediately (rare).

(c) **Mechanical irritants**, as, for example, a hernia, which may produce a localized peritonitis.

(d) Peritonitis may be due to a direct extension of infective processes from the intestinal tract or other adjacent organs (*secondary peritonitis*). The bacteria often penetrate the intestinal wall and gain the peritoneum by way of the lymph-channels. The disease is often secondary to pleurisy, the irritants passing through the diaphragm along the course of the lymphatics. Peritonitis may be secondary to chronic Bright's disease, gout, and arteriosclerosis; in such cases the special irritants probably reach the membrane through the general circulation.

(e) The disease is very rarely *primary (idiopathic)*. These so-called idiopathic cases are probably instances of cryptogenetic infection.

Clinical History.—The symptoms are of a *local* and a *general* nature. In sthenic cases of perforative peritonitis they occur simultaneously with great severity and suddenness. On the other hand, in asthenic cases, such as occur frequently in those already afflicted with some serious disease that is apt to result in perforation (for example, typhoid fever), both the local and constitutional symptoms are more or less overshadowed by the disturbances due to the primary affection. Again, circumscribed abscesses of the peritoneum often lead to diffuse suppurative peritonitis, and the change may take place so insidiously as to defy detection. These anomalies from the typical onset and course of the disease are by no means exceptional, and should ever be distinctly borne in mind by the physician.

Local Symptoms.—Among these, *pain* is the chief. The seat of greatest intensity of the initial pain corresponds, in most instances, with its point of origin. Hence the character of the causal disease is often betrayed by the location of the chief pain. For instance, if this appears in the region of the stomach and is referred to the back or shoulders, we would think of gastric ulcer; if in the ileocecal region, of appendicular disease, and so on. It follows that quite commonly the severest pain is in the lower half of the abdomen. It is almost constant, increases in severity, and finally becomes general and excruciating; it is also much increased by deep respiration, by pressure, and by

bodily movements. It remits, but does not intermit, though it may be slight in asthenic (*secondary*) cases. Here the patient is excessively weak, while his sensibilities are greatly blunted by the primary infection. Gastro-intestinal symptoms are prominent, more particularly *vomiting*, which occurs early and is apt to recur with comparative frequency. It may follow the taking of food, though, in my experience, it has more commonly taken place spontaneously; the *vomit* then consists of a watery liquid greenish in color and containing mucus. In rare instances it is a dark brown liquid. Vomiting may sometimes be absent, however, owing to the presence of marked *asthenia* or *coma*. *Eructations* and, later, *hiccup*, are common, and *constipation* is usually present and may become exceedingly obstinate. On the other hand, there may either be *diarrhea* throughout the disease, or this symptom may precede the constipation. It is to be ascribed to an increased peristalsis due to intestinal catarrh. Constipation is due chiefly to paralysis of the musculature of the intestine. The *apex* of the heart is elevated; the *tongue* at first is furred and moist, and later it is dry, brown, and often fissured.

Constitutional Symptoms.—At the onset the patient in *sthenic* cases is seized with a *rigor* that may be repeated. The *shock* sustained by the nervous system in acute peritonitis is most intense; the *temperature* rises immediately, though it does not, as a rule, attain a high level, and it frequently presents a curve more or less characteristic of suppuration. The rectal temperature is often relatively high; the respirations are shallow (costal) and much accelerated, ranging from 30 to 40 per minute. We have, as factors to account for this increased frequency, (a) a crowding upward of the diaphragm, (b) the greatly enfeebled heart, and (c) the pain occasioned by throwing the diaphragm into action. The *heart* becomes weak, the pulse-rate at first, however, ranging from 100 to 130, with a rise in the blood-pressure. The pulse toward the close becomes exceedingly frequent (130 to 150 beats per minute) and is almost imperceptible. Other evidences of more or less marked *circulatory collapse* soon manifest themselves. The patient wears an anxious facial expression, the eyes are sunken, the features pinched and cool, the lips cyanotic, and the extremities are likewise cold and somewhat livid. The patient invariably assumes the *supine position*, with the lower extremities drawn up, so as to lessen the tension of the abdominal muscles, and thus to secure the greatest possible comfort. The *urine* is scanty in amount, high colored, and contains indican. There may be a retention of urine; though oftener, perhaps, micturition is more frequent than in health. A polynuclear leukocytosis occurs, if we accept the fulminating cases in which leukopenia may be found. Marked *nervous symptoms* do not appear; indeed, the mind usually remains quite clear to the close. Moderate delirium, however, which sometimes gives way to mild stupor, is met with occasionally. In the *asthenic form* of acute peritonitis the constitutional features differ from those described above. The *temperature* is usually subnormal (except in the rectum), the pulse is exceedingly feeble and running, and the signs of collapse are well marked from the onset.

Physical Signs.—*Inspection* reveals the gradually increasing abdominal distention, that frequently becomes excessive if the intestinal walls are more or less completely paralyzed. Often the amount of effusion soon becomes large, when the abdomen appears widened. The degree of distention bears a definite relation to the severity of the inflammatory process, and is in inverse ratio to the development of the abdominal muscles. Thus, when the latter are poorly developed or greatly relaxed the expansion is enormous. On the other hand, when they are strong the muscles are apt to be quite tense, permitting of a relatively slight enlargement; the abdomen may even show a small

concavity, in which case the walls are of a board-like hardness. The cardiac apex-beat is displaced upward and outward, occupying the fourth interspace.

Palpation elicits extreme tenderness, more particularly in the vicinity of the umbilicus. Rigidity of the abdominal wall is the most important symptom in perforative peritonitis (J. C. Wilson). In not a few instances of acute peritonitis have I been able to detect a distinct friction-rub. *Percussion* gives at first an exaggerated tympanitic note. There is often an absence of liver dullness in the mammary line, and rarely also it is absent in the midaxillary line. In pneumoperitoneum, resulting from perforation of the gut or stomach, we often meet with an absence of liver dullness, especially when a large purulent effusion coexists. Again, a great diminution in, or even the total effacement of, the dull area may be caused by coils of intestine forcing their way up between the anterior surface of the organ and the abdominal wall. When air is present within the abdominal cavity and the patient lies upon his right side, splenic dullness disappears from displacement by the air. The lower level of cardiac dullness is as high as the fifth rib.

By means of *percussion*, sooner or later, fluid effusions are usually detectable in sthenic cases. On the other hand, there may be in markedly asthenic cases an amount of liquid exudation present that is often too small to admit of detection. When the effusion is considerable in quantity, there is percussion dullness over the most dependent parts; when tympanitic distention is excessive, however, even a copious effusion may be so effectually hidden as to elude discovery in this way. I have elsewhere reported one such instance.¹ When the decubitus can be altered, the line of dullness will be found to be movable, but the degree of mobility varies exceedingly, depending upon the extent of the peritoneal adhesions present. The effused material is partly contained in pouches, giving rise to areas of circumscribed dullness.

Course and Prognosis.—Asthenic forms, with rapid pulse, leukopenia, and persistent low temperature, are perhaps invariably fatal. Though the local signs are not marked, the characteristic evidences of collapse or of septicæmia appear. The *duration* in sthenic cases rarely exceeds one or two days; in asthenic cases it is longer, lasting from four or five to six or eight days. Death sometimes occurs quite suddenly, owing to cardiac exhaustion or primary shock. The clinical peculiarities and the course are greatly influenced by the etiology—*e. g.*, cases due to *Streptococcus pyogenes*, *Bacillus pyocyaneus*, and *Bacillus coli* are extremely fatal, while those due to the gonococcus and pneumococcus are more benign. Acute generalized peritonitis arising from perforative appendicitis, puerperal sepsis, or from external injuries is usually of a violent form and ends fatally, unless subjected to early operation. Perforation of a gastric or duodenal ulcer gives a better prognosis, since the number of colon bacilli steadily diminishes from the ileocecal valve to the stomach (Cushing and Livingood). When the disease is traceable to rheumatism or exposure, recovery may take place. A case of the sort occurred in my own practice in which acute serofibrinous peritonitis with considerable effusion was associated.

Peritonitis in Children.—Syphilitic peritonitis may be congenital, and peritonitis caused by an inflamed cord may be met in the newborn. In children the common causes are trauma and appendicitis.

The *symptoms* differ from those presented in the adult. However severe the pain, the child merely utters a short cry or whine. Constipation and vomiting are less conspicuous features. Meteorism is pronounced and fever high. Convulsions not rarely occur. The condition is extremely grave in young children.

¹ *Internat. Med. Clinics*, vol. iii, second series, p. 82.

LOCALIZED OR PARTIAL PERITONITIS

(Circumscribed Peritonitis; Visceral Peritonitis)

This is a localized form of inflammation of the peritoneum that is coextensive only with the serous covering of single organs, and involves a limited portion of the membrane. Hence, to the various forms of circumscribed peritonitis such terms as perihepatitis, perisplenitis, perinephritis are applied. The condition is found in its most important form in *appendicitis*, but the points that are characteristic of localization in this disease have been mentioned elsewhere (*vide* Appendicitis, p. 807). Localized peritonitis may also be caused by carcinoma.

Pyopneumothorax subphrenicus is the term applied to a circumscribed peritoneal abscess containing air, situated between the liver and diaphragm. The condition is described under the heading Acute Perihepatitis (p. 858).

Local pelvic peritonitis (perimetritis) is the most frequent variety, and is secondary, as a rule, to inflammation about the uterus, fallopian tubes, and ovaries. The leading causes are tuberculosis, puerperal septicemia, and gonorrhea. F. Billings points out that when abdominal rigidity is absent in this form rectal examination will disclose rigidity of the pelvic muscles.

Symptoms.—The *local* clinical features do not differ from those described under the diffuse form, but their area of distribution is more or less strictly limited to definite regions. By eliciting the *physical signs* with care fluid collections are sometimes demonstrable. The *constitutional symptoms* are likewise similar in character, though less marked than those belonging to the diffuse variety. There may be *rigors*, and *pyemic symptoms* appear, together with the temperature-curve peculiar to this condition. The danger of involvement of the general peritoneal cavity as the result either of rupture or of an extension of septic inflammation is a constant menace. When the peritonitis remains localized these cases may pursue a subacute or even a chronic course, though grave constitutional disturbance finally develops.

Diagnosis.—In attempting to diagnosticate acute generalized peritonitis it is of the utmost importance to keep in remembrance the sthenic and asthenic forms of the affection. The character and gravity of the symptoms are such as to render the diagnosis of the sthenic form entirely easy. Especially valuable local features are the *constant pain*, the *marked tympany*, the *excessive tenderness under pressure*, and the *vomiting at intervals of a greenish fluid material*. Of equal importance are general disturbances previously depicted, particularly the *cool, sharpened features* and the *ever-increasing weakness and rapidity of the pulse*. These clinical manifestations clearly foreshadow cardiac exhaustion or fatal collapse. When the cases are not seen until the advanced stage has arrived, however, the diagnosis presents many difficulties. Nothing is now more important than the consideration of the previous history, with a view to determining the point of origin and the probable cause of the disease (usually some such primary disease as appendicitis or gastric ulcer), as well as the accompanying symptoms and physical signs.

The smaller number of cases belonging to the adynamic type are from the start extremely difficult of diagnosis. Here a history that is clearly indicative, the presence of moderate tenderness, and augmented tension of the abdomen, with profound collapse, would point to this condition.

General Differential Diagnosis.—*Hysteric peritonitis* (so-called) simulates the genuine form so closely as to make the distinction an insurmountable difficulty, unless there be accompanying hysteric manifestations. Previous similar attacks point to hysteria. In my experience the tenderness has been out of proportion to the gravity of the constitutional disturbance. The patient

often complains bitterly before the abdomen has been touched; on the other hand, when his attention has been otherwise engaged, firm and prolonged pressure can be made.

Acute generalized peritonitis occasionally supervenes on *typhoid fever*. In such cases it is caused either by perforation of the intestine or by a direct extension of inflammation from a deep typhoid ulcer. If consciousness be retained, sudden severe pain, tenderness followed by excessive tympany, a peculiar indescribable *facies*, and signs of collapse will establish the diagnosis. Peritonitis, however, develops more often in those grave cases of typhoid that are attended with coma, marked meteorism, and profound adynamia, and under such conditions it often remains unrecognized (*vide Typhoid Fever*, p. 33).

In *acute enteric catarrh* the meteorism and sensitiveness under pressure are usually less pronounced; the disease also lacks the marked constitutional symptoms of acute peritonitis. The pain is colicky, is characterized by exacerbations, and even intermits in enterocolitis, while it is constant in peritonitis. The pain in acute enteric catarrh is often followed by diarrheal stools.

Intestinal colic is distinguished by the flatulence, the borborygmi, and the wandering pain in the absence of all other phenomena.

Rheumatism of the abdominal muscles excites pain, which, however, is superficially located (the disease affecting the muscular layer), and is frequently associated with rheumatism in other parts of the body. There may also be a clear history of previous rheumatic attacks.

Pleuropneumonic diseases may simulate peritonitis, since the early symptoms, especially the pain, may be referred to the abdomen. The temperature is apt to be higher and the respirations more rapid in intrathoracic affections—points that should lead to a thoracic examination.

Tubal pregnancy (after rupture) has also been confounded with acute peritonitis, but its differential diagnosis is fully discussed and must be looked for in special works on gynecology and obstetrics.

Rupture of an abdominal aneurysm and *embolism of the superior mesenteric artery* are also conditions that give rise to peritonitic symptoms—meteorism, recurrent vomiting, and violent collapse.

Acute generalized peritonitis in its symptomatology bears a close resemblance to acute intestinal obstruction, and the discriminating points have already been tabulated (*vide* p. 818).

Prognosis.—This is less grave than in the diffused form, and recovery may often be expected. Timely surgical intervention, particularly if a tendency to spreading be shown, is often helpful or may even lead to prompt recovery.

Sequelæ.—If recovery should take place, the inevitable result is the formation of adhesions and fibrous bands, the contraction of which may cause constriction of the bowels, bile-ducts, and other structures.

Treatment.—Hygienic and Dietetic.—The patient should be placed in the sitting posture in order to favor drainage into the pelvis, and should be kept absolutely undisturbed. The sick-room should be of good size and well ventilated; the temperature should be kept at from 65° to 70° F. (18.3°–21.1° C.). The diet demands careful attention. Food, as a rule, should be interdicted, as it promotes peristalsis. If it is given for any reason, but very small amounts of liquid food should be administered, such as pancreatized milk. Other liquid food-stuffs, as meat-juices and egg-white (diluted), may also be allowed. In asthenic cases alimentation must be generous, although solid articles of food are to be avoided.

Medicinal.—Surgical measures are recommended by most writers in the treatment of generalized peritonitis, although it is now generally conceded that in cases due to infection by the gonococcus and the pneumococcus noth-

ing is to be gained by immediate operation, but the formation of a localized abscess should be waited for before opening the abdomen. This is especially true of a gonococcus peritonitis as shown by Hunner and Harris.¹ Whenever, however, there is reasonable doubt regarding the diagnosis, operation should not be delayed. Formerly the opium method of treatment, first instituted by the late Alonzo Clarke, was followed by the bulk of the profession. His plan was to administer $\frac{1}{2}$ gr. (0.0325) of morphin or its equivalent (gr. ij—0.13) of opium, and repeat the dose every second hour until the respirations were lowered to 10 or 12 per minute. The pupils were then observed to be contracted, the pulse from 76 to 80, the pain relieved, and peristalsis arrested. This latter effect was obtained, even though in the case of some patients larger doses of opium than here indicated were necessary; in others smaller doses sufficed. The bowels were absolutely let alone. It is explained that in favorable cases the bowels moved spontaneously at the end of one week, and that the patient then entered upon convalescence. This method of treatment is at present adhered to only by the ultraconservative element of the profession. Stockton² advocates the opium treatment in the milder cases before the peritoneal inflammation has become generalized. The moderate use of opiates, however, results only in covering up symptoms, not in curing the patient. Stockton believes that the proper treatment of oncoming septic peritonitis is immediate operation. *Purgatives are absolutely contraindicated.* They promote peristalsis, favoring perforation and spreading infection.

In cases in which the vital forces are profoundly depressed, as shown by the symptoms of collapse and there is not even a reasonable suspicion of perforation, opium should be tried. When, however, the evidences of perforation into the general peritoneal cavity are complete and competent surgical skill is not at hand, large doses of morphin are imperative, with a view to relieving pain, keeping the patient at absolute rest, and sustaining the heart against the exhausting effect of shock. The value of serum and vaccine therapy in this disease is as yet uncertain (Fowler). For the systemic collapse and for combating thirst and vomiting I can warmly recommend *saline infusion*, preferably according to Murphy's drop method of rectal irrigation. Saline solution may also be given by hypodermoclysis or intravenous injections in order to "combat shock, relieve thirst, stimulate excretion, counteract toxemia, and restore the body fluids" (Jopson). Many surgeons simply give tap-water by the rectum, or if acidosis is feared as a result of long withdrawal of food, Crile's glucose (2 per cent.)—sodium bicarbonate (3 per cent.)—solution may be used.

Local Treatment.—The ice-bag or ice-poultices are often of distinct service in the earlier stages. Later, in localized peritonitis, blisters may be useful, although objectionable in the event of surgical intervention becoming necessary.

In order to relieve the *tympany* turpentine stupes are serviceable. I have also had favorable results from the insertion of the long rectal tube (soft esophageal) well up in the colon. Pituitary extract and eserine are reliable drugs to relieve tympany if there is no fear of promoting peristalsis, as after operation and drainage.

Pain.—No matter what general plan of treatment is pursued, the pain must be relieved by opium in some form. *Thirst* is to be relieved by chipped ice, over which a little brandy may be sprinkled, and by hypodermoclysis and proctoclysis. The *vomiting* is best treated by carbonated water exhibited in small quantities, or by iced champagne similarly administered. One-drop doses of creosote are also of value. Failing to control the vomiting by these methods is an indication for gastric lavage.

CHRONIC PERITONITIS

Definition.—Chronic inflammation of the peritoneum.

Pathology and Etiology.—The anatomic characters presented by different cases are greatly varied, though for convenience of study they may be considered under two divisions (as in the acute form): 1. *Local*. 2. *General*. The latter may be (a) **Adhesive**, when the peritoneal layers are inseparable and indistinguishable, with an obvious thickening, and the intestinal coils are everywhere seen to be grown together. The cause is usually a previous acute attack, and, doubtless, the condition is commonly produced by the *acute progressive form* (Mikulicz), which is *localized* at the start. Rheumatism is also an occasional factor, and adhesive peritonitis, confined, as a rule, to small circumscribed areas, may be engendered by the trocar used for tapping in ascites.

(b) **Proliferative Peritonitis.**—“The essential anatomic feature is great thickening of the peritoneal layers, usually without much adhesion” (Osler). It has been found to be associated with cirrhosis of the stomach, liver, and other abdominal organs. The amount of liquid effusion, varying in composition from serum to pus, is usually moderate, and it may, owing to adhesions, be loculated. The omentum is sometimes rolled up in the form of a massive cord, its long axis taking the transverse direction. In an autopsied case of chronic peritonitis apparently secondary to hepatic cirrhosis I observed in the thickened membrane numerous small hard nodules that were at the time regarded as being tuberculous in nature. It is to be pointed out, however, that a number of cases of pseudotuberculosis have been recently reported. In several of these an operative incision was followed by recovery, and this was put down as a cure of tuberculous peritonitis till the microscope showed the nodules to be fibrous. Among *etiologic factors* chronic alcoholism stands first. In one case that I saw, acute followed by chronic rheumatism seemed to be the only assignable cause. The condition is sometimes secondary to chronic nephritis, to syphilis, or a general fibroid process.

(c) **Cancerous Peritonitis.**—Quite often in connection with cancerous growths in the peritoneum a well-marked peritonitis is evident. There may be a liquid exudation, which is apt to be bloody and chylous.

(d) **Chronic Tuberculous Peritonitis.**—This is the most important variety, and it may be part of a multiple serositis. The inflammatory lesions are quite pronounced, as a rule, and lead to marked thickening of the layers—changes that are to the naked eye identical in appearance with those noted under the preceding forms, but which on histologic examination show the presence of tubercles and caseous degeneration. The amount of liquid effusion varies within wide limits and is usually blood-stained. The frequent association of hepatic cirrhosis with tuberculous peritonitis should be remarked. From tuberculous peritonitis tuberculosis of the peritoneum is also to be distinguished clinically; the latter may be acute or chronic, and the lesions consist in the deposit of various sized tubercles without much collateral inflammation. Acute and chronic tuberculosis of the peritoneum have received due consideration in their appropriate place (p. 267).

(e) **“Chronic Hemorrhagic Peritonitis.”**—This term should be limited in its application to that form first described by Virchow, in which the peritoneum is at intervals partly covered by a membrane of new connective tissue that alternates, as it were, with layers of hemorrhagic extravasation. A similar condition results from the frequent use of the trocar for ascites.

Chronic Localized Peritonitis.—This is of frequent occurrence, and is confined most commonly to the serous covering of the spleen, liver, and certain portions of the bowel, particularly of the appendix. The condition results

in the formation of *firm adhesions*, with matting of the intestinal coils and fibrous bands. It is usually the *sequel* of localized acute peritonitis occurring in connection with inflammatory diseases of the different abdominal organs.

Symptoms of the General Forms.—Whether chronic peritonitis follows the acute form or not, it always develops insidiously. Most cases remain quite obscure, and not a few are totally devoid of clinical manifestations. The patient may complain of disorders of the *alimentary tract*, and especially of *constipation*. On the other hand, *diarrhea* is observed in tuberculous peritonitis from associated intestinal ulceration. Rarely pressure, from the traction force of the adhesions, on the common duct or portal vein gives rise to obstructive *jaundice*, or *ascites*, as the case may be. I saw an instance recently in which compression of the veins leading to the lower extremities caused unilateral *edema*. *Subjective abdominal sensations*, as uneasiness, oppression, heat, and pain (often colicky in character), are experienced. Sometimes pain is entirely absent.

General symptoms appear, though they are quite vague as a rule. An irregular fever, hectic in type, is occasionally observed. Later, increasing general weakness, emaciation, and general nervous disturbance become rather prominent clinical features. Some of these phenomena, however, may be due to associated affections. When the peritonitis is tuberculous we frequently see clinical evidence of the primary process in other parts of the economy (*vide Tuberculous Peritonitis*, p. 267).

Physical Signs.—*Inspection* usually shows the belly to be slightly, though unequally, enlarged. As in acute peritonitis, so here we may find the belly flat, or even concave, with great tension of its walls. Fluctuation is sometimes obtainable over limited areas only, since the fluid is not free, but encapsulated. The rolled-up and shrunken omentum may be *palpable* as a sausage-shaped transverse coil, and thick bands of adhesion may also not rarely be felt, in different places, as hard, uneven masses simulating neoplasms. The *percussion-dullness* varies considerably with the amount of effusion, its arrangement, the degree of peritoneal thickening, as well as with the character and locality of the fibrous bands. It follows that in some cases irregular areas of tympanitic percussion-resonance and of dullness are to be found side by side. Obviously, too, changing the patient's posture would not give movable dullness, owing to sacculation of the fluid. A marked sense of resistance is experienced on percussion over the dull area. *Friction-fremitus* can sometimes be elicited, and less frequently *friction-sounds* also during forced breathing.

Symptoms of Chronic Local Peritonitis.—This condition is often entirely latent. When not so, the most characteristic indication is constant *pain*, distinctly colicky in nature and often quite intense. The *physical signs* are negative as a rule. Very rarely a resistant, ill-defined mass, corresponding with the seat of greatest pain, can be felt. A fibrous band may be so arranged as to form a snare through which a knuckle of bowel may pass, with resulting strangulation. Fitz's analysis of 295 cases of strangulation showed 63 to be caused in this way.

Differential Diagnosis.—That form of chronic peritonitis (serous or granular) most frequently seen in females at the commencement of puberty is hard to discriminate from *tuberculous peritonitis*, since the latter may be more or less latent. Tuberculous peritonitis is generally attended with fever, more pain and tenderness, and there is a more rapid accumulation of the exudate. Again, the general features, debility and loss of flesh, progress more rapidly than in granular peritonitis. The detection of conclusive evidence of the disease in persons closely related, or on physical examination of associated pulmonary tuberculosis or pleuritis, would render the diagnosis of tuberculous

peritonitis almost certain. In obscure cases the guinea-pig should be inoculated with the exudate (see *Pleurisy*, p. 558).

Course and Prognosis.—The milder varieties of simple chronic peritonitis may, though rarely, reach a favorable issue. In cases belonging to this category the disease takes a chronic course, and leads gradually to a condition of extreme debility, even if it does not, as is usually the case, materially shorten life. Tuberculous peritonitis has, until recently, been regarded as being almost uniformly fatal at the end of several months. Cures that must be attributed to the surgeon's work, however, are at present by no means uncommon. Rarely, spontaneous cures also occur, particularly in peritoneal tuberculosis without fever or with only slight fever. "This form runs in itself a favorable course" (C. Fenger).

Treatment.—The patient should be enabled to enjoy the benefits of good sanitary surroundings. Close attention is to be paid to the *diet*, the coarser vegetables and sweets being prohibited, since they increase the pain by exciting the production of gas. A change of air has improved the condition in several instances occurring in my own practice. The usual constipation may be relieved by simple enemata or by the use internally of the fluidextract of cascara sagrada. Tonics and alteratives may also be employed. In the early stages some degree of relief, or even a curative effect, may be secured by *local means*, as the application of equal parts of belladonna and iodine ointments until mild counterirritation is produced. Ichthyol ointment is also serviceable. After all, however, little is to be gained from therapeutic measures, and it is to surgery that we must look for fresh triumphs in the treatment of this truly distressing complaint. Cases of chronic localized peritonitis with adhesions have been operated upon successfully by W. E. Ashton, H. A. Kelly, and others. Instances of chronic generalized peritonitis, whether tuberculous or not, in which the fluid effusion reaccumulates rapidly after repeated tapings, also furnish adequate indications for operative procedures.

ASCITES

(*Hydrops Peritonei; Dropsy of the Peritoneum*)

Definition.—An accumulation of serum in the peritoneal cavity resulting from stasis (obstruction) in the branches of the portal vein.

Pathology.—The quantity of liquid contained in the peritoneal cavity is quite variable, though it often amounts to several gallons. It is clear and transparent, or slightly opalescent, especially on standing, and the specific gravity ranges from 1010 to 1014. In color it often has a faint lemon-yellow tint; it may, however, be either distinctly yellow, brownish (in cirrhosis), bile-stained (as when jaundice is present), or slightly blood-stained. In reaction it is usually alkaline; very rarely it is either acid or neutral.

The ascitic fluid usually contains much albumin, resembling in this respect blood-serum, as would be expected from its source. The percentage of albumin may be approximately ascertained by noting the specific gravity of the fluid by the urinometer. Thus, in true ascites the specific gravity ranges from 1010 to 1014, and the variation in the percentage of albumin is from 1 to 2. In effusions due to *peritonitis* the percentage of albumin ranges higher (2.5–6 per cent.); hence the specific gravity ranges correspondingly higher (1015–1024). The standing specimen may show to the unaided eye a minute coagulum of fibrin. In the lower layer of the fluid the microscope discloses leukocytes,

red blood-corpuscles (in abundance when ascites is due to general venous stasis), fat-cells, endothelium, and cholesterin crystals. In ascites the microscopic appearances of the peritoneum are usually normal, while in instances of peritonitis the membrane, including the subperitoneal fibrous tissue, is opaque and slightly thickened.

In the so-called *chylous ascites* the fluid resembles milk; it contains fat-droplets, a few lymphocytes, and sugar (Hodlmoser). This condition may be associated with a collection of milky fluid in the left pleural sac, when there is thrombosis of the subclavian vein at the point at which the thoracic duct enters. The term *ascites adiposus* is applied to a milky fluid, in which the origin of the fat is the debris of degenerated epithelial cells, with few fat-droplets and no sugar (Quincke and Senator), to the exclusion of other morphologic elements.

In long-standing cases the abdominal and the thoracic organs become atrophied from pressure exerted by the dropsical fluid.

Étiology.—Among the chief causal factors are those that hinder or arrest the return of venous blood from the peritoneal membrane, as the following: (a) Pressure upon the branches of the portal vein within the liver, due to contraction of surrounding tissues, as in hepatic cirrhosis (including malarial atrophy—De Brun), syphilis of the liver, and cancerous infiltration. (b) Numerous conditions in the course of which pressure may be made upon the portal vein external to the liver, as enlargement of the glands in the fissure, carcinoma, hydatids, or abscesses of the liver. Tumors of any adjacent organs (*e. g.*, pancreas) may produce it. (c) Thrombosis of the portal vein. (d) Pressure upon the inferior vena cava after it receives the hepatic trunk (Roberts), or upon the latter itself, or the lymphatics. (e) The portal circulation is also impeded in chronic pulmonary affections (cirrhosis and emphysema) and heart diseases (*e. g.*, ascites due to “pericarditic pseudocirrhosis of the liver”—Pick). Swelling of the liver causing increase of portal pressure is an important factor in the development of ascites of hepatic origin (Hoover). (f) A new growth in the peritoneum may compress the smaller veins or the root of the mesentery. (g) Diminished resistance of the walls of the portal vessels, due to chronic affections that diminish the albuminous constituents of the blood and impair the nutrition of the peritoneum, as Bright’s disease, carcinoma, syphilis, chronic malaria, pernicious anemia, leukemia, amyloidosis. (h) Chylous ascites is caused either by a leakage of the lacteals (due to ulceration, injuries, or the presence of filariæ) or by the obstruction of the thoracic duct (due to thrombosis, cicatrices, compression). Cases of lactescent ascites in which the fluid is milky (not chylous) have been reported. The nature of the fluid is as yet unknown. (i) Adipose ascites has for its direct cause fatty cellular degeneration, such as is found in carcinoma and tuberculosis of the peritoneum.

Symptoms.—Slight peritoneal dropsy gives rise neither to symptoms nor to abnormal physical signs. When the sac contains 1 quart (1 liter) of fluid or over, however, the first subjective *symptoms* that are due to the mechanical effect of the fluid appear. They are a sense of weight and fulness, with slight uneasiness. As the proportion of transuded serum becomes gradually increased these symptoms become more pronounced. There may, in addition, be a *dragging pain* in the loins, *gastro-intestinal disturbance* (meteorism, constipation), and dyspnea (owing to the resistance opposed to the descent of the diaphragm, resulting in compression of the lungs). The latter symptom is much increased upon exertion or on assuming the recumbent posture. Since the heart is displaced upward, an embarrassment of its action (rapidity and irregularity) would be expected. *Syncope* is not infrequent for similar reasons.

Frequent *micturition* from pressure upon the bladder is common, and the kidneys, owing to compression of the renal vessels, secrete an *albuminous urine*, which is greatly lessened in amount.

Physical Signs.—After the serum has collected in considerable amount the physical signs afford characteristic evidence of the condition. From *inspection* we learn many valuable points: (a) The belly is uniformly prominent (the degree depending upon the amount of serum present), giving it a rounded form. Changing the posture of the patient shifts the point of greatest pouching. (b) The skin is seen to be tense, smooth, and shining, and sometimes shows *lineæ albicantes*; the umbilicus commonly bulges forward; less frequently it is obliterated, and the surface veins are often enlarged. (c) The thorax appears small except at the base, where it is distended, and the ensiform cartilage is sometimes abruptly curled up. (d) The respirations are hurried and are of the thoracic type, the abdominal movements being slight or entirely wanting. As soon as the belly walls become moderately tense *fluctuation* is elicited by placing the palm of the left hand vertically upon one side of the abdomen, and then, with the finger-tips of the right hand, tapping lightly the opposite side; impulses thus sent through the fluid will be distinctly felt by the hand in contact with the abdomen. When the dropsical fluid is small in quantity the patient should assume the erect posture during the examination. In palpating the solid organs (liver, spleen, abdominal tumors) when ascites is present, the tips of the fingers only are placed upon the skin, and then are suddenly “dipped,” displacing the fluid, thus touching the solid organ or new growth. *Percussion* gives flatness over the fluid, although some degree of resonance may be transmitted from the subjacent bowel. The upper level of dulness, in the recumbent posture, is not represented by straight transverse lines, but presents a concavity that is pointed to the head. The dulness is extremely movable, shifting with change of posture. When the decubitus is supine the most dependent portions of the abdomen give dulness. Again, if the patient be made to lie on either side, the opposite or uppermost flank will be found clear, the ascitic fluid always gravitating to the bottom of the sac. Tyson has observed that the flanks are tympanitic with considerable frequency in ascites, and my experience has been similar, tympany over the head of the colon being almost constant except in pronounced cases. Moreover, to obtain reliable results, if the layer of fluid be thin, the pleximeter finger is pressed lightly upon the surface, and the gentlest percussion only is allowable. The patient should be placed on the hands and knees if the fluid be small in amount, when a zone of dulness will be found around the umbilicus. The cardiac region may present percussion resonance as high as the fourth rib, and occasionally a murmur is heard at the base. The condition should be regarded as the counterpart of hydrothorax and not of pleuritis.

Diagnosis.—In order to arrive at a positive diagnosis a clear history of one or the other of the known causative conditions is requisite, joined with distinct evidence of the presence of fluid—viz., fluctuation and movable dulness. For the early diagnosis of ascites the patient should be placed in the knee-elbow position, when dulness can be readily elicited in the umbilical region.

The **diagnosis of chylous ascites** and **ascites adiposus** rests upon insecure ground unless aspiration be resorted to, although the presence of the causative conditions in the case may afford a basis for suspicions.

Differential Diagnosis.—Ascites is most apt to be mistaken for an *ovarian cyst*. The accompanying table presents the principal points of discrimination:

ASCITES

Clinical History

General health is bad prior to the appearance of the enlargement.
History of disease of liver, lungs, heart, kidneys, or other organ.
Swelling begins below and gradually extends higher; more noticeable when sitting than in the standing posture.

OVARIAN CYST

General health is good before the development of the tumor; failure afterward.
Frequent history of dysmenorrhea, negative as to organic affections.
Swelling is unilateral at first, gradually becoming more central.

Physical Signs

Enlargement is symmetric, the abdomen being rounded and most prominent about the umbilicus; in the supine posture the abdomen flattens, with lateral bulging; the umbilicus is often pouched and thinned.
Fluctuation is general from side to side and in a vertical direction.
No aortic pulsation felt.
Vaginal examination often shows the uterus to be movable. A pouch may project into the vagina, but no cyst is detectable.
When standing, the upper line of dullness presents a concavity; rarely shows irregularities due to fluid running up into "bays" between coils of intestine.
In the supine position the flanks are especially dull with tympany in front.
Percussion-dullness shifts its position with that of the patient.
Ascitic fluid has a specific gravity of 1010-1014, and is usually clear. It is of a pale straw color.

Enlargement is asymmetric or irregular, unless the tumor be very large, when it may fill the entire abdomen. The greatest circumference is below the umbilicus, which never bulges.

Fluctuation is circumscribed, corresponding to the limits of the tumor.
Aortic pulsation is sometimes evident.
Vaginal examination shows the uterus to be displaced. A cyst may be felt and outlined in the pelvis.

When standing, the upper line of dullness is generally a convexity.

In the supine position dullness is still in front and the flanks are resonant.
Percussion-dullness not movable.

Ovarian fluid has a specific gravity of 1018-1024. It is of a thick, turbid character, and the color is variable.

Large cysts may also spring from the *pancreas* and *liver*; the elimination of the latter conditions, however, does not, as a rule, offer marked difficulty. Ascites must be distinguished in practice from the exudation due to *chronic peritonitis*, and the points of differentiation have been arranged thus:

ASCITES

A previous history of organic disease of the liver, heart, kidneys, or other organ is obtainable.
No pain is experienced.
The abdomen is symmetrically enlarged.
Fluctuation is general in the transverse or vertical directions.
Palpation detects no hard masses of irregular prominence.
Percussion-dullness is always movable upon altering the position of the patient.
Fluid serous, limpid, specific gravity of 1010-1014, is pale straw-yellow in color, greenish tinge at times. Contains 1 to 3 per cent. of albumin. Few cellular constituents (lymphocytes, endothelial cells, erythrocytes). Cryoscopy, freezing-point higher.

CHRONIC PERITONITIS

There is a previous history of acute peritonitis, tuberculosis, or inflammatory diseases of the female pelvic organs; sometimes a history of injury.
Pain is a prominent symptom.
Abdomen is irregularly prominent, and rarely flat.
Fluctuation is often limited to circumscribed areas due to loculation of fluid.
Palpation often detects resistant, uneven prominences.
Dullness often not changeable on varying the position owing to adhesions.
The fluid is either serofibrinous, seropurulent, or milky in nature. It is often viscid, its specific gravity is 1018-1024, and its color variable; 3 to 6 per cent. of albumin. Cytologic studies show more polynuclear neutrophilic leukocytes. Freezing-point lower.

Overfilling of the bladder has been confused with ascites, and this organ has been tapped under the mistaken notion that the condition was one of dropsy of the peritoneum. Catheterization of the patient before tapping for ascites will obviate this error. Ascites may be mistaken for a deposit of fat in the abdominal wall. It is to be distinguished by pinching up the belly wall within the grasp of the hand.

Prognosis.—The duration of ascites may be many months or even years. In most instances the prognosis is unfavorable, though modified by the character of the causal condition in individual cases. The immediate cause of death may be either syncope, asphyxia, pulmonary atelectasis, or it may be the primary disease.

Treatment.—**Dietetic.**—The diet should be largely nitrogenous, light, nutritious, and given at stated periods with a view to maintaining the normal proportion of albuminous material in the blood.

Medicinal.—By means of therapeutic measures we should aim to accomplish two things: First, the improvement or cure of the original disease; and second, to relieve the chief symptoms by removing the ascitic fluid on which they depend. Though the causative affection is usually chronic and incurable, every effort should be made to remove or mitigate its pernicious activity in accordance with the principles laid down in appropriate portions of this work. Of medicines used to remove the transudation, hydragogue cathartics are most potent for good, and particularly when the ascites is due to cardiac or renal disease. Calomel and jalap in combination, or salines in full doses, administered after the Matthew Hay method, should be tried. Diuretics are recommended, but are often disappointing in their effects. Rolleston points out that they sometimes appear to succeed after paracentesis. English authors greatly praise copaiba and its resin. The bitartrate and other salts of potash, either alone or in combination with juniper and digitalis, are of value. Equally important with the exhibition of the above remedies is the use of tonics, including hematinics, to promote the general nutrition of the patient. I have reported one instance, occurring at the Philadelphia Hospital, in which a cure was effected perhaps solely as the result of measures intended to assist the nutritive processes. Based upon the experiments of Fleischer and Loeb, which indicate that adrenalin injected intraperitoneally hastens absorption from the peritoneal cavity, T. M. Tyson and H. D. Jump¹ employed such injections in 2 cases with encouraging results. On the other hand, autoserotherapy is said to retard transudation into the peritoneum and produce lasting polyuria. The fluid is to be withdrawn from the peritoneal cavity with a sterile hypodermic syringe and at once reinjected subcutaneously. The dose should be progressively larger (*e. g.*, 3, 5, 8, and 10 c.c.), and repeated at six-day intervals for two months. In ascites due to cirrhosis of the liver recourse should be had to *paracentesis abdominis*, not as a last resort only, but “as a systematic method of treatment” (Roberts). A single tapping is rarely sufficient, and a repetition of the measure from time to time, until the collateral circulation is established, is to be advised and encouraged. In cases in which the transuded serum has rapidly re-formed after its removal by tapping, Southey’s tubes, by means of which permanent drainage is secured, have been used with good results. Drummond affirms that ascites due to liver cirrhosis can be cured, and has proposed an operation whereby adhesions between the abdominal contents and its parietes are secured, in which new blood-vessels are formed, thus establishing a collateral circulation. B. M. Bernheim² presents the claims of saphenoperitoneal anastomosis, which has given most promising results.

NEW GROWTHS IN THE PERITONEUM

The most frequent and important of the new growths of the peritoneum are (a) carcinoma and (b) tuberculous deposit and tuberculous peritonitis, the latter two having been already considered.

CARCINOMA OF THE PERITONEUM

There occur the usual varieties—scirrhus, encephaloid, and colloid—the latter most frequently involving the omentum. Primary carcinoma of the peritoneum is rare. Primary endothelioma, however, is occasionally met with. It resembles true carcinoma in macroscopic as well as in microscopic appearances, though it is in reality to be ranked with the sarcomata on account of its origin. Carcinoma of the peritoneum is almost always secondary to carcinoma of the stomach, liver, or pelvic organs. The peritoneum may either be the seat of numerous small round miliary tumors, or, less commonly, of larger nodular masses, the most extensive development being presented by the colloid variety. Cancerous peritonitis is often found to be an associated condition, and the retroperitoneal lymph-glands may show cancerous development.

Etiology.—More cases occur in the female sex than in the male. Age has also a potent influence, most cases appearing late in life. Trauma may operate as an influential causative factor.

Symptoms.—When *primary*, carcinoma of the peritoneum is obscure during the early part of its course. Local *pain* and discomfort are complained of, and clinical evidences of the *cancerous cachexia* develop early, but these symptoms are not at first striking enough to be entirely characteristic. Later, however, the *nodules* can often be plainly felt (unless the liquid effusion be too marked), and the *ascites* (blood-stained), *loss of flesh*, *weakness*, and *anemia* are now sufficiently developed for diagnosis. In the colloid variety ascites is often absent, the abdominal cavity being the seat of a large, semisolid, non-fluctuating mass.

The *secondary form* usually follows carcinoma of the stomach or the ovaries, and the cachexia will have been developed before the peritoneum is secondarily involved in consequence of the presence of the primary growth. Hence, any symptoms referable to the general abdominal cavity are strongly suspicious. Among other *constitutional symptoms*, apart from those already mentioned, is fever (rarely absent), which may be due in small measure to the anemia, though in a greater measure to the associated peritonitis.

Physical Signs.—The abdomen protrudes if effusion be present or if the carcinoma be of the colloid form, though not invariably. Even when the tumor is large, dropsy of the peritoneum may make its detection impossible. On practising palpation after tapping, however, the nodules can be made out, either extending from side to side or being more or less localized and not adherent to underlying structures.

Differential Diagnosis.—It will be remembered that an oblong tumor lying transversely across the abdomen below the stomach is met in certain forms of *chronic peritonitis*. This offers the same physical signs that are presented by peritoneal carcinomata, unless the tumor masses in the latter affection be of considerable size. Carcinoma, however, is most apt to occur in persons past middle life, while nodular tuberculous peritonitis appears almost exclusively in children and young adults. Evidences of tuberculous disease elsewhere, past or present, and particularly suppuration about the umbilicus, would point to tuberculous peritonitis. Moreover, in all forms of abdominal carcinoma the inguinal glands are apt to be indurated and enlarged. Cyto-diagnosis might serve to distinguish carcinoma from tuberculosis of the peri-

toneum. *Proliferative peritonitis* usually gives a history of chronic alcoholism. The differentiation of *hydatid cysts* of the peritoneum from carcinoma depends upon the history of the case, the presence of hydatid fremitus, the finding of the hooklets in the fluid, and the less rapid growth of the tumor, and the lessened amount of pain, fever, and cachexia in the latter disease. *Carcinoma of the intestine* may simulate somewhat the disease under consideration, but the signs of increasing stenosis, as evidenced by the colicky pain, the discharge of blood and pus with the stools, and the ribbon-like character of the feces, will serve to separate the conditions. *Retroperitoneal tumors* (sarcomata) are discriminated with the greatest difficulty. As pointed out by J. D. Steele, in tumors behind the peritoneum the signs of intestinal obstruction, coupled with neuralgic pains or edema of the lower extremities from pressure upon their nervous and venous supply, are important discriminating features. Moreover, tumors of the peritoneum, whether of the omentum or mesentery, are movable, while those behind the peritoneum are generally fixed. In retroperitoneal sarcoma "the tumor may fluctuate and may move with respiration, or be movable by palpation." Omental tumors lie in front of the intestines (as can be shown by inflation of the bowel); mesenteric new growths sometimes have a coil of intestine in front of them. On the other hand, retroperitoneal tumors are always crossed by loops of intestine (colon). Peritoneal tumors (particularly the omental) follow the movements of respiration, while the retroperitoneal are, as a rule, immobile. The latter always cross the central long axis of the body, while the former may be confined to one or the other side. Finally, the only sure method of determining the character of tumors behind the peritoneum is by an exploratory celiotomy.

The **prognosis** is always unfavorable.

Treatment can accomplish nothing beyond a more or less complete relief from the distressing symptoms.

Other Tumors of the Peritoneum.—Primary sarcoma produces larger or smaller areas of thickening of the peritoneum. Secondary sarcoma, the commoner variety, assumes the form of large nodular masses or of numerous miliary growths. The symptomatology has been given under Carcinoma of the Peritoneum.

Fibromata and *lipomata*—the former as fibroid nodules varying in size from a millet seed to a split pea, the latter as localized overgrowths of fatty tissue showing great variation in their size—are among peritoneal and retroperitoneal neoplasms. The lipomata, however, are the more frequent. Mr. Anderson points out that fibromata may merge, on the one hand, into the lipomata (*fibrolipomata*); on the other, into the myomata (*fibromyomata*). It is probable that lipomata usually spring from the retroperitoneal tissue in the neighborhood of the kidneys and iliac fossa. Less commonly, however, they "originate in the subperitoneal tissues of the mesenteric or omental folds, where general fatty overgrowth in varying degree is frequently observed" (Allchin).

Peritoneal lipomata may be associated with extreme obesity, but this is by no means invariably the case. The *diagnosis* is rarely made, particularly in the female, owing to the close resemblance of these growths to ovarian cysts and other tumors found in connection with the female genitalia. They have been mistaken also for ascites, which is not rarely a symptom of fibromatous and lipomatous neoplasms. The *prognosis* is unfavorable, although, if early recognized, the tumors may be successfully removed.

PART IX

DISEASES OF THE URINARY SYSTEM

I. DISEASES OF THE KIDNEY

MOBILITY OF THE KIDNEY

(*Movable Kidney; Dislocated Kidney; Floating Kidney; Wandering Kidney; Ren Mobilis; Nephroptosis*)

Definition.—A distinction is made between two common varieties of mobile kidney, according to the degree of displacement, as follows: (1) *Movable kidney*, the upper end of which can be felt during deep inspiration, and which can be pushed down in the retroperitoneal space to the level of the umbilicus. (2) *Floating kidney*, which is freely movable below or beyond this point—*i. e.*, possessing a larger arc of mobility. In the so-called *palpable kidney* the lower edge of the organ can barely be felt on deep pressure.

Etiology.—The condition may be congenital (rare). An abnormally long renal artery may predispose to the development of a movable kidney. Emaciation with a marked wasting of the fatty capsule in which the kidney is embedded is a frequent underlying cause of movable kidney. Women are oftener affected than men, and results from multiple pregnancies, tight lacing and girdling, and traumatism (falls, heavy lifting, and the like) have frequently caused displacement and mobility of the kidney. Suckling observed that a number of girls who served beer, and were therefore obliged to stoop and immediately stand upright with considerable frequency, were likely to have movable kidney. Heavy tumors of the organ, the pressure of adjacent tumors (as of the liver), and the traction of hernias may likewise cause the condition. Watson's series of experiments proved that the structures vital to the restriction of the kidney's mobility within its normal excursion are those which form the attachments along its posterior surface and upper pole.

In *enteroptosis*, or Glénard's disease, in which there is a downward displacement of all the viscera, mobility of the kidney is often associated. Although either kidney, or even both kidneys, may be abnormally mobile, the right one is usually affected. Sometimes a floating kidney becomes fixed by peritoneal adhesions in an abnormal position, as in the right iliac fossa; an instance of this occurred in a seaman, under my care, admitted to the Medico-Chirurgical Hospital of Philadelphia.

"The body form is an important etiologic factor of movable kidney, and not only explains the greater frequency in women than in men, but also the reason why the right organ is more often displaced than the left" (Ashton). The body cavity is subdivided into three zones by two transverse planes, and

in women the middle zone is liable to be contracted in various directions with a consequent displacement downward of the organs occupying this region. The right kidney is pushed downward, owing to backward compression of the liver, which tilts its superior pole forward. Becker and Lenhoff, from a study of the relation between the length and circumference of the body cavity, found that the greater the contraction of the middle zone, the higher will be the body index; this is arrived at as follows:

$$\frac{\text{Distance from suprasternal notch to symphysis}}{\text{Circumference of body at lower border of tenth rib}} \times 100 = \text{body index.}$$

They concluded that when the body index was below 75 no displacement occurred, but when the index was above 77 the kidney was almost invariably situated abnormally low.

Symptoms.—Movable kidney may exist without any symptoms whatever. It may be discovered accidentally by physical examination, and not infrequently it is found *postmortem* in a similar manner.

The symptoms of movable kidney are local, reflex, and general, the *local* and *reflex symptoms* being the most prominent in the average case. The reflex symptoms, though usually abdominal, may become general. The local symptoms are most marked in extreme mobility of the kidney (floating kidney), although many of the symptoms are due to the associated sagging of other organs, while in moderate mobility the reflex symptoms usually predominate over the local.

Most frequently there is a troublesome dragging pain, or a sense of weight or pressure in the loins or abdomen, especially after long walking or standing or hard labor; this may be referred to the sacral region. Sometimes the pain may be quite sharp and colicky in nature. Pain in the kidney itself is seldom complained of, due to congestion by pressure or traction upon the renal veins or obstruction of the ureter.

Reflex gastro-intestinal disturbances are common. *Indigestion* is usually complained of, and occasionally vomiting and nausea are noted. Dilatation of the stomach may possibly be caused by a dislocated kidney pressing upon the duodenum. Pressure jaundice is also an unusual concomitant of the floating kidney, and J. Hutchinson, Jr., records 2 cases that caused both hepatic colic and obstructive jaundice. *Cardiac palpitation*, constipation, flatulence, and edema of the lower extremities (from pressure on the inferior vena cava) may attend, and disturbances of the pelvic viscera have also been noted occasionally (dysmenorrhea, abortion, and irritable bladder). Improvement is usually considerable in pregnancy. Some cases of displaced kidney are characterized by sudden and severe attacks of nephralgic or gastralgic pains, chills, fever, vertigo, nausea and vomiting, and general collapse. These attacks are often periodic, occurring sometimes at the menstrual period, and are known as *Dietl's crises* or *incarceration symptoms*. They may be excited, also, by a too free indulgence in eating and drinking. It is most probable, as Dietl himself suggested, that these cases are due to a twisting or bending of the renal vessels or of the ureter, or, perhaps, to circumscribed inflammation of the mobile kidney. An acute hydronephrosis may thus develop. The urine is concentrated, and may contain uric acid or oxalates in excess. After three or four days, as the attack subsides, micturition becomes free, the kidney becoming movable once more. These attacks of *transitional hydronephrosis* may occur intermittently (*vide* Hydronephrosis). Pyonephrosis has also been noted and in rare instances may result in gangrene by occlusion of blood-vessels. When a loose kidney causes rigidity of the muscles of the abdominal

wall ("splint-belly"), it may produce gastric hyperacidity, congestive appendicitis, or parenchymatous nephritis.

Floating kidney associated with Glénard's disease, in which the transverse colon, pancreas, stomach, intestines, and other viscera are prolapsed, gives rise to symptoms similar to those stated above, only with the addition of greater discomfort and nutritive and nervous disturbances. Sometimes there is albuminuria and rarely hematuria.

The *general symptoms* of movable kidney are those of neurasthenia or hysteria. Mental anxiety, leading to melancholia, sometimes follows the discovery of a movable abdominal tumor. Cephalalgia, backache, paresthesias, neuralgias, nervous dyspepsia, hypochondriasis (in men), and hysteric manifestations may arise and prove a perpetual annoyance. The condition, however, may arise in a previously neurasthenic or hysteric subject.

The **physical signs** of movable or floating kidney are highly important and diagnostic. *Palpation*, especially bimanual, as by Israel's method: The patient lying in a semirecumbent position, counterpressure (the left hand being placed over the lumbar region, the right next the skin in front, manipulating the abdomen from above downward) may detect a firm, movable tumor of renal size and shape in either flank (usually the right) just below the ribs (movable kidney), or in the inguinal or umbilical regions (floating kidney). Or, the patient may stand and, grasping the back of a chair, may lean slightly forward, while the examiner, at the patient's side, presses with one hand over the loin, and with the other feels over the abdomen below the ribs. Though comparatively easy to outline, the tumor is nevertheless hard to grasp; it is often, however, readily pushed into place. Deep breathing may affect a palpable or movable kidney, but has no effect upon one that freely wanders about the abdomen (floating kidney). Pulsation of the renal artery may be felt in the last-named cases.

Inspection and percussion of the lumbar region in movable kidney are uncertain, and therefore unreliable. Visible depression here is rarer than a visible tumor anteriorly. I have noted increased tympany over the affected side as compared with the opposite side.

A **diagnosis** is possible only after a careful and thorough physical examination. When this is made, an abnormally mobile kidney is usually discovered without difficulty. The size and shape of the organ, its right-sided position, and its mobility, associated with a train of local, reflex, or general nervous disturbances, especially in a thin, emaciated woman, are quite distinctive. A knee-elbow posture is sometimes more favorable than the recumbent position for determining a movable kidney.

Differential Diagnosis.—Floating kidney is, of course, more easily diagnosed than the movable type, and partly because of the fact that in instances of the latter *tumors of the gall-bladder* especially and *wandering spleen* must first be excluded. The absence of a well-defined splenic notch, the presence of pulsation of the renal artery, a tympanitic note over the usually intervening colon, and an unchanged area of splenic dullness will assist in the diagnosis; in addition, there is the fact that wandering spleen is a comparatively rare affection.

Tumors of the gall-bladder are frequently mistaken for movable kidney; occasionally the opposite error is made; sometimes both conditions may exist. They are both common to women; they both may present as tumors in the right hypochondriac and umbilical regions; they are more or less movable, firm, smooth, slightly tender, round or oval in shape, with variable percussion-signs and dyspeptic symptoms; and either may give rise to paroxysms of severe colic or to jaundice. Jaundice, however, is rare in movable kidney, while

emaciation and general nervous disorders are more common; the floating tumor may vary in size (hydronephrosis), the diminution being accompanied by a marked increase in the flow of urine. If the gall-bladder be filled with calculi, the consistence is firmer than that of the kidney, and fremitus may be felt. Moreover, the movements of the gall-bladder are usually lateral within a short arc of a circle, the center of which is a point beneath the edge of the right lobe of the liver; while those of floating or movable kidney may be either vertical, oblique, or lateral in arcs of a much larger radius. Again, tumors of the gall-bladder descend with inspiration, as is not the case with wandering kidney.

In some cases it is necessary to distinguish between "Dietl's crises" and *renal, hepatic, or intestinal colic*, acute intestinal obstruction, affections of the genital organs, and appendicitis. *Tumors of the ovaries and bowel* are rarely confounded with wandering kidney.

Prognosis.—In uncomplicated cases life is never endangered, and a cure may be effected in numerous cases in which suitable combined medical and surgical treatment is pursued. The general nervous symptoms are usually very obstinate, but after relief is afforded from the accompanying local symptoms, they subside or cease altogether.

Treatment.—Since emaciation and loss of perirenal fat is a frequent cause of wandering kidney, it is often advisable to resort to measures that will tend to increase the weight and fat of the body. The "rest-cure," with its forced feeding, may be all that is necessary in highly nervous subjects having but a slightly movable kidney. In all cases more or less prolonged intervals of rest (lying down) throughout the day aid markedly in ameliorating the symptoms. Other hygienic measures, as the avoidance of overexertion, extreme bodily movements, straining—as at stool—and so forth, should also be enjoined.

For several years, and until recently, the operation for anchoring the mobile kidney has been advised as appropriate in nearly all cases. This is now wisely deprecated; and a reversion to the careful, patient, and constant use of suitable abdominal pads and binders in certain cases is meeting with much success. Watson states that from 90 to 95 per cent. of movable kidney producing symptoms can be relieved by a suitable *corset*. Gallant¹ recommends a corset as long in front as can be worn, specially made or straight-front corsets being chosen. It must be at least 2 inches less than that formerly worn, and laced at the back from top to bottom as an open V. Having put the corset around the waist, the patient lies down, draws up the knees, and then fastens the corset from below upward, drawing the lax abdominal wall up at each step. In severe cases of renal displacements, in which recurring attacks of hydronephrosis, strangulation crises, pain with marked gastro-intestinal disturbances, profound nervous and mental disturbances, or other grave renal complications occur, some such surgical procedure as nephrorrhaphy should be strongly urged. This may prove an effectual cure, although the anchorage is often torn loose by a sudden or severe physical effort. Suckling states that surgery offers the only cure for nephroptosis. The hypodermic injection of morphin and atropin and the external application of heat are indicated in the crises of Dietl.

¹ *Saunders' American Year Book*, 1903, p. 453.

CIRCULATORY DISORDERS OF THE KIDNEYS

ACTIVE HYPEREMIA

(Acute or Active Congestion)

Definition.—An acute, temporary engorgement of the vessels of the kidneys, with little or no exudation.

Pathology.—The kidney is swollen, deep red in color, and engorged with blood, which flows freely on section. *Microscopically*, there may be seen cloudy swelling of the cortical epithelium.

Etiology.—Acute renal congestion is due mainly to the action of irritants present in the circulation, as in the acute infectious (especially the eruptive) fevers. The stimulating diuretics and certain poisonous drugs, as copaiba, squills, cantharides, potassium chlorate, and carbolic acid, also sudden contraction of the peripheral blood-vessels by exposure to cold while the body is overheated, act as causes. Postoperative acute hyperemia (ether?) is frequently met with. When prolonged the congestion passes into an acute nephritis. It may be caused in one kidney as a result of either nephrectomy of its fellow or blocking of the ureter by a calculus, clot, etc., of the opposite side.

Symptoms.—There may be a dull pain in the lumbar region, with a slight elevation of the temperature and pulse-rate. The *urine* either is scanty, or, as in cantharides-poisoning, it may be altogether suppressed. It is dark, the specific gravity is increased and it contains some free blood, a trace of albumin, and a few hyaline tube-casts.

Diagnosis.—The absence of a marked quantity of albumin, of the numerous and various casts, of dropsy, and of uremic symptoms distinguishes active hyperemia from *acute nephritis*.

The **prognosis** is quite favorable upon the removal of the cause. A frequent repetition of the attacks, however, may lead to a nephritis.

Treatment.—Absolute rest and a liquid diet should be ordered. Cupping over the loins or the use of hot fomentations should be practised. The free use of water and other diluents or mucilaginous drinks should be encouraged. Saline laxatives to freely open the bowels, and the use of hot air or a hot pack to promote sweating are important aids in relieving the congested kidneys.

PASSIVE HYPEREMIA

(Chronic or Passive Congestion)

Definition.—A chronic venous engorgement of the renal vessels, generally secondary to diseases of certain other viscera.

Pathology.—There is in the later stages a characteristic condition of the kidneys called “cyanotic induration.” Earlier in the case the organs are enlarged, firm, and of a dark, bluish-red color. The capsule is usually non-adherent. On section the medullary substance is seen to be darker red than the cortex and coarsely fibrous in appearance. Microscopic examination shows the capillaries (both glomerular and medullary) somewhat dilated and the walls thickened. The epithelium may either be unchanged or a little cloudy and swollen, or, later, even fatty; the interstitial tissue may be slightly increased.

Etiology.—Most commonly the renal congestion is a part of a general venous engorgement due to chronic cardiac, pulmonary, or hepatic disease. It is found in mitral valvular disease with ruptured compensation of the heart (common); in pulmonary emphysema, fibroid phthisis, and chronic adhesive pleurisy; and in cirrhosis of the liver. Less frequent causes of congested kid-

neys are tumors, the pregnant uterus, and ascites, all of which bring about the condition through pressure upon the renal veins. Again, angulation, as in nephroptosis, kyphosis, and the like, may be a cause. Only rarely may passive renal congestion be due to thrombosis or embolism of the ascending vena cava or of the renal veins.

Symptoms.—These are accompanied by those due to the primary diseases that are manifested in the general venous congestion, as *edema* of the lower extremities. There may be a sensation of weight in the loins. The *urine* is diminished in quantity, of a higher specific gravity, and darker in color; it contains a little albumin, some blood-corpuscles, and a few hyaline casts and epithelial cells, depending upon the chronicity and intensity of the congestion. Urates may be deposited in the standing urine.

Diagnosis.—From *nephritis* passive renal congestion may be differentiated by the comparative absence of albumin, casts, general dropsy, and uremia, and by the undiminished quantity of urea.

Prognosis.—This depends upon the primary cause. Chronic congestion may pass into chronic nephritis with fluctuation of the oliguria and albuminuria according to the functional activity of the heart.

Treatment.—Rest and a light and easily assimilable diet, together with cardiac tonics and diuretics, are indicated. The infusion of *digitalis* serves a good purpose by increasing the quantity of urine and clearing it of albumin. Basham's mixture is a useful adjuvant.

EMBOLIC INFARCTIONS

Anemic and hemorrhagic infarctions of the kidney are of pathologic rather than of clinical significance. Cicatrices may result from these infarctions—"embolic contracted kidney." Very rarely the *sudden appearance* of a slight amount of *blood* in the *urine*, associated with cardiac disease, and tenderness of the kidney, and possibly with a sudden severe pain over the loin, may point to hemorrhagic infarction.

SPECIAL PATHOLOGIC STATES OF THE URINE

HEMATURIA

Definition.—The presence of blood in the urine.

Etiology.—(1) *Local or renal causes* of hematuria include congestion (including that due to torsion of the renal vessels in certain cases of floating kidney), acute inflammation of the kidneys, and acute exacerbations of chronic nephritis, embolic hemorrhagic infarction, renal calculi and pyelitis, tuberculosis, malignant renal disease, diffuse myxangiomatous condition of the pelvic submucous tissue (Myles), actinomycosis (O. Isreal), hydatids, traumatism, and parasites (the *Filaria sanguinis hominis* and *Distoma hæmatobium* (Billharz)).

(2) *Affections of the Urinary Tract.*—In the *ureter*, calculi or lacerations due to traumatism, as in protracted abdominal sections; in the *bladder*, calculi, malignant tumors, acute cystitis, ulceration and rupture of varicose veins at the vesical neck; and in the *urethra*, gonorrhea, calculi, parasites, and traumatism—may all cause hematuria.

(3) *General Diseases.*—Acute specific fevers and certain blood dyscrasiæ (purpura, gout, scurvy, hemophilia, malaria, and leukemia) may produce hematuria. Malarial hematuria in mild form is not an uncommon feature of paludism in the Middle States of this country, and may occur after the manner of intermittent malarial paroxysms. That due to the renal congestion of chronic

heart, lung, or liver disease is not a marked condition, and has not been of frequent occurrence in my experience.

(4) *Essential Hematuria*.—Senator describes a form of hematuria that is sometimes seen in young persons whose health may be quite fair, the blood often appearing paroxysmally and without apparent cause ("renal hemophilia"). The view is gaining ground, with added experience, that so-called symptomless bleeding from the kidney is usually due to localized disease in the cortex. Obscure cases may be occasioned by latent purpura (Fonio). There is an idiopathic (family) or congenital hematuria. Hematuria may be also a manifestation of vicarious menstruation.

(5) *Endemic hematuria* is that variety found in some of the tropical regions where the *Distoma hæmatobium* (a trematode worm) abounds.

Diagnosis.—This has for its object the discovery (1) of blood in the urine, and (2) of the source of the hemorrhage. Bloody urine varies in color according to the quantity of blood present, to its condition (coagulability), disposition, and the length of time present in the urine. A light reddish tinge or "smoky" hue may indicate a slight quantity of blood. A dark coagulum may be at the bottom as a sediment, with small clots floating above in a deep red, turbid layer, above which, again, the urine may show but the slightest tint of red. *Microscopically*, the blood-corpuscles are readily discovered, establishing the diagnosis from hemoglobinuria, in which condition they are absent.¹ When red corpuscles are associated with tube-casts, renal hemorrhage may be positively diagnosed. In ammoniacal urine the corpuscles are very pale and shadowy (dissolved hemoglobin). After remaining in ordinary acid and diluted urine they lose their disk-like shape and swell into spheres of a smaller diameter. Urine containing blood always shows the presence of albumin. According to Newman a ratio of albumin to hemoglobin in excess of 1 to 1.6 indicates not only an independent albuminuria but also a renal affection as the cause of the hematuria.

Chemically, the blood-pigment may be detected by Heller's test, which consists in adding liquor potassæ, boiling the urine, and observing the flakes of precipitating phosphates, which become reddish-yellow or brown from the added hemochromogen. The guaiacum test is also used. The spectroscope is sometimes employed to discover the bands of alkaline hematin in the precipitate which is conclusive. Leede recommends the accumulation of as many erythrocytes as possible by filtering a large amount of urine and applying the guaiac, or other chemical, tests to the residue left on the filter.

The *source of the blood* is of great diagnostic and therapeutic importance. In *renal hemorrhage* the blood is thoroughly mixed with the urine, giving a uniformly red, "smoky," or brown color (due to methemoglobin), as in hemorrhagic nephritis. Blood-casts and leukocytes may also be found. The disease causing hematuria may be traced sometimes by a study of the urine; thus, in valvular cardiac disease the sudden appearance of hematuria would indicate *infarction* of the kidney. The discovery of a few red blood-corpuscles in a concentrated urine would point to renal congestion. In profuse renal hemorrhages clots representing molds of the renal pelvis and of the ureters may be discharged. Hemorrhage due to *calculus* is usually small in amount and appears at more or less prolonged intervals. Tuberculous hemorrhages may occur. Blood from the ureters is usually molded in clots in the shape of curved cylinders, and appears like small dark worms in the urine. Casts from the ureters are often secondary to hemorrhages; in such cases the hematuria may alternate

¹ Hutchinson and Rainy, *Clinical Methods*, p. 337, point out a source of fallacy: "In alkaline urines, especially if they have stood for some time, the red cells are apt to swell up and disappear."

with the passage of clear urine, owing to temporary hemorrhages or to the blocking of the ureter on the diseased side. (See also Fibrinuria.)

Vesical hemorrhages may be copious. The blood and urine are not intimately mixed, and large clots settle on standing. The first portions of urine discharged may not be bloody, while the last may consist of pure blood. *Urethral* blood is discharged before the urine, and either comes away freely or may be "milked out" independently of urination.

The endoscope has been used successfully to determine the source of the hemorrhage (which kidney?). It is especially useful in women.

Prognosis.—This varies with the primary source of the hematuria.

The **treatment** consists primarily in rest in bed. If the hemorrhage is an evidence of the blood dyscrasie, then measures to control hemorrhage as recounted in the section on Purpura are indicated. The treatment of hematuria, otherwise, is that of the causative condition.

HEMOGLOBINURIA

Definition.—The presence of blood-pigments in the urine.

Etiology.—The direct cause of hemoglobinuria is a condition of the blood in which, as a result of increased destruction of the red cells, the hemoglobin of the plasma reaches an amount sufficient to be excreted by the kidney.

(1) The **causes of the hemolysis** are principally *toxic*, and include the following: (a) Poisons (carbolic and pyrogallie acids, snake-venom, potassium chlorate, naphthol, phosphorus, arseniuretted hydrogen, carbon dioxid, lipoidal solvents, as ether or chloroform). (b) The ingestion of poisonous fungi or of tainted edible mushrooms (*Helvella esculenta*). (c) In some diseases it may be due to the action of hemolytic bacteria. It occurs in scurvy, purpura, and such diseases as an evidence of the increased blood destruction. Syphilitic infection may cause it (paroxysmal often). It is one of the manifestations of congenital hemolytic jaundice. (d) Extensive burns, the absorption of hemorrhagic effusions, and the transfusion of blood of a species differing from the donor, or at times from transfusion of blood from one individual to another when the blood of the former contains isohemolysins. (e) Rarely it may be due to exposure to cold and to violent physical exertion. (f) The so-called *epidemic hemoglobinuria* (Winckel's disease) occurring in the newborn.

(2) **Paroxysmal hemoglobinuria**, a rare variety, may occur without any apparent cause in persons enjoying otherwise good health, but usually following exposure to cold with subsequent warming. Donath and Landsteiner have shown that the disease is due to the presence of an autohemolysin which is activated by cooling to combine with the erythrocyte, and later, upon warming, to destroy the red cells. Thus, placing the hand of a susceptible individual in ice-water and then warming it is followed by hemoglobin excretion. The paroxysms are usually symptomless and of short duration.

(3) It appears as a symptom of *malaria* in the southern part of this country. This is termed *malignant malarial hemoglobinuria* or *hemoglobinuric fever*. In Africa it is called *black-water fever*.

Symptoms.—These are generally the symptoms of the condition that accompanies hemoglobinuria. In paroxysmal hemoglobinuria the attacks are usually sudden, brief in duration, and sometimes *intermittent*, especially when of malarial origin. An anemic condition seems to be essential to the production of malarial hemoglobinuria. *Jaundice* may be an associated symptom. The hemoglobinuria seldom lasts for more than two days, though very grave cases take on the aspect of a pernicious malarial attack. There may be lumbar pains, chills and fever, and gastric disturbances. Urticaria and purpura

have also been noted, as has anemia in cases in which frequent attacks have taken place.

Diagnosis.—This is made by an examination of the urine. Macroscopically, it is of a red-brown color, slightly turbid, with a reddish-brown or brownish-black sediment. The reaction is usually acid and the specific gravity slightly lowered. The microscopic features that distinguish hemoglobinuria from hematuria are variable. In the former condition few or no red corpuscles are present, and the few that may be seen are usually colorless ("shadows") or fragmentary. Small flakes or granules of disintegrated hemoglobin are found and are brownish-black in color. There may be also brown-tinged casts and epithelium. Chemically, the urine is found to contain albumin, for the discovery of which Heller's and the guaiac or benzdin tests for blood-pigment may be tried. The former has been described in the preceding discussion of Hematuria. By means of the spectroscope the three absorption bands of methemoglobin may be seen (red, green, and yellow). The blood-serum in hemoglobinuria may be somewhat red-tinged on account of the dissolved hemoglobin. The hemoglobinuria is further marked by the aplasticity of the red corpuscles, by their pallor, by poikilocytosis, and by the presence of the irregular flakes of hemoglobin.

The **prognosis** is favorable in the ordinary paroxysmal form. Malignant malarial hemoglobinuria, however, is often fatal.

Treatment.—Hemoglobinuria is rather intractable. During the paroxysms external warmth is needed, along with hot drinks to encourage perspiration. In malarial cases quinin, and in syphilitic, the iodids, should be administered; although by some it is believed that quinin may aggravate the syndrome in particular cases.

ALBUMINURIA

Definition.—The presence of albumin in the urine.

Pathology and Etiology.—The immediate cause is the escape of the normal blood constituents, serum-albumin and serum-globulin, from the vessels into the renal tubules. This transudation of albumin indicates either a transient and slight or a permanent and grave nutritional disturbance of either the epithelium lining the glomeruli or of that of the contained tufts of capillaries, or, possibly, of the *membrana propria* or the epithelium of the uriniferous tubules. These changes induce and offer an abnormal perviousness to the albumin of the blood.

The principal *causes* of albuminuria are: (1) Those associated with definite lesions of the kidney; nephritic, acute and chronic; renal congestions, active and passive (the latter being secondary to chronic liver, heart, and lung diseases, pregnancy, or tumors).

Albuminuria occurs also in conditions in which (2) the renal lesions are either slight or undemonstrable: (a) Thus, it is present in blood-changes, as in scurvy, purpura, syphilis, leukemia, or extreme anemia, and in cases in which urobilin or bile-pigment and sugar (glucose) circulate in the blood. Again, slight albuminuria may be present in saccharin diabetes and after etherization. In certain affections of the *nervous system* albumin is found in small quantity, as after an epileptic paroxysm, in tetanus, apoplexy, and exophthalmic goiter.

(b) The so-called *accidental* or *spurious* albuminuria is due to the presence of pus or blood; in such cases the condition is not a true renal albuminuria, since it is commonly associated with cystitis, pyelitis, urethritis, or is the result of hemorrhage from the pelvis of the kidney, from the ureters, bladder, or urethra. Chemical injury of the bladder may cause a reflex albuminuria (Evans, Wynne, and Whipple).

(c) *Febrile albuminuria* is of rather frequent occurrence in diseases accompanied by pyrexia, especially when long continued. Among these are typhoid fever, small-pox, yellow fever, diphtheria, and even influenza, follicular tonsillitis, and pneumonitis. The renal changes in these cases are, I believe, merely a transitory cloudy swelling in the glomeruli, which, together with the albuminuria, rarely lasts longer than the fever.

(d) Other forms of albuminuria have been styled *physiologic* or *functional*, *transient*, *dietetic*, *neurotic*, *intermittent*, and *cyclic*: in these no definite lesions of the kidney are found, and are denied by some to exist. Recent observers are inclined to believe that trivial, non-progressive renal changes occur in these cases. Slight albuminuria certainly does occur in some cases after a heavy meal rich in albumin, after marked and prolonged muscular exertion, intense emotion, and cold bathing.

Physiologic, functional albuminuria has come to be of greater interest and importance in later years, particularly as it bears upon the prognosis and upon life-insurance risks. In this variety there are a periodic appearance and absence of albumin in the urine. The albuminuric paroxysms are very variable, recurring usually after meals or on exertion. The albumin is present in but small quantity, and only rarely are casts (hyaline) found. The accompanying signs and symptoms common to nephritis are absent. Orthostatic or cyclic albuminuria is the most frequent of the different types of physiologic albuminuria. The urine is albumin-free as long as the patient is flat on the back. The assuming of the upright position is followed by the appearance of albumin. Thus, the urine voided the first thing in the morning has no albumin in it; about noon it is found in greatest amounts. Under careful management these cases ordinarily recover. However, an insidious degeneration of kidney structure may manifest itself many years later. Patients suffering from this type of albuminuria are usually delicate and slender. Jehle has shown that such patients, usually adolescents, have a marked lordosis, the control of which usually relieves the condition. Albuminuria may rarely be *hereditary* (Renault). Slight *senile albuminuria*, without evidence of renal disease, is not uncommon.

Diagnosis.—This rests upon the discovery of albumin in the urine. For the diagnosis of cyclic albuminuria, specimens of urine passed at different times of the day must be examined.

Differential Diagnosis.—Inquiry and careful inference concerning the etiology of a given case must be made. *Renal albuminuria* is persistent and of considerable quantity except in chronic interstitial nephritis. Tube-casts are usually present. *Functional albuminuria* is slight and inconstant. Tube-casts are absent in the latter. Again, in the former variety general symptoms, as dropsy, cardiac hypertrophy, anemia, and uremic prodromes, are present. It is true that slight edema is sometimes found in cyclic albuminuria, but this is probably due to the marked anemia that is so often seen. Gleet and leukorrhea must also be excluded.

Tests for Albumin.—A specimen from the well-mixed total quantity voided in twenty-four hours should be examined for albumin. The smallest quantity can be detected only by its coagulum rendering the urine turbid; hence any turbidity present before the given test is made should be removed by filtration, unless this turbidity be due to urates, when a little warming of the tube will render the urine clear.

(1) *Boiling Test.*—This is the commonest and, I think, the most reliable practical test for albumin. The tube is filled about two-thirds full of urine. If alkaline or neutral in reaction, a drop of acetic or nitric acid is added; an excess of acid must be carefully avoided, lest the albumin (if present) be

converted into a non-coagulable form. The tube, held aslant, is then applied to the flame, and slowly revolved with the fingers, so that the upper portion of the column of urine is brought to the boiling-point. A comparison of this with the lower portion of the urine is made. Any turbidity is due to albumin or phosphates. If albumin, adding a few drops of nitric acid or 30 per cent. acetic acid will increase and thicken the coagulum; if phosphate, the opaqueness will be cleared at once.

(2) *Heller's Nitric Acid Test*.—This is both delicate and satisfactory. About 1 c.c. of nitric acid is poured into a tube, and some urine is allowed to flow slowly from a pipet and settle upon the acid. The presence of albumin is indicated by a white ring at the point of contact of the two liquids. Uric acid, urates, and certain urinary coloring-matters form a pink or deep red ring or zone; this forms, as a rule, above the juncture of the acid and urine. Albumose also gives a white zone, but does not respond to the boiling test as does serum-albumin.

Boston's Pipet Method.¹—"Reagents: (1) concentrated nitric acid, or (2) nitric acid 1 part and saturated solution of magnesium sulphate 9 parts. "Albumin causes a white cloud to appear in the form of a ring at the zone of contact of the two liquids (reagents and urine), and this test, when carefully applied, must be regarded as one of great value.

"1. A pipet is filled for a distance of from 1 to $1\frac{1}{2}$ inches with the urine to be tested. The urine is then removed from the surface of the pipet by washing or by wiping.

"2. The pipet, with its contained urine, is then placed near the bottom of a bottle containing nitric acid, when the pressure of the index-finger is lessened and the acid allowed to flow gradually up into the pipet.

"3. When the pipet is seen to contain about equal amounts of acid and urine, the finger is again pressed firmly upon the top of the pipet, which is then removed from the bottle and held toward the light on a level with the eye. If albumin is present, a distinct white ring of coagulated albumin appears at the junction of the urine and the reagent."

(3) *Johnson's Picric Acid Test*.—To filtered urine in a test-tube are slowly added a few drops of a saturated watery solution of picric acid. Immediate turbidity indicates albumin. Some authorities prefer that 1 or 2 drops (4.0–8.0) of the yellow fluid be placed gently on the surface of the urine, when, if albumin is present, a white zone at once is apparent, together with a haziness that spreads downward with the diffusion of the liquids. Heating emphasizes the evidence of the test, which is extremely sensitive.

(4) *Roberts' nitric magnesium test* is also very delicate. It consists in using the following mixture, just as in Heller's test: 1 volume of concentrated nitric acid, added to 5 volumes of a saturated solution of magnesium sulphate.

(5) *Trichloroacetic Acid Test*.—This will discover minute traces of albumin, but has the disadvantage that it responds to nucleo-albumin as well as to serum-albumin. A few crystals may be dropped into the urine, or a saturated solution may be used after the "contact method," when, if albumin be present, a white coagulum forms. This and the Geisler test-papers (Vierordt) constitute portable and handy tests.

(6) The *acetic acid and potassium ferrocyanid test* is minutely sensitive, but gives a precipitate with other albuminoid bodies. The urine is first acidulated with acetic acid. A few drops of a freshly prepared solution of potassium ferrocyanid are then added, and if either albumin or albumose be present, it will be precipitated.

(7) *Quantitative Test*.—The twenty-four-hour urine must be collected and

¹ *Medical Diagnosis*, 2d ed., Anders and Boston, p. 645.

measured and not less than 200 c.c. (about 7 ounces) examined; if forwarded to the laboratory, a note of the total must be appended. *Esbach's Albuminometer*.—This consists in using a graduated test-tube, into which definite amounts of urine and a reagent composed of 10 parts of picric acid, 20 of citric acid, and enough water to make 1000 parts are carefully mixed by reversing several times the stoppered tube. After allowing this to stand about twenty-four hours, the height of the precipitated albumin is read off on an etched scale, which will indicate approximately the parts per thousand. Not less than 0.5 part per thousand can be estimated correctly, however. Tsuchiya has suggested the use of a solution of phosphotungstic acid as follows: Phosphotungstic acid, 1.59 grams; hydrochloric acid (conct.), 5 c.c.; ethyl alcohol, q. s. ad 100 c.c. This solution is substituted for the picric acid solution, and is used in Esbach's tubes. Should there be a hematuria, if the percentage of albumin by Esbach's method, divided into the number of red cells per cubic centimeter of urine, is less than 30,000, it suggests a purely hematuric albuminuria; if greater, it suggests an independent albuminuria (Goldberg).

Prognosis.—Etiologic considerations bear heavily in this matter. The febrile, hemic, cyclic, and paroxysmal varieties usually clear up with convalescence and with advancing years (in the latter case). The persistence of albumin in these cases, however, even in slight amounts or at variable periods, should cause suspicion. Personal observation leads me to believe that in many cases the function of the renal epithelium has suffered. Especially is this true when there is associated a gradually increasing arterial tension. The presence of tube-casts is conclusive of structural change in the kidneys.

ALBUMOSURIA

Albumose may appear in the urine as a result of pathologic conditions, especially myeloma, and is dependent upon the decomposition of organized proteins. It is a body more or less closely allied to peptones, globin, histon, and the digestion albumoses, but it displays certain characteristics unknown to these substances. The nature of the *exciting cause* is unknown.

Anders and Boston¹ have reviewed all the cases of albumosuria available in the literature up to 1903—30 in number—and gave an account of 3 examples that fell under their observation. These studies appear to warrant the following inferences: Nearly all cases of albumosuria manifest themselves after forty years of age. Males are affected in 80 per cent. of the cases. Multiple myeloma figured in 80 per cent., hence albumosuria is suggestive of myeloma and may be diagnostic.

Symptoms.—Albumosuria may be persistent, transitory, or, less commonly, remittent, and it occurs in variable degrees at different hours during the day. The urine may show the presence of combined serum-albumin, but tube-casts are present in rare instances only. Pain is an almost constant feature and is aggravated on pressure over the affected bones. Of interest is the albumosuria of pneumonia, in view of the recent theory that resolution in this disease is the result of the action of certain ferments. Other forms of albumosuria include the *enterogenic form*, noted in various intestinal diseases; the *hemotogenic form*, seen in scurvy, pregnancy, dermatitis, and so on; the *vesical form*, due to proteolytic ferments in decomposing albuminous urines; a *septic form*, observed in suppurative conditions and other disorders associated with a leukocytic increase; a *digestive form*, following ingestion of albumoses in large quantities. Urines are tested for albumoses by acidifying with acetic acid, and adding an equal amount of saturated salt solution. A precipitate occurs, if albumoses are present, which dissolves on boiling and reappears upon cooling.

¹ *Trans. of the College of Physicians*, vol. xxiv, *The Lancet*, January 10, 1903.

Bence-Jones albumose is found in pathologic conditions involving the marrow of the long bones, as multiple myeloma, cancer, myeloid leukemia.

It is distinguishable from ordinary albuminuria by the production of cloudiness in the urine when heated to 122° or 140° F. (50° or 60° C.), and by solution of the precipitate at higher temperatures. It is of grave prognostic significance and runs a fatal course within two years.

INDICANURIA

Definition.—The presence of a pathologic quantity of indican in the urine. Indican occurs in the urine in health in very small quantities, and is, chemically speaking, indoxyl-potassium sulphate.

Pathology and Etiology.—Indican is increased abnormally in the urine by any disorder whereby large quantities of albuminous matters are decomposed. Thus, it occurs in ileus, which produces a stagnation of the contents and a consequent decomposition from bacterial action. Under such circumstances indol and phenol are formed. The former, being absorbed and oxidized into indoxyl, finally appears in the urine in combination with potassium sulphate. Acute and chronic peritonitis, wasting diseases, and cachectic conditions in which there is a considerable destruction of albuminoids (as in Addison's disease, neoplasms, cholera Asiatica, and empyema) usually have an associated indicanuria. Increased indicanuria occurs when there is an impediment to peristalsis of the small intestine, hence is not seen in simple uncomplicated constipation. It is stated (Piseuti) that any obstruction preventing the flow of the pancreatic juice into the bowel would be reflected in a diminished quantity of indican in the urine. An increased indicanuria is encountered when anachlorhydria or hypochlorhydria exists (*e. g.*, gastric carcinoma—Simon).

Diagnosis.—This depends upon the demonstration of indican by adding strong oxidizing agents, which decompose this product and set the indigo or pigment free. At times the urine may present a cloudy, bluish, or even blue-black appearance. This may be seen in urine that has been standing for some time, the sediment giving a bluish reflection, or there may be a blue turbid film on the surface.

Tests.—*Jaffe's* well-known test consists in mixing equal volumes of urine and hydrochloric acid, and then adding, drop by drop, a concentrated solution of chlorinated lime, shaking the tube after each addition. A strong indigo-blue color appears if there is much indican.

A good modified test is the use of fuming nitrohydrochloric acid and urine (equal parts) and a saturated solution of chlorinated potash, used as in the above method. A blue-black cloud or ring appears below the surface. If a few drops of chloroform are then added and the mixture is agitated slightly, a blue color settles at the bottom, owing to the chloroform carrying with it the oxidized indican.

PYURIA

Definition.—The presence of pus in the urine.

Etiology.—Pyuria is due to (1) suppurative inflammation along some portion of the genito-urinary tract, or (2) to the rupture of adjacent abscesses into the tract.

Pyelitis and Pyelonephritis.—Pus from the pelvis of the kidney may be due to calculous, tuberculous, or other irritation. It is associated at times with the "railed" or transitional epithelium usually seen early in the case. In pyelonephritis casts may indicate renal involvement, although it should be borne in mind that in abscess of the kidney pus may be discharged continuously without

the appearance of any casts in the urine whatsoever. One such case came to necropsy under the observation of H. S. Anders, in which small uratic calculi were discharged now and then for several years. Later, several larger stones were removed from the bladder by Willard by suprapubic cystotomy. The abdominal opening healed in a few months, but pyuria persisted. Death occurred, and it was found *postmortem* that a large abscess occupied the lower third of the left kidney, which was filled with small, dark, and irregularly shaped calculi. A thick pyogenic membrane surrounded the purulent and calculous contents. No casts were found at any time during life, and renal symptoms were altogether absent.

The pyuria is sometimes *intermittent*, one ureter becoming temporarily occluded (on the side of the disease), the clear, normal urine from the healthy kidney passing until the ureteral obstruction is relieved, when pus again appears. Purulent urine from the kidney is usually acid in reaction except when the pyelonephritis is secondary to cystitis, when it is more apt to be alkaline and to contain a decided quantity of mucus. *Cystitis*.—Pyuria in this affection is fetid in most cases. Bladder symptoms are marked. The urine is alkaline, and a stringy, tenacious mucopus comes with the last portions. Triple phosphates are often found. The pus and urine are not so intimately mixed as in pyelonephritis.

Urethritis.—The pus is in small quantities, is passed in advance of the urine, and can be "milked out." There is a history of a urethral infection, and the gonococcus may be demonstrated in most cases.

Rupture of contiguous abscesses into the urinary tract is accompanied with a sudden discharge of a large quantity of pus in the urine, preceded by symptoms of abscess elsewhere, as in the pelvis or right iliac fossa (suppurative appendicitis) or perinephric abscess. The pyuria disappears as abruptly as it came on, or lasts but a few days.

Diagnosis.—Pus gives a greenish-yellow or yellowish-white tinge to the urine and sediment, the latter very often becoming very tenacious or jelly-like from the presence of mucus. It may resemble a phosphatic precipitate, as in cystitis; the latter, however, is white, lighter, more granular, and not so thick or tenacious. *Microscopically*, a positive diagnosis is made by the discovery of pus-corpuscles (or leukocytes) with their granular protoplasm, which has the faculty of clearing up and showing one or more nuclei upon the addition of acetic acid. The corpuscles are either more or less swollen and clear, or opaque, granular, or even nucleated, according to their number, the length of time in the urine, and the degree of alkalinity or acidity of the latter. A few phosphatic crystals and epithelium may be seen.

Chemically, there is slight albuminuria, a marked amount of albumin usually indicating renal disease. Reinecke has proposed a method for determining whether all the albumin can be accounted for by the pus. After shaking up the twenty-four-hour specimen to diffuse the pus evenly through it, he counts the cells present by means of a hemocytometer. He finds that 100,000 pus-cells per cubic millimeter should correspond to 1 per cent. of albumin (Esbach). It is obvious that this method falls short of accuracy, although approximately reliable. Nephritis may be diagnosed in connection with pyuria by the discovery of casts. On the addition of liquor potassæ to urine containing pus the latter is converted into a clear gelatinoid substance; mucus, on the other hand, becomes thin and flocculent. Mucus may also be distinguished from pus by its failure to react to cold nitric acid, while the albumin of purulent fluid coagulates.

CHYLURIA

Definition.—The presence of chyle in the urine.

Etiology.—This interesting condition may be either *parasitic* or *non-parasitic* in origin. The former type is more common in the tropics, and is caused by an engorgement and rupture of the bladder or renal lymph-vessels, due to obstruction of the larger branches of the thoracic duct or in the duct itself, by the *Filaria sanguinis hominis* (*vide* Filariasis). It is held to follow injuries to the lymphatic ducts, and may be associated with pregnancy.

Diagnosis.—The urine is increased in quantity, and has a milky turbidity (*galacturia*) due to the emulsified fat. After standing for a time a light coagulum settles to the bottom and a creamy pellicle of fat rises to the surface. The sediment contains also the fibrin of the chyle. Sometimes as much as 2 or 3 per cent. of fat is present (*lipuria*); this may be tested by agitating a portion of the urine with ether, whereupon the turbidity disappears. Owing to the serum-albumin in the chyle, the various tests for that substance would show traces of its presence in chyluria. Hematuria may be associated with chyluria, especially in parasitic cases, and both the blood and urine should be carefully examined for filaria. *Microscopically*, chyle-containing urine resembles milk in its millions of fine granules and fat-droplets.

Prognosis.—Chyluria is intermittent in its appearance, corresponding to the times of rupture of the vesical lymphatics, and may last for years. The prognosis of non-parasitic chyluria is good as to life, but unfavorable as to cure.

CHOLURIA

Definition.—The presence of bile-pigment in the urine.

Etiology.—Choluria may be caused by any disease, local or general, in which *jaundice* is a symptom.

Diagnosis.—Bile-stained urine has a color varying from a greenish-yellow to a brownish-green or brown-black, resembling porter. When shaken its foam assumes a characteristic yellow or greenish-yellow color. White filter-paper dipped in the urine is stained yellow.

Tests.—The *chloroform* test consists in adding this substance to the urine and allowing it to settle to the bottom of the tube. If bile or pigment be present, the gravitated chloroform will be colored yellow.

Gmelin's test is most commonly employed, though it is not the most delicate. A few drops of urine and nitric acid are allowed to run together on a white porcelain plate; if bile-pigment (bilirubin) be contained in the urine, a play of colors ensues, the green predominating, followed by the blue, violet, and red, each shade representing a new form of pigment. The first color noticed (green) corresponds to the biliverdin or normal bile-pigment of herbaceous animals. This oxidation of bilirubin into biliverdin is better accomplished by nitric acid containing a little nitrous acid. Hence, the test may be improved by adding enough fuming nitric to ordinary nitric acid to form a yellow trace of the nitrous acid. This may be placed in a test-tube, and some of the urine added gently from a pipet. Bile-pigment will be indicated by successive rings of green, blue, violet, and red from above downward; this occurs, however, only when considerable bile-pigment is present.

Rosenbach's test is a modification of Gmelin's, and is more distinct. The urine is first filtered, and a drop or two of the nitric-nitrous acid is then poured upon the filter-paper, when the characteristic colored rings will appear if bile be present. According to Penzoldt, the Gmelin-Rosenbach test is made more distinct by acidulating the filtrate with acetic acid and pouring a thin layer into a white shallow dish. The acetic acid assumes a greenish-yellow,

and later a green, or even a blue-green shade if bile be in the urine. This reaction is quickened or intensified by the application of heat to the liquids.

In the *Marechal-Rosen test* a mixture of 1 part of the tincture of iodine and 10 parts of alcohol is spread in a deep layer over the suspected urine in a test-tube or glass. A grass-green ring forms at the point of contact in choluria.

Bile-acids.—These are principally the glycocholic and taurocholic acids. Traces are found in normal urine, and their clinical significance or diagnostic importance, as far as is known, is practically *nil*.

Other constituents of the urine in choluria of long standing are slight quantities of albumin and icteric or yellow bile-stained hyaline or finely granular casts.

A point in **differential diagnosis** should be noted. *Certain drugs*, as rhubarb and santonin, when given internally may produce a discoloration of the urine similar to that caused by the presence of bile. On agitation, however, there will be no yellow foam and no reaction to the tests for bile, while the addition of liquor potassæ causes a red color.

UROBILINURIA

Definition.—The presence of quantities of pathologic urobilin in the urine. It is derived from bilirubin as a product of the reduction of this substance.

When present in large quantities urobilin gives to the urine a red-brown color. This is seen in fevers, varying in depth of shade according to the degree of pyrexia; also in diseases of the liver, after hemorrhagic effusions (due to resorption), in the hemorrhagic diathesis, in purpura, and in progressive pernicious anemia.

Diagnosis.—The presence of urobilin is best detected by a spectroscopic examination. A marked absorption band between Fraunhofer's lines (f and h), fading off from the green into the blue, is characteristic. Chemically, the addition of a few drops of a watery solution of zinc chlorid to the urine will cause the peculiar red-green fluorescence of urobilin to appear.

GLYCOSURIA

Definition.—The presence of sugar (glucose) in the urine. Normally, a trace of sugar is present in the blood (glycemia); abnormally, it may be excreted in the urine when the blood concentration reaches a certain point—0.15 per 100 c.c. blood. Folin,¹ however, with an extremely sensitive reagent, found sugar in every case on examining the urine of about 100 students.

Etiology.—A continuous excretion of sugar is seen chiefly in untreated cases of diabetes mellitus. At times lesions affecting the floor of the fourth ventricle may cause persistent glycosuria. A normal person may take by mouth 100 grains of glucose without the occurrence of a glycosuria. A diminished tolerance, or inability to metabolize properly smaller quantities than this, will be followed by a glycosuria, an alimentary or digestive glycosuria, and which occurs frequently in the following conditions: Certain diseases, like gout, cholera, typhoid, typhus, and scarlet fevers, whooping-cough, diphtheria, malaria, tetanus, and phthisis; hepatic cirrhosis; organic nervous diseases, especially those affecting the medulla and involving the floor of the fourth ventricle; psychic causes, as excessive mental exertion, extreme emotional activity (grief, worry, and shock), from injuries and after operations (Brown), as cerebral concussion and hemorrhage, and fracture of the skull, from apoplexy, cerebrospinal meningitis, and after epileptic paroxysms; pregnancy (40 per

¹ *Jour. Biol. Chem.*, 1915, xii, 327.

cent. of the cases—Wormmüller); certain toxic agents, among these being carbon monoxid, morphin, atropin, hydrocyanic acid, amyl nitrite, curare, chloral, alcohol, mercury, arsenic, turpentine, copaiba (Bettman), adrenalin, phloridzin, and various coal-tar derivatives, as salicylic acid and salol; obesity (pituitary disturbance); pancreatic disease (chronic interstitial pancreatitis and, less commonly, pancreatic calculi, carcinoma, and cysts); exophthalmic goiter or other disturbances of the thyroid; ingestion of alcohol, carbohydrates, or glucose in excess. A renal type of glycosuria is occasionally met with in which the renal threshold is so lowered that even when there is a small amount of blood-sugar, glucose is excreted by the kidneys.

Diagnosis.—The daily quantity of the urine of typical glycosuria—*i. e.*, when masking saccharine diabetes—is greatly increased (60 fluidounces—2 liters—and over *per diem*); it is of high specific gravity (1025 and over), of a clear, pale-yellow color, a “ripe-fruit” odor, a sweetish taste, and an acid reaction that is intensified on standing, owing to the fermentation of the sugar. Albuminuria may be associated with glycosuria, and the albumin should be removed before testing for sugar.

Tests.—These depend mainly upon the peculiar property of glucose in reducing the blue oxid of copper to the orange or red suboxid.

(1) *Fehling's Test.*—Two solutions are used, equal parts being mixed to form Fehling's solution, as follows:

Solution I contains 34.64 gm. of cupric sulphate, dissolved in enough water to make 500 c.c. Solution II: 173 gm. of Rochelle salt are dissolved in 480 c.c. of sodium hydroxid; this is then diluted with water up to 500 c.c.

Application: Dilute 1 c.c. of Fehling's solution (about 10 drops of each of the above solutions) with about 1 dram (4 c.c.) of water in a test-tube, and heat to the boiling-point. If the clear blue color remains, the solution is ready for use; should it change color, however, the solution is unfit for use and should be discarded. The suspected urine is added, drop by drop, heating occasionally, when, if glucose be present, the blue color will be discharged by a yellow turbidity, which increases until finally a deep-yellow or orange-red precipitate falls. Bluish-white flakes and a greenish discoloration of the mixture simply indicate cupric hydroxid, and not glucose. This test serves for the detection of .001 per cent. of glucose (Wormley). It cannot be applied to strongly ammoniacal urine.

(2) *Trommer's Test.*—To about 5 c.c. of urine in the tube add one-third or one-half its volume of potassium or sodium hydroxid, and then, drop by drop, add a 10 per cent. solution of cupric sulphate. If a bluish-white precipitate falls, either filter or agitate the liquid until it assumes a slight and uniform turbidity; then heat, and, if sugar be present, a yellow or red deposit of cuprous oxid falls: 0.01 per cent. of glucose may be detected in this way.

There are certain other substances which when present in urine make the copper tests fallacious by reducing the cupric to cuprous oxid (mucin, lactose, uric acid, pyrocatechin, hydrochinon, bile-pigments, glycosuric acid, the products of elimination after the ingestion of chloral—urochloric acid—and benzoic and salicylic acids). Among normal constituents that can reduce cupric oxid are uric acid, creatinin, and hippuric acid. “Alkapton” urines also reduce Fehling's solution. If care is taken to heat the urine almost to the boiling-point, but not actually boil it, the great majority of these substances will not reduce the copper, which, however, will be precipitated if glucose is present.

(3) *Nylander's reagent* may be employed. This consists of 2 parts of basic bismuth nitrate and 4 parts of sodium tartrate to 100 parts of an 8 per cent. solution of caustic soda. One part of the reagent is boiled with 10 parts of

the urine for a few minutes, when a change from the original to a brown or black color will indicate the presence of glucose. This test is quite distinct, but has the fallacy that is common to all the bismuth tests, of forming a black precipitate with the sulphur compounds.

(4) *Fermentation Test*.—Though not always convenient to apply, this is, nevertheless, a most reliable test. It depends upon the action of yeast in breaking up glucose into alcohol and carbonic acid gas (carbon dioxid). It is performed easily by adding a small piece of compressed yeast to the urine in a test-tube, inverting the latter in a dish of the same, and standing aside for twelve to twenty-four hours, the temperature being kept at about 80° to 100° F. (26.6°–37.7° C.). The evolution of gas resulting from the fermentation of the sugar takes place, with a consequent reduction of the specific gravity of the urine. The yeast may be tested simultaneously for its purity and strength by placing one portion in a test-tube containing about two-thirds mercury and filling with normal urine, and a similar portion in a second tube with mercury and a thin, watery solution of sugar or glucose; the fermentation test of the suspected urine may be made at the same time, and all three tubes inverted over a dish of mercury. Obviously, the first tube should not show the presence of carbon dioxid if the yeast was free from sugar; but the second tube should show this gas to be present or the yeast was inert.

Other tests, such as *Moore's liquor-potassæ-and-boiling test*, *Johnson's picric-acid test*, and the *phenylhydrazin test*, are more intricate.

The *quantitative estimation of sugar* may be made with Fehling's solution in two parts, as recommended above for the qualitative test. This method is based upon the fact that the cupric oxid of 1 c.c. of Fehling's solution will be reduced by not less than 0.005 gm. of glucose. Place 1 c.c. of the solution in a test-tube and dilute with 4 c.c. of water (5 c.c. dil. sol.). Heat to the boiling-point, and add 1 c.c. of urine, and heat the liquid again. If reduction has taken place, 0.005 gm.—0.5 per cent. or more—glucose is present; if no reduction has occurred, less than 0.5 per cent. is present. If 2 c.c. urine are used before the color of the Fehling solution is discharged, there will be 0.25 per cent. glucose. If $\frac{1}{2}$ c.c. is used, 1 per cent. is present. If $\frac{1}{10}$ c.c. urine is all that is required (about 2 drops), then 5.0 per cent. of glucose is present. The sample examined should be taken from a twenty-four-hour collection.

Roberts' differential-density method depends upon a loss in the specific gravity of the urine, due to the fermentation of glucose. According to Roberts, each degree in specific gravity lost is equivalent to 1 grain of glucose in 1 imperial fluidounce (437.5 gr.) of urine, or one degree represents 0.23 per cent. glucose. Pavy's method is also convenient for clinical purposes. (See works on Urinalysis.)

Circumpolarization.—Finally, sugar may be determined by the saccharimeter or polariscope. Glucose polarizes light to the right. The percentage may be calculated by reading the vernier scale indicating the degree of reflection, and multiplying the number read by the factor of the apparatus used, after making any required corrections.

ACETONURIA, DIACETONURIA, AND OXYBUTYRIA

Acetonuria, diacetonuria, and beta-oxybutyria are so closely allied chemically they frequently occur together in the body. They are grouped together as the ketone or acetone bodies, and are apparently responsible for diabetic coma.

Acetonuria may exist to a minute degree in health, the acetone being a product of the normal metamorphosis of albumin. It may be present also in—(1) diabetes; (2) carcinoma; (3) febrile conditions; (4) inanition; (5)

psychoses; (6) intestinal toxemia, especially with fatty acids in the stomach and intestines (enterogenous acetonuria); (7) pregnancy; (8) after anesthesia; (9) in cyclic vomiting; (10) in certain intestinal complaints of children. Urine that contains acetone in pathologic quantities has a fruity (apple-like) odor or one resembling that of chloroform.

Tests.—(1) *Gerhardt's* original test consisted in the addition of a few drops of the tincture of the chlorid of iron, which produced a Burgundy-red color with acetone or, rather, with the aceto-acetic acid.

(2) *Nitroprussid Test.*—To a fluidounce (30.0) of the urine add 1 or 2 drams (4.0–8.0) of a solution of sodium nitroprussid (gr. v to ʒj—0.3–30.0) and a few drops of strong aqua ammoniæ. On standing a rose-violet color appears. According to Legal, proportionately smaller quantities of urine and the reagent may be used, and strong liquor potassæ. A bright red color develops, and fades rapidly, but upon adding acetic acid this changes to purple or violet red (Vierordt). This is a better test.

(3) Perhaps the most accurate and, at the same time, satisfactory test for acetone is the following: Distil the urine with a little phosphoric acid, and add to the distillate a few drops of sodium hydroxid and of Lugol's solution. If acetone be present, yellow crystals of iodoform will form, with the characteristic odor.

Diacetonuria and **oxybutyria** never occur normally. They are often associated with acetonuria in diabetes, and sometimes in fever, or occur as an independent disease (V. Jaksch). "The persistent excretion of more than 25 grams of beta-oxybutyric acid indicates impending coma" (Simon). Stadelmann affirms that of like value in diabetes is the determination of a marked and increasing amount of ammonia in the urine (1 gram—gr. xv—and more *per diem*), as indicating the imminence of diabetic coma. Diacetonuria is found to occur in certain acute diseases of children, accompanied with convulsions.

Tests.—The presence of diacetic acid is demonstrated by the chlorid-of-iron reaction, as in the case of acetone, except that the urine is boiled previously. This is done to avoid fallacy, since in unboiled urine acetic, formic, and oxybutyric acids may strike a Burgundy red also; in urine that has been previously boiled these do not react, while the diacetic acid does, if present. Tests for the latter, therefore, need not be detailed here (*vide* Tests for Acetone).

LITHURIA

Definition.—A persistent excess of uric (lithic) acid and urates (lithates) in the urine. Uric acid occurs in the urine in combination with alkalies, but may become free, separating out as a crystalline deposit.

Normal urine contains about 0.4 part of uric acid to 1000 parts of urine (about gr. x—0.6—*per diem*), or it exists in the proportion of about 1 to 45 of urea, the principal solid constituent.

Etiology.—An excess of uric acid may be excreted in the following conditions: (1) gout and rheumatism; (2) fever; (3) leukemia and pernicious anemia; (4) pulmonary affections in which the interchange of gases is interfered with; (5) a highly nitrogenous diet. Certain other conditions of the urine may diminish its power of dissolving the uric acid shortly after voidance, and may cause a deposit that should not be mistaken for an excess. Such are: (a) temporary increase in the quantity of uric acid from an overindulgence in nitrogenous food; (b) temporary high acidity; (c) deficiency in mineral salts.

Diagnosis.—By the ordinary clinical tests it is impossible to estimate with any degree of accuracy the amount of uric acid eliminated, though from time immemorial it has been customary to consider the precipitation of uric acid crystals as a definite sign of increased elimination. Careful quantita-

tive estimations should be made. More useful, however, and more readily performed are the microchemical tests for the uric acid in the blood.

Urates.—These are increased in pathologic conditions that give rise to uric acid in excess, and are usually present with the latter in some quantity. It is not rare, however, in healthy individuals for a deposit of urates to occur in concentrated urine exposed to a cool atmosphere. Urates appear also in the scanty urine from any cause, *e. g.*, profuse perspiration, diarrhea, fever, and after a meal rich in albuminous elements.

Urates occur principally as acid sodium urate, calcium urate, and ammonium urate. They appear macroscopically as a flesh-colored or “brick-dust” (lateritious) sediment; this is usually abundant and very finely granular in appearance, while the urine above is cloudy. Upon heating such urine it becomes clear, the urates being completely dissolved. *Microscopically*, the sodium and calcium salts of uric acid occur as needle- or dumbbell-like crystals or as fine dark, amorphous granules. Ammonium urate is found in alkaline urine, often with triple phosphates when some putrescence has ensued. It is seen in dark brown or green spiculated spherules; these are sometimes called “hedge-hog” or “thorn-apple” crystals. On the addition of a drop of hydrochloric acid under the cover-glass uric acid crystals may be seen to develop.

OXALURIA

Definition.—A persistent excess of calcium oxalate in the urine. A few crystals may occur in normal urine (about one urine out of every three), especially after standing for a long time.

Transient oxaluria may follow the ingestion of subacid fruits, as pears, or of vegetables containing oxalates (tomatoes, asparagus),

Pathology.—Oxaluria has been described by some English physicians as an independent disease or special diathesis in which marked dyspepsia and hypochondriasis or neurasthenia are associated. The condition is better explained, probably, as one of a disturbed metabolism—particularly of the fats and carbohydrates. Oxaluria is present in wasting diseases, as in tuberculosis and diabetes mellitus, and in the cancerous cachexia; it may appear in catarrhal jaundice, spermatorrhea, also with the “mulberry calculi” and in general paresis, of the insane. Slight albuminuria is not infrequently associated.

Diagnosis.—Oxalate-of-lime crystals appear in the urine in two forms—most commonly as minute, regular, highly refracting octahedra, or, more rarely, as hour-glass- and dumbbell-shaped crystals.

The octahedral crystals have two crossed axes, giving a star or envelope-like appearance. Oxalates sometimes give a glittering and scintillating effect to floating mucus in urine that has undergone fermentation. The finding of calcium oxalate in the urine does not necessarily imply an increased excretion of this salt. The precipitation is due to the absence of the sodium phosphate which keeps it in solution.

PHOSPHATURIA

Definition.—A persistent excess of phosphates in the urine.

Phosphoric acid salts may be precipitated in normal urine that has become temporarily alkaline. These acid sodium and potassium phosphates in normal acid urine are derived from the alkaline phosphates (neutral sodium and potassium phosphates) of the blood. In normal urine 1.2 parts of alkaline phosphates per 1000 and 0.8 part of earthy phosphates are appreciable.

Etiology and Pathology.—Conditions that produce an alkaline fermentation of the urine cause a deposit either of *amorphous earthy phosphates* (of calcium and magnesium) or of *alkaline phosphates* (of potassium, sodium,

and ammonium). They are also found in the decomposing urine of chronic cystitis, of phosphatic vesical calculi, of paralysis, and in undue retention of urine. In this alkalinity, due to the ammoniacal fermentation of urea, ammonium carbonate reacts with the phosphates of magnesium to form the triple ammonio-magnesia-phosphatic crystals, the commonest variety of phosphaturia. Here the phosphates are deposited before or immediately after the urine is passed, giving a milky appearance to the last portion. Deposits of phosphates, and especially of triple phosphates, however, do not indicate an actual phosphaturia. This must be determined by chemical analysis. *Amorphous carbonate of lime* in small quantity may be present also if the urine is strongly alkaline and ammoniacal (Beale). The *calcium phosphates* are generally more abundant than the magnesium, and may be found in cases of nervous or atonic dyspepsia, neurasthenia, and other debilitated conditions. The alkaline phosphates (which represent three-fourths of the phosphoric acids), being easily soluble, do not form a deposit.

A quantitative estimation of the daily output of phosphates shows a decided increase in wasting diseases, as tuberculosis, leukemia, chronic articular rheumatism, and acute yellow atrophy of the liver. The phosphoric acid, however, is not increased. The so-called "phosphatic diabetes" is characterized chiefly by excessive phosphaturia.

Diagnosis.—Phosphatic urine has usually a stale ammoniacal odor, a whitish turbidity, and a copious light colored granular sediment falls on standing. *Microscopically*, the calcium phosphate crystals appear singly as "knife-blade," "arrow-head," or "slender wedge-shape," or in stellate clusters. Acetic acid dissolves them. The ammoniomagnesium phosphate crystals are transparent rhombic or triangular prisms, large and small—"coffin-lid shaped." These also are soluble in acetic acid; oxalate of lime crystals are not so.

On heating phosphatic urine an increased cloudiness is produced that simulates albumin, but on acidifying, as with a drop of nitric acid, this is cleared up at once.

LEUCINURIA AND TYROSINURIA

Definition.—The presence of leucin and tyrosin in the urine. These are strictly pathologic substances, and are usually found together. They are products of the decomposition of albumin.

Etiology.—The principal causes of leucinuria and tyrosinuria are acute yellow atrophy of the liver and acute phosphorus-poisoning (in both of which fatty degeneration is conspicuous). They occur in traces constantly in diseases of the liver, cholelithiasis, catarrhal jaundice, specific infectious diseases, as typhoid fever, small-pox, and yellow fever, and pernicious anemia.

Diagnosis.—Leucin is the more soluble, hence is rarely found in the urinary sediment. Tyrosin, on the other hand, may be discovered sometimes as a fine greenish-yellow deposit. Bile-pigment and a trace of albumin may be found not infrequently in urine containing leucin and tyrosin. Urea is, as a rule, markedly diminished. Leucin and tyrosin may be detected by evaporating a few drops of urine on a glass slide and examining microscopically. Leucin appears in the form of slightly glistening, greenish-yellow spheres that may show radiating lines and concentric rings. Tyrosin is recognized by the slender tufts of fine, needle-like crystals arranged in star- or cross-like fashion.

If the residuum after evaporation be heated with a drop of nitric acid, slowly evaporated to dryness, and then touched with a drop of sodium hydroxid, the leucin, if present, will assume a yellowish-brown hue. Tyrosin becomes red in color when boiled with Millon's reagent of mercurous nitrate, and a violet color when warmed with a little sulphuric acid, and then treated with a drop of the solution of phenic chlorid.

CYSTINURIA

Definition.—The presence of an excess of cystin in the urine. This is rare, “but when it occurs it may be copious, and is not unlike a sediment of fawn-colored urates” (Hutchison and Rainy). The *causes* of cystinuria have not been well made out, though *hereditary influences* seem to have an important bearing on the etiology. Insufficient nitrogen metabolism, as occurs similarly in such allied conditions as gout and obesity, seems to give rise to cystinuria.

Brieger points out a probable significance in the discovery of the associated presence of ptomains with cystinuria. Thus, in certain infectious diseases, as intestinal mycosis, a ptomain-cystinic product is supposed to be formed, then to be absorbed, and finally decomposed in the urine, thus setting free the cystin. Cystitis may be caused by ptomains.

Diagnosis.—The sediment is light, and not very unlike that of the amorphous urates. It is not dissolved by heat, however, though soluble in ammonia. Under the microscope cystin occurs in the form of thin, transparent, hexagonal crystals. Care should be exercised in forming a diagnosis of cystinuria that a contamination with iodoform be excluded, since the microscopic appearance of that substance is similar to that of cystin. On account of the sulphur contained in cystin, a test may be employed by which hydrogen sulphid is liberated, as by boiling the suspected urine with a solution of lead oxid and sodium hydroxid, black lead sulphid resulting from the reaction if cystin be present.

VARIOUS OTHER CONDITIONS

Urea.—This occurs in solution in the normal urine as a product of the perfect decomposition of the nitrogenous elements of food and tissues. In 1000 parts of urine about 20 parts are constituted of urea (2 per cent., equivalent to about 450 gr.—30.0—daily). The quantity of urea is *increased* in the urine after the ingestion of a considerable quantity of protein food; sometimes after exertion; in acute inflammation and in fevers—either relatively or absolutely, as in pneumonia; in diabetes and other morbid conditions in which metabolism is accompanied by an increase in the tissue waste. In febrile states its excretion increases or diminishes with the exacerbations and remissions of temperature respectively.

Urea is *diminished* in quantity in all forms of nephritis, and markedly so in uremia; in organic liver diseases; in cachectic and anemic states; and in dropsy, inanition, and allied conditions.

The quantitative estimation of urea may be made according to one or more of several methods: Fowler’s hypochlorite test (with Labarraque’s solution) is perhaps the most practical for ordinary clinical purposes.¹ Fowler’s method is based upon the loss of specific gravity upon the liberation of the nitrogen of the urea. The mean specific gravity of a mixture of 1 part of urine and 7 parts of the solution of sodium hypochlorite is taken while quiescent, and is then subtracted from the specific gravity of the mixture taken after agitation several times during about two hours. The difference which is due to the liberation of the nitrogen (as is shown by the effervescence), multiplied by the factor 0.77, gives the approximate percentage of urea in the urine.

Urine evaporated to a syrupy consistence and then treated with nitric acid shows crystalline quadratic plates of urea nitrate.

Chlorids.—About 10 parts of the chlorids of sodium and potassium in 1000 parts of urine are excreted daily. They are *increased* in the urine after muscular exertion, during the resorption of mechanical or inflammatory transuda-

¹ See works on Urinalysis.

tions and exudations, and in intermittent fevers, owing to the destruction of the red corpuscles.

Pathologic *diminution* in the quantity of chlorids occurs in fevers, in the nephritides, in cachectic conditions, and especially in such diseases as pneumonitis, pleuritis, and rheumatism. In the last-named class the chlorids diminish as exudation continues, and may even totally disappear from the urine in extensive pneumonic consolidations, to reappear again with the resorption of the exudate.

Test.—The chlorids may be detected, after first removing any albumin that may be present, by acidulating with a few drops of nitric acid (to keep the phosphates in solution), and by then adding, drop by drop, a strong solution of argentic nitrate. According to the abundance of the resultant white, curdy precipitate of argentic chlorid a rough estimate may be made of the total quantity of chlorids in the urine.

Lipuria is a term applied to the presence of fat in the urine. It may result from the steady use of cod-liver oil or of fatty food, or it may be found in pyonephrosis (Ebstein); in phosphorus-poisoning; in prolonged suppuration; in the lipemia of diabetes mellitus; in the "large white kidney" with fatty degeneration of chronic Bright's disease; in beer-drinkers, and in chyluria. Fatty urine becomes clear upon agitating after the addition of ether.

Lipaciduria, or urine containing volatile fatty acids (acetic, butyric, and propionic), is as yet without diagnostic significance.

Melanuria, or urine containing the pigment melanin, is found in cases of melanotic sarcoma. The urine is dark, either just after being voided or after some exposure and oxidation.

Hematoporphyrinuria (*Urospectrin*).—This term implies the presence of hematoporphyrin (iron-free hematin) in the urine. It occurs after long-continued use (even in small doses—Müller) of saffron and certain coal-tar products (sulfonal, trional). Stockton found it in acute ascending paralysis.¹ In addition to the gastric and nervous *symptoms* in poisoning from these substances is a cherry-colored or dark blue-red urine, the abnormal appearance of the latter being due to the presence of hematoporphyrin resulting from the destruction of the red blood-corpuscles. The condition has proved fatal in cases in which the kidneys were diseased. The urine is always quite acid. According to Garrod, hematoporphyrin is a scanty though constant ingredient of normal urine. He extracts it by adding 100 c.c. of urine to 20 c.c. of a 10 per cent. solution of sodium hydroxid. This precipitates the phosphates, which are washed with water and redissolved with rectified spirits. After acidulation with hydrochloric acid the solution shows spectroscopically bands of acid hematoporphyrin. The *treatment* consists in the withdrawal of these drugs and the administration of alkalies.

Pneumatinuria, or gas formation in the bladder, rarely occurs. Heyse records a case of myelitis in which this condition was present.

Fibrinuria.—In certain conditions of the genito-urinary tract, particularly pyelitis and ureteritis, fibrinous (and mucous) shreds are found in the urine. Fibrinuria may follow nephrolithiasis (v. Jaksch).

Bacteriuria.—The tubercle bacillus is not uncommon in the advanced stage of pulmonary and in renal or vesical tuberculosis. Typhoid bacilluria occurs probably in about 25 per cent. of the cases of typhoid fever (Horton Smith, Gwyn). Dick and Dick² have shown the presence of bacteria in the urine in a considerable number of patients (66 per cent.) with manifest foci of infection.

Lactosuria.—Lactose is found in the urine of some puerperæ.

¹ *Amer. Jour. Med. Sci.*, July, 1900.

² *Arch. Int. Med.*, 1917, xix, 493.

Inosituria.—Inosite occurs in the urine in diabetes mellitus, diabetes insipidus, and chronic interstitial nephritis.

Alkaptonuria.—Alkapton (so called by Bredeker) is an obscure substance that is sometimes found in the urine of phthisical cases, or at times in that of patients without any apparent local or general disease. Alkaptonuria is congenital in a few cases. On exposure the urine darkens in color from above downward, also upon the addition of liquor potassæ. It gives the sugar reaction with Fehling's solution (Osler). It gives a dark-brown ring in Ehrlich's diazo-test (C. Mitchell¹).

DRUGS.—Urine as affected by the administration of drugs—as carbolic acid, salol, antipyrin, and potassium iodid—responds to certain chemical tests, for the study of which the reader is referred to works on urinalysis.

Cholesterinuria has been found in cases of pyonephrosis, hydronephrosis, renal hydatids, epilepsy, and severe dyspepsia.

ESTIMATION OF RENAL FUNCTION

1. **The Phenolsulphonephthalein Test.**—Phenolsulphonephthalein was introduced in 1910 as a functional test by Rowntree and Geraghty.² The technic is as follows:

Twenty minutes after drinking 10 ounces of water the patient should receive an intramuscular injection of 1 c.c. of a sterile solution containing 0.006 gm. of the drug. The bladder should be empty at the beginning of the test. The patient should urinate or, if necessary be catheterized one hour and ten minutes after the injection, and again an hour later.

Each of these specimens should be rendered decidedly alkaline by the addition of sodium hydroxid (25 per cent. solution) and diluted with sufficient distilled water to make accurately 1 liter. A small portion of each sample is filtered and examined in a colorimeter, such as the instrument devised by Rowntree and Geraghty.³

Fairly accurate estimations can be obtained by comparison of the specimens prepared as above, with an equal quantity of a standard solution (6 mg. of phenolsulphonephthalein to the liter). The darker fluid should be diluted with distilled water until both correspond in depth of color, when they will contain the same percentage of the drug. As the amount in the standard solution is known it is easy to calculate the amount in the total quantity of urine.

If it be impossible to make the color comparison within a few hours, the reaction of the specimens must be kept acid. Under normal conditions from 40 to 60 per cent. of the drug is eliminated during the first hour, and from 60 to 85 per cent. during the first two hours.

If an estimation of the functional capacity of each kidney is indicated, the urine should be obtained by ureteral catheterization and examined as described above.

2. **Test-meal for Renal Function.**—Hedinger and Schlayer⁴ have proposed a test of urinary function as measured by the specific gravity, salt and water excretion, in two-hourly periods, following test-meals. Mosenthal⁵ has simplified the meals to make the test applicable to private practice. It is

¹ *Med. Rec.*, May 21, 1910.

² *Jour. Pharm. and Exper. Therap.*, 1909, ii, 579.

³ *Arch. Int. Med.*, 1912, lx, 284.

⁴ *Deutsch. Arch. f. klin. Med.*, 1914, cxiv, 120.

⁵ *Arch. Int. Med.*, November, 1915, p. 733.

only necessary for the patient to eat three full meals a day (at 8 A. M., 12 M., and 5 P. M.), writing down the approximate quantities taken. No food or fluid is allowed except at meal times.

The urine is to be collected every two hours from 8 A. M. to 8 P. M., while the night specimen consists of the urine excreted between 8 P. M. and 8 A. M. Punctual collection of the urine is essential to accurate results.

A normal test yields "a maximum specific gravity of 1018 or more, the specific gravity varies 9 points or more from the highest to the lowest, and the night urine is small in amount (400 c.c. or less) and of high specific gravity (1018 or over)."¹ Diminished renal function is indicated by lowering of the maximal specific gravity with fixation of the specific gravity and nocturnal polyuria.

This simple procedure of estimating the volume and specific gravity of the urine following test meals gives important information regarding the ability of the kidneys to excrete concentrated urine and is of especial value in the earlier stages of chronic nephritis. However, in some instances it is advisable to determine the salt and nitrogen content of the total day and night urines as estimated by the Volhard and Kjeldahl methods respectively.²

3. **Ambard's Coefficient.**—Ambard³ has devised a formula expressing numerically the relationship existing between the concentration of the urea in the blood and the rate of urea excretion in the urine. The quotient is as follows:

$$K = \frac{Ur}{\sqrt{D \times \frac{70}{P} \times \frac{1/C}{1/25}}}$$

In which K = The coefficient of urea excretion.

Ur = Urea grams per liter of blood.

D = Urea grams excreted in urine in twenty-four hours.

C = Urea grams per liter of urine.

P = Body weight in kilograms.

70 = Standard body weight in kilograms.

25 = Standard concentration of urea grams per liter of urine.

The blood urea and urea of the urine may be estimated according to the technics outlined by Marshall.⁴ The normal coefficient usually ranges from 0.06 to 0.09. Values above 0.09 indicate some impairment of power of the kidneys to excrete urea.

McLean⁵ has modified the original formula as follows:

$$\text{Index} = \frac{\text{G. urea per 24 hours} \sqrt{\text{gms. urea per liter urine} \times 8.96}}{\text{Wt. in kilos} \times (\text{gm. urea per liter of blood})^2}$$

Indices below 80 indicate more or less impairment of renal function.

4. The Concentrating and Diluting Capacity of the Kidney.—

Normally the kidney is capable of concentrating the urine when small amounts of fluid are ingested, or of diluting the urine when fluid to excess is taken in. In disease these two functions may be markedly disturbed, so that, for example, no matter how dry the diet is, the concentration of the urine as estimated by the

¹ Mosenthal and Lewis, *Jour. Amer. Med. Assoc.*, September 23, 1916.

² For technic, consult standard works on Clinical Diagnosis.

³ *Physiologie normale et pathologique des reins*, Paris, 1914.

⁴ *Jour. Biol. Chem.*, 1913, xiv, 283, and xv, 487.

⁵ *Jour. Exper. Med.*, 1915, xxii, 212.

specific gravity cannot be increased, and the diluting capacity may be lost, though usually this does not disappear until advanced nephritis occurs. When such is the case a urine of constant fixed low specific gravity is eliminated.

5. The Salt Test.—Under normal conditions the addition of 10 gm. of salt to a constant diet is followed by the excretion of this salt in twenty-four hours. In the nephritides accompanied largely by tubular injury or in passive congestion of the kidney the salt is eliminated but slowly without much immediate effect on the salt concentration of the urine or upon the total quantity of the urine (tubular hyposthenuria). Where vascular injury is present, the total quantity of ingested salt is promptly eliminated in twenty-four hours, but as a result of the stimulation of the extremely sensitive vessels by the salt, urine in large quantities is eliminated, which is not concentrated.

6. The Non-protein Nitrogen of the Blood.—This method of testing kidney function depends upon the fact that an insufficient kidney is unable to excrete certain substances, which consequently collect in the blood and tissues. Normally the non-protein of the blood is between 22 and 26 mg. per 100 c.c. of blood. Serious renal injury is indicated when these figures are markedly increased up to 100 mg., while even higher figures (300 mg.) may occur in the last stages of nephritis. With normal figures of non-protein nitrogen approximately 50 per cent. is urea nitrogen. As the amount of non-protein nitrogen increases the percentage of urea nitrogen also increases markedly, so that it may make up some 90 per cent. of the non-coagulable nitrogen. Other blood constituents that have a diagnostic and prognostic importance when their percentage in the blood is increased are uric acid and creatinin. Myers and Lough consider blood-creatinin over 5 mg. per 100 c.c. to be of such serious import that death will occur in a short time, before two months have elapsed.¹

THE NEPHRITIDES

Before considering the several varieties of nephritis, and especially the clinical history peculiar to each variety, it may be well first to describe certain general manifestations of renal diseases that are more or less common to all. Reference to these symptoms under the different forms of nephritis will, it is hoped, thus make possible a clearer apprehension of their significance and clinical importance, as well as render unnecessary any further elaboration.

One of these conditions has already been described—viz.: (1) *Albuminuria*. It remains to speak of (2) the *Morphologic constituents* of the urine in nephritis, (3) *Edema (anasarca, dropsy)*, and (4) *Uremia*.

THE MORPHOLOGIC CONSTITUENTS OF THE URINE IN RENAL DISEASE: CASTS, EPITHELIUM, ETC.

1. Tube-casts.—These are undoubtedly the most important morphologic elements in the urine of a nephritic. Albuminuria is coincidentally present, and the occurrence together of these two pathologic constituents furnishes indisputable evidences of renal disease, although, on the other hand, hyaline casts may occur in many pathologic states minus albuminuria. According to the nature and number of the casts also may be determined the character and variety of the affection of the kidneys in most instances. Casts, as their name implies, are simply cylindric bodies molded in the renal tubules, and composed

¹For a very complete summary, with a full bibliography, of the various tests for renal function, see Rowntree's article in *Hand-Book of Practical Treatment*, W. B. Saunders Co., Philadelphia, 1917, iv, 788.

essentially of the coagulable substances in the blood-serum. The coagula of the tubules are mostly albuminous. Other morphologic elements may be mixed with casts—epithelium, red blood-cells, pus-cells, and the granular matter and fat-droplets due to degeneration of the renal epithelium.

Singly, the casts are invisible to the naked eye, but in acute nephritis they may be so abundant as to form a cloudy sediment.

(a) Microscopically, the *unmixed* or *hyaline* cast—the commonest—appears either long or short and narrow or broad, of a clear, homogeneous substance, delicate in outline, and often showing ends with a cheesy or wax-like fracture. They may be straight or slightly curved and tortuous. Rarely, a cast may be found equal to a millimeter in length. The so-called *narrow casts* are about equal in width to the diameter of a leukocyte, while the *medium* and *broad casts* are from three to four times this size. Hyaline casts are usually associated with other varieties of casts, though in fevers, renal congestion, chronic interstitial nephritis, and in amyloid kidney they may occur unassociated with other forms. Burri's India-ink method of staining for the detection of casts is highly recommended by Stövesandt.¹

(b) *Granular* casts are nothing more than hyaline casts with fine or coarse granules superadded. The granules represent minute, opaque particles of urates, albumin, fat, cellular debris, and even bacteria (*bacterial casts*). It should be remembered, however, that granular casts may be simulated by casts of coagulated albumin covered with particles of hematin or of urates, especially in acute nephritis. The hematin can be recognized, however, by the brownish-yellow coloration.

(c) *Epithelial* casts are hyaline casts more or less covered with renal epithelium, indicating desquamative nephritis (Fig. 61). The epithelial cells may show evidence of granular or fatty change.

(d) *Blood-casts* consist of soft hyaline casts having blood-cells embedded in them. These are present in acute hemorrhagic nephritis and acute renal congestion.

(e) *Waxy* casts are similar in appearance to hyaline casts, though better defined, broader as a rule, and of an opaque, slightly yellowish tint. They often show broken ends (Fig. 61). They do not necessarily indicate amyloid disease of the kidney, as was formerly held. They may, however, sometimes show the amyloid reaction with iodine and potassium iodide, and are always suggestive of serious renal disease.

(f) *Fatty* casts are such as have left upon and in them fat-droplets or granules (Fig. 60), which, if abundant, are indicative of fatty degeneration of the kidney. They occur in serious forms of chronic nephritis of any type, which has become unusually protracted. Cells showing granulation may be seen.

Rolled casts or *pseudocasts* (sometimes made by sliding a cover-glass over a specimen of urine) of urates should not be mistaken for genuine tube-casts. Blood-casts (due to hemorrhage), consisting of fibrin and epithelial pseudocasts (hollow), in cases of desquamative nephritis, also belong in this category. Cylindroids are distinguishable from hyaline casts by their greater length, tapering ends, and by being at times beset with leukocytes, red corpuscles, epithelial cells, and certain crystals. Cylindroids are of no significance unless present in considerable numbers, when they indicate kidney irritation and an abnormal increase in mucous secretion.

2. **Epithelium.**—Renal cells are found in the urine of those forms of nephritis that are characterized by a catarrhal or desquamative and exudative process in the tubules. Epithelial cells from the kidney are polygonal or spheric in

¹ *Practical Med. Series*, 1911, i, 384.

contour, with an indistinct cell wall; they have a large oval nucleus, and are either abundantly granular or show a fatty change. These cells are about the size of the white corpuscle.

3. **Leukocytes**.—Only when attached to casts can it be positively affirmed that leukocytes are of renal origin (Strümpell). The pus-cells are frequently seen to be without nuclei in marked or chronic pyuria.

4. **Red Blood-corpuscles** (*vide* Hematuria, p. 916).—In acute hemorrhagic nephritis and in severe renal congestion free red blood-corpuscles are generally to be found.

5. **Fat-globules** and **fatty degenerated cells** are seen especially in sub-acute and chronic nephritis with fatty degeneration of the proliferated epithelium, or in the fatty stage of large white kidney.

DROPSY OF RENAL DISEASE

Since, as in other conditions, renal dropsy or edema is an abnormal accumulation of watery fluid transuded from the blood-vessels into the cellular tissues and lymph-spaces, the question arises, "What is the rationale of its development in nephritis?" On the ground that in most forms of nephritis the urine is diminished, it was formerly held that the dropsy was due to the saturation of the tissues with the water that was not excreted by the kidneys. This theory is not tenable, however, for there are some cases of edema unaccompanied by any diminution in the daily quantity of urine; on the other hand, certain instances of renal disease in which there is almost a state of anuria show no evidence of dropsy whatever. Landerer holds that the relaxation of the tissues (which may be caused by the increased transudation of stasis, or by hypnutrition from hydremia), and their consequent loss of elasticity, prevent that forcing of the lymph into circulation that exists in the normal state, and as a result a watery infiltration of the tissues is permitted. From recent experiments edema is due, at least in part, "to toxic substances accumulating in the blood and exciting an injurious action on the endothelium of the capillaries" (Edsall). Pearce¹ concludes that plethoric hydremia and vascular injury have equal value with nephritis in the production of edema, and that none of these three factors acting alone, and no combination of two acting together, is sufficient to cause edema. The chlorid retention theory, namely, that there is an abnormal amount of sodium chlorid in the tissues of persons manifesting renal dropsy (in consequence of which an accumulation of water in order to keep the chlorids in solution occurs), is widely accepted at the present day. Jürgens studied concentration camps of prisoners of war and described an "edema disease," resulting from a metabolic upset from dietary deficiency, and wherever this was recognized and a more varied diet provided, the men soon threw it off or its appearance was averted. Martin H. Fisher holds that the edema of nephritis is due to acidosis.

The dropsy of the nephritides may be either slight or marked, local or general (anasarca), and sudden or slow in onset. It is purely renal in origin perhaps only in acute Bright's disease or in the earlier stages of chronic Bright's disease. In all forms of chronic nephritis the dropsy may be due, in part, to the venous stasis of cardiac incompetency. In chronic interstitial nephritis, especially, edema is slight, and usually is the result of weakness and dilatation of the heart. I desire to mention here those rare cases of dropsy that simulate Bright's disease in which no satisfactory causative lesion is apparent or discoverable, and also those cases, rarer still perhaps, that have a peculiar family or congenital origin.

¹ *Arch. Int. Med.*, Chicago, June, 1909.

Physical Signs.—The recognition of edema is made possible by both *inspection* and *palpation*. Renal dropsy is manifested first by puffiness of the skin of the face, and especially of the eyelids. At other places where there is loose subcutaneous cellular tissue, and in particular where the parts are dependent, dropsy is most apt to be seen early, as under the malleoli of the ankles, the dorsum of the foot, and the scrotum. Later, the limbs and the lower part of the back become swollen, and the whole body is involved in severe cases. The skin has a peculiar waxy pallor and a glossy appearance. When vascular or cardiac changes exist, so as to permit of increased dropsy from engorgement, as in cirrhotic kidney, a cyanotic or muddy color of the skin may prevail. Palpation detects pitting due to loss of elasticity in edematous tissues.

Pathologic Features.—Dropsy is most constant and most persistently decided in the large kidney of subacute or chronic nephritis; it is most uncommon and irregular in chronic interstitial nephritis (contracted kidney). There is also a doughy or putty-like consistence. In very marked cases of dropsy the deeper parts, such as the muscles, become affected. The serous cavities also in general anasarca show evidences of effusion, and thus give rise to hydrothorax, hydroperitoneum, and hydropericardium. Less frequently there may be edema of the larynx, uvula, conjunctiva, and other mucous membranes. Edema of the brain, either local or general, may be the cause of grave uremic symptoms in chronic nephritis, or of unilateral convulsions or paralysis and apoplectic seizures. The dropsical liquid is chemically similar to a diluted blood-serum. A minute quantity of albumin and urea is present.

UREMIA

Definition.—Uremia is the term applied to a group of manifestations, mainly nervous and either acute or chronic, resulting from a toxemia due to the retention in the body of certain products which should normally be eliminated by the kidney or else which are the result of perverted metabolism during kidney disease.

Our present knowledge of the **pathology** and **etiology** of uremia, as of renal edema, is based largely upon theoretic views. The theory that attributes uremic symptoms to the retention of the excretory products appears to have the strongest proofs to support it. Thus, many cases of uremia are seen in whom the non-protein, the uric acid, the creatinin, and urea nitrogen of the blood are very markedly increased. That the increased urea may have a very distinct effect is suggested by the experiment of Hewlett and his co-workers, who developed dizziness, sleepiness, and headache following the ingestion of 100 gm. of urea, when the blood urea was over 70 mgm. On the other hand, uremia without nitrogen retention frequently occurs. It may be presumed from the experiments of Foster, who isolated a toxic substance from the blood of convulsive uremics which, when injected into animals, caused death, that toxic substances arise as a result of disturbed renal metabolism.

Not only some of the solid urinary constituents accumulate in the blood in uremia, but the water also is only partly eliminated, and its presence in the blood renders the latter hydremic and of lower specific gravity. Notwithstanding the fact that most cases of uremia may be traced to a marked simultaneous diminution in the quantity of urine passed, there remain still certain instances of renal disease in which uremic symptoms appear without any such perceptible diminution. Even more frequent perhaps are those perplexing cases of anuria now and then reported in which no uremic symptoms appear. In the latter instances it is probable that the elimination of products normally excreted by the kidneys may be accomplished through other channels, as by the

skin and bowels; in the former it is still likely that the solid urinary constituents are retained.

Foster² differentiates three basic types: "The first is a simple retention of urinary nitrogenous waste, a urinary poisoning; the second is due to defective water and salt metabolism, resulting in cerebral edema; the third type is a toxemia, resulting from an abnormal catabolism."

The **symptoms** of uremia may be either acute or chronic in onset, severity, and course. In **acute uremia** the *severest nervous symptoms* come on suddenly; they last but a comparatively short time, and terminate fatally, with convulsions and coma, dyspnea, feeble cardiac action and pulse, fever, and pulmonary edema. These acute symptoms are not infrequently preceded by mild *uremic prodromes*, as headache, somnolence, nausea, malaise, slight dyspnea, increased blood-pressure (200 mm. Hg. or over), and uneasiness. Curschmann claims that in threatened uremia the Babinski reflex often become positive before either mental disturbance or an increase of the tendon reflexes appear.

Chronic uremia is characterized by the *absence* of the marked symptoms referred to above, the milder manifestations alone appearing and lasting over a considerable length of time. Here the general prostration, the feeble cardiac and arterial states, the occasional stupor and delirium, transient dimness of vision, anorexia and nausea, irregularly hurried breathing, and muscular twitchings, indicate the grave condition of the patient. To gain a more thorough knowledge of this condition a divisional study of the symptomatology is necessary.

Cerebral Symptoms.—These vary from a slight headache, tremors, and the restlessness of anxiety to the most violent maniacal delirium and convulsions; from somnolence, low muttering, and mental stupor to profound coma; and from slight visual disturbances to complete amaurosis. The onset of a noisy delirium, and less commonly of a marked mania, is often abrupt, and may be the first manifestation of Bright's disease in an individual. Delusional insanity (*folie Brightique*) is seen in a few cases. Bischoff has observed only 2 cases of purely uremic psychoses among 3000 cases of insanity. Melancholia and the delusion of persecution, with suicidal and homicidal tendencies, may occur. The most characteristic symptom of uremia, however, is the convulsion (uremic eclampsia). *Uremic convulsions* are epileptiform in type, although they may be either unilateral or local. They are supposed to be due to a local or general edema of the brain, and are probably allied to the *apoplexia serosa* of early writers (Osler). The convulsions of uremia may come on suddenly or may be preceded by headache, vertigo, dropsy, nausea, and vomiting. As in the epileptiform convulsion, after the early tonic rigidity there may follow at short intervals the clonic spasm, with cyanosis, fever, and contracted arteries, and the intervening periods of unconsciousness, shallow or noisy respiration, and slow, hard pulse. *Coma* may come on gradually as well as during the convulsive attacks. It may be preceded by headache, apathy, and insomnia, and continue progressively to deepen. A *typhoid state* not infrequently accompanies uremic coma. The temperature is usually lowered, and moderate dilatation or contraction of the pupils may be evidenced.

Uremic Amaurosis.—Blindness may follow uremic convulsions, or, rarely, it may come on without motor disturbances. It is of purely centric origin (the cortex of the occipital lobe), and its duration is short, lasting but a few days in most instances. Retinal hemorrhage may occur. *Uremic deafness*, which is probably also of centric origin, is a less common manifestation. Other nervous phenomena, as hemiplegia, monoplegia, contractures, aphasia, pruritus, paresthesiæ, and cramps in the calf-muscles are not so frequent in occurrence.

¹ *Jour. Amer. Med. Assoc.*, September 23, 1916, p. 927.

Circulatory Disturbances.—The pulse is moderately slow, tense, and full in uremia, but with the onset of acute and severe symptoms, as convulsions, it usually becomes accelerated, small, and feeble. The blood-pressure remains high until convulsions supervene, after which it rapidly declines. Indican has been demonstrated in the blood in uremia; this is absent in other pathologic states.¹ G. Dörner concludes the presence of indican in the blood in large quantity is characteristic of outspoken uremia, and when present in considerable amount it is also found in pleural exudates and anasarcaous fluid. Blood nitrogen is markedly increased in many cases.

Respiratory Symptoms.—Renal dyspnea, which is sometimes called “uremic” or “renal asthma,” is a marked and often an early symptom of uremia. I believe that it is the most constant symptom of this serious condition. The respirations are deep and often stertorous in coma, or they may be irregular, accelerated, and shallow, sometimes assuming the Cheyne-Stokes type. Dyspneic attacks are especially apt to occur at night. In chronic uremia slight dyspnea may be continuous for a long time. Again, alternating paroxysmal exacerbations may arise. The uremic dyspnea is probably due to the acidosis so frequently associated with kidney insufficiency. It may, however, be the result of cardiac weakness or of dropsy or pulmonary edema.

Gastro-intestinal Symptoms.—Uremic stomatitis is generally seen. The breath is foul, the tongue, lips, and gums are red, swollen, and painful, and the saliva is increased. Uremic vomiting is also usually of centric origin. The vomiting may come on suddenly and be persistent. Uncontrollable hiccup and sometimes uremic diarrhea may be associated. There may be produced in the intestines a catarrhal or diphtheritic inflammation, and ulceration even. Uremic diarrhea may also exist apart from any gastric disturbances.

General Symptoms.—The *skin* of the face is usually pale in uremic coma. The skin is often harsh and dry, as in chronic interstitial nephritis. Itching of the skin is intense. The *temperature* is generally lowered, but uremic fever frequently accompanies the convulsions or they may be preceded by “uremic chills.” In some cases the temperature rises to 105° to 107° F. (40.5°–41.6° C.) just before death, while in other cases, characterized by coma that deepens into collapse, the temperature may be so low as 91° or 93° F. (32.7°–33.8° C.).

There is not infrequently an *ammoniacal odor* about a uremic patient. The *urine* is diminished in quantity and is generally highly albuminous. A previous dropsy is sometimes markedly reduced upon the appearance of acute uremic symptoms.

Duration and Prognosis.—Acute uremia is manifested by coma and convulsions, seldom lasting more than a few days. Chronic uremia, in which milder nervous symptoms, nausea and vomiting, and dyspnea are more prominent, may persist, however, for many weeks. While a grave condition, uremia, even in its most acute and violent forms, is not at once necessarily fatal, for under proper treatment—as by venesection, for instance, followed by judicious hygienic measures—life may be considerably prolonged. Sooner or later, however, barring a possible death from some intercurrent affection, a fatal result is inevitable. Indicanemia, while not toxic in its effects, is, nevertheless, a sign of approaching exitus, as a rule. Likewise, a steadily increasing amount of non-protein nitrogen and an increase in the blood urea with marked change in the percentage of the urea of the blood nitrogen is indicative of a fatal outcome. The converse, on the other hand, shows that improvement is likely to occur. The phthalein elimination is also a valuable

¹ For test, see *Zentralblatt für Innere Medizin*, December 23, 1911; by W. von Moraczewski and E. Herzfeld.

prognostic aid, a low phthalein output, 20 per cent. and under in two hours, or failure to eliminate the dye at all in this period of time, being a decidedly unfavorable finding.

Diagnosis.—Uremia may be recognized by the history, the marked arterial tension, and the accentuated second sound of the heart; also by the albuminuria (the urine has to be withdrawn), the blood findings, the very low phthalein output, the temperature, and the odor of the breath. The presence of dropsy in some cases is a valuable indication of the nephritic origin of uremic manifestations. *Pseudo-uremia* is met in arteriosclerotic nephritis due to arterial changes in the brain.

Differential Diagnosis.—Uremic unconsciousness coming on suddenly may simulate *alcoholism*, *cerebral hemorrhage* (*apoplexy*), *cerebral tumor*, or *meningitis*. The points of dissimilarity between the first two conditions and uremia are here tabulated (Herrick):

CEREBRAL HEMORRHAGE	ALCOHOLIC NARCOSIS	UREMIA
Pupils unequal or dilated.	Pupils contracted or dilated; eyes injected.	Pupils generally dilated; albuminuric retinitis.
Stertorous, puffy breathing, and flapping cheek.	No stertorous breathing.	Sharp, hissing stertor.
No odor.	Odor of alcohol.	No odor, unless urinous.
Paralysis; hemiplegia.	No paralysis, usually.	No paralysis.
Unconsciousness absolute.	May be aroused.	May or may not be aroused.
Pulse slow and strong or irregular; arteries often atheromatous.	Pulse frequent and feeble.	Pulse at first strong, later weak and rapid; tension strong; arteriosclerosis.
Coma sudden and deep.	Coma gradual.	Coma gradual or sudden.
Convulsions late; may be unilateral.	No convulsions.	Preceded by general convulsions, headache, etc.
Urine generally negative.	Urine generally negative.	Urine albuminous.
Apoplectic habit; heart may show hypertrophy.	Red face and nose, heart often weak, dilated, myocarditic.	Edema and pallor; heart hypertrophied.

In *meningitis* the mode of onset, the rigidity of the neck, incoherence or mild delirium, photophobia, and pronounced fever point to the distinction.

Uremic coma must also be differentiated from *opium-poisoning* and *diabetic coma*. Chronic uremia must not be confounded with the asthenic state of *typhoid fever* and *acute miliary tuberculosis*. In *opium-poisoning* the pupils are contracted and do not respond to light. Again, in *opium-poisoning* the respirations are slow, deep, and full, and the patient may answer rationally when aroused. In uremic coma, it will be remembered, consciousness is abolished. In *diabetic coma* the history must be learned, the harsh, dry skin and emaciation noted, and especially are the ethereal odor and the Burgundy-red reaction of the urine (acetone) with the tincture of the chlorid of iron to be observed; sugar is also present. *Pseudo-uremia*, mentioned above, is distinguished from true uremia by there being no retention of nitrogen and no indicanemia.

The **prognosis** is grave, but guarded; it is even favorable in many cases, so far as immediate results are concerned.

Treatment.—This will be detailed in the discussion of the various forms of nephritis. Suffice it to say that the supreme indication is the prompt elimination of the poisons in the blood. When diaphoresis and catharsis fail, venesection should be employed; the latter measure is also probably the most reliable in urgent cases of uremic convulsions or coma. The counter-injection (intravenous) of normal salt solution may be indicated in cases of profound weakness threatening collapse. Bäumlér advises against the intro-

duction of salt solution and the use of salt in the diet. Frey recommends lumbar puncture to evacuate toxins and reduce pressure on the brain in the convulsive type.

AMYLOID KIDNEY

Definition.—Amyloid (waxy or lardaceous) degeneration of the kidneys is usually coexistent with a similar degeneration of other viscera.

Pathology.—Macroscopically, the amyloid kidney appears pale, greenish or yellowish-white, firm, and uniformly enlarged, and the surface is smooth, glistening, and often mottled, owing to the prominence of the stellate veins. On section a homogeneous, anemic or "bacon-like" surface presents itself, particularly in the cortical region. The cortex is wider than normal; the pyramids may be red in color and slightly infiltrated; and the glomeruli may show an infiltration by the glistening, translucent amyloid (albuminoid) material. On the application of Lugol's solution of iodine to the amyloid areas a mahogany-red color is produced. Brushing over the amyloid substance with a solution of iodine, and then with dilute sulphuric acid, gives a blue or violet tint. Similarly used, a 1 per cent. solution of methyl-violet strikes a red color. The capsule of the kidney is thickened, though not always adherent.

Microscopically, the amyloid change is generally found in the early stages to affect the walls of the capillaries of the malpighian tufts. The walls are swollen with the homogeneous material and the vessel lumen is diminished or obliterated. The straight uriniferous tubules are also infiltrated later perhaps, the deposit occurring primarily in the membranæ propriæ. A diffuse nephritis is nearly always an associated condition. The tubules generally contain hyaline casts. Fatty degeneration of the epithelium, glomerulites or waxy glomeruli, and a thickening of Bowman's capsule are common in markedly amyloid kidneys. In advanced cases most of the secretory structure becomes atrophied. Amyloid infiltration of the smaller granular kidney is less common than of the large white kidney, with intense parenchymatous changes.

Hypertrophy of the heart is not always present in amyloid disease of the kidneys. Amyloid infiltration of other organs, however, as of the liver and spleen, is usually associated with waxy kidneys.

Etiology.—The causes of amyloid kidney are those of the amyloid change affecting (either simultaneously or nearly so) other organs, as the spleen, liver, and intestines.

Commonly, amyloid disease is marked also in the other solid organs named above; it is secondary to wasting diseases, cachexiæ, and the like. Perhaps the most frequent cause of the waxy kidney is tuberculosis, especially of the lungs ("chronic ulcerative phthisis"); tuberculosis of the intestines also is often associated. Next in order are the prolonged suppurations, particularly of the bones, as in osteitis of the vertebræ and hips (usually tuberculous). Chronic empyema, intestinal ulcers, vesicovaginal fistulæ, and other purulent affections, chronic in nature also, have the same etiologic effect. Amyloid kidney is often present in syphilis, especially in the tertiary stage, when ulceration of the mucous surfaces and of the bones is present. Rarely, gout, malaria, leukemia, cancer, and chronic valvular endocarditis with insufficiency seem to produce amyloid disease. Frank¹ claims to have discovered a bacillus, only slightly pathogenic, of the capsulatus group and thinks it possible that it is Friedländer's *Bacillus capsulatus*.

¹ *Munch. med. Wchnschr.*, March 28, 1916.

Symptoms.—These vary greatly according to the extent to which the amyloid degeneration has encroached upon the normal kidney structure, and may be overshadowed partially or completely by those of the dominant causal affection.

The *urine* is pale yellow, clear, and variable in quantity, and the amount passed in twenty-four hours is sometimes normal or may be slightly diminished. More frequently, perhaps, it is increased, and especially in marked or advanced cases. The specific gravity is apt to be low (1015–1005), and there is seldom any sediment.

Serum albumin and *globulin* may both be present in the urine; but a highly significant condition, and one that is seemingly diagnostic, is the high proportion of globulin as compared with the serum albumin (Salkowski, Senator). *Tube-casts* may be found, but their presence may be only temporary; they are usually wide, hyaline, fatty and granular, and very few in number (Fig. 61). The amyloid reaction may be elicited with the hyaline casts; symptoms referable to the kidney are often absent in comparison with those of the nephritides. *Dropsy* is not invariably present, and when present is but moderate in degree and generally in the legs only. It is proportionately prominent with the increase in the anemia, circulatory depression, and wasting of flesh and strength. The latter manifestations, constituting a cachectic appearance, are quite commonly observed in amyloid kidney.

The associated enlargement and the firm, sharp outlines of the liver and spleen are of diagnostic significance. *Marked diarrhea* may be due to coexisting amyloid infiltration of the intestines or to tuberculous intestinal ulcers, and is often seen in advanced cases.

Diagnosis.—This can seldom be made upon the urinary manifestations alone. Important and often necessary adjuncts are the histories of causation and of the associated symptoms and physical signs. Thus, there will be evidenced in most cases tuberculosis, chronic bone-suppurations, or syphilis, while coexisting hepatic and splenic enlargements, wasting, and cachexia are usually present. In any of the diseased conditions mentioned amyloid kidney may be diagnosticated with reasonable certainty upon the development of an increased quantity of pale clear urine of low specific gravity and containing a large amount of albumin, or even with slight albuminuria.

From *parenchymatous nephritis* amyloid kidney is to be differentiated by the history, by the more marked and generally distributed dropsy, and by the albuminuric retinitis that characterize the former. In *chronic interstitial nephritis* there are less marked albuminuria and dropsy, and there are present arteriosclerosis, cardiac hypertrophy, and a pronounced tendency toward uremic symptoms.

Prognosis.—This varies with the cause. Incipient bone disease or tuberculosis, with only slight evidences of amyloid change in the kidneys, may be controlled. As a rule, however, the structural alterations are so far advanced, and the constitutional powers of resistance so much enervated, before the amyloid infiltration can be distinctly apprehended that in the majority of instances the prognosis is entirely unfavorable. In decided cases death ensues in from several weeks to as many months.

Treatment.—This also depends upon the causal affection. Hygienic and dietetic measures are always useful, however, with a view to improving the general nutrition. The iodid of iron has been recommended as an alterative, and easily assimilable and palatable fats and tonics may also be tried. Tuberculous cases require creasote or allied preparations; syphilitics require mercurials and iodids; while malarial subjects do best under the systematic use of arsenic, iron, and quinin.

NEPHROLITHIASIS

(*Renal Calculi; Pyelitis Calculosa; Renal Colic; Gravel*)

Definition.—A condition characterized by the formation of fine or coarse concretions in the kidney substance or in the renal pelvis by the precipitation of certain of the solid urinary constituents.

Varieties.—According to their size, renal concretions are variously termed—(1) **Renal sand**, of which the particles are fine and pulverized. (2) **Renal gravel**, consisting of coarse grains or even of pea-sized concretions. (3) **Renal stone**, or **calculus**, when larger masses than the preceding exist, either more or less rounded or as stony casts or molds of the pelvis of the kidney, its infundibula, and calyces (*dendritic* or *coral calculi*).

According to their composition, the chemical varieties of renal concretions are: (1) *Uric acid calculi*. Urates are often associated in the calculus with uric acid, thus producing stratification. These concretions may occur as sand, gravel, or large stones; they are usually quite hard, reddish-brown or black in color, and have a smooth though irregularly shaped surface. The fracture is crystalline. Pure uratic stones may occur in children. Mackarell, Moore, and Thomas have shown that the most common constituents of renal calculi are calcium oxalate and calcium phosphate.

(2) *Calcium oxalate* concretions occur more rarely in the kidney. They constitute the so-called “mulberry calculi,” from a fancied resemblance to the mulberry, owing to their dark brown or black color and very irregular and nodulated or prickly appearance. They are also quite dense; lamination, however, is not common, although they are sometimes formed about a uric acid nucleus.

(3) *Phosphatic* calculi of the kidney are still less common than the oxalate, but they are more common in the bladder. They may consist of calcic phosphate or ammoniomagnesian phosphate, and may possibly be associated with calcic carbonate. Phosphatic salts are most often deposited secondarily about uric acid or oxalate calculi in the alkaline urine of a cystitis set up by the irritation of the true renal stones. Phosphatic calculi are grayish-white in color and are comparatively soft.

(4) Renal stones composed of *cystin*, *xanthin*, *carbonate of lime*, *fatty* or *saponaceous matters* (urosteolith), *indigo*, and *fibrin*, though of extreme rarity, have been occasionally reported. Cystin calculi have a pale-yellow color and a waxy luster.

Pathology.—The anatomic changes of the kidney vary with the degree and persistence of the irritation, the size of the calculi, and their passage or retention. Sometimes numerous granular and pea-sized concretions are found in the renal pelvis, with desquamated epithelium and a turbid urine. Interesting cases are those in which a dendritic stone occupies a great portion of the atrophied kidney substance, as well as the entire pelvis of the organ. In one of my own patients the left kidney was, apparently, nearly twice the normal size, owing to the presence of a large coral calculus (uric acid and urates), connected by an isthmus with a rounded stone in the inferior portion quite as large as a large walnut. The pelvis of the right kidney also contained a dendritic calculus.

Secondary Lesions.—Perhaps the most usual result of renal concretions is a pyelitis: this may be simple catarrhal, diphtheritic, or purulent, with or without hemorrhages, depending upon the intensity of the mechanical irritation. A pyelonephritis may follow in severe cases, as may even a general suppuration (pyonephrosis) or perinephric abscess and perforations. Renal pus cavities are sometimes found *postmortem* containing numerous small stones. Hydro-

nephrosis is another important pathologic sequel, in which the cause is to be attributed to the blocking of the ureter by an erstwhile passing stone or by the closing of the aperture of a ureter from within the pelvis. Pressure-necrosis and perforation may thus be induced. Owing to the prolonged pressure of a dendritic calculus, there is commonly a distinct and marked atrophy of the renal parenchyma, resulting in chronic diffuse nephritis with little or no exudation.

Etiology.—The definite causation and the exact manner of formation of renal concretions are still unestablished. We may infer not a little, however, with some good reason, since the *predisposing causes* are rather distinct. Thus, in children and in advanced life (before fifteen and after fifty years of age) the occurrence of calculi is most common. Men are subject to nephrolithiasis more often than women. Gout, and the various influences that induce this condition, as an excessive meat (protein) diet or a sedentary life, seem to predispose to stone. Heredity, I believe, plays a prominent part in many cases.

Broadly speaking, any habit of the system that encourages the precipitation of insoluble abnormal ingredients or of normal ingredients in excess, owing to chemical changes in the urine, tends to the formation of calculi. It should be stated, however, that the *primary causes* of calculus formation is the presence of some substance in the urinary tract that affords a nucleus about which the successive layers of crystals may deposit and adhere, such as bits of mucus, colloid material, epithelial shreds, parasitic ova, bacteria, blood-clots, and tube-casts.

It is generally believed that the requisite conditions for the formation of a renal calculus are—a highly acid or alkaline urine, a nucleus, and a disturbance of the colloidal chemistry of the urine.

Symptoms.—These may be slight, progressive, and chronic, or they may be intensely acute and comparatively short in duration, though subject to repetition—*i. e.*, *renal colic*. It is not unusual for patients to pass uric-acid sand and gravel for years without much complaint. A sudden blocking of a ureter, however, or a slowly passing stone of distending dimensions produces great agony at times. A smooth, snugly fitting dendritic calculus in the pelvis may not cause any symptoms for years until the destruction of tissue by its weight and mechanical irritation ensues; there is then a progressive failure of health, a constantly increasing pain in the back, *occasional hematuria*, tenderness on pressure over the diseased kidney, both anteriorly (deep) and posteriorly, and finally *uremia* and death.

The characteristic symptoms of stone in the kidney appear as an attack of *renal colic*. This happens when a calculus in its passage down the ureter acts as a mechanical irritant, or when it is caught and stopped in the passage. The large “gravel” or pea-sized and more or less rough stones usually cause the attack, which comes on, as a rule, quite suddenly, although it may be preceded by a chill and some general uneasiness or by slight pain in the region of the kidney. It may be excited by a sudden muscular effort. The pain is tearing in character, and rapidly reaches an agonizing maximum of severity, starting from the lumbar region and extending down along the ureter into the groin, and often into the testicle and inner side of the thigh. There are cases in which the stone has been found in the unsuspected kidney, pain having been reflected from the diseased kidney to its fellow. The paroxysm may appear in the form of a diffuse abdominal and lumbar pain in some instances. There is local tenderness on pressure, and nausea and repeated vomitings are frequent. The patient is often collapsed, and perspiration, a rapid, small, and feeble pulse, trembling, anxiety, bodily twistings about, convulsions

even, and syncope may ensue. There may be moderate fever. The *urine* is scanty or may be suppressed for a time, and is often bloody. Frequent and painful attempts at urination are made, with the passage of but a few drops at a time, owing perhaps, in part at least, to a reflex spasm of the vesical sphincter (vesical tenesmus). The presence of pus and of pelvic epithelium in the urine indicates a pyelitis. When a large quantity of clear urine is passed it may be looked upon as having come from a healthy kidney.

The *paroxysm* of renal colic ends when the impacted stone passes out of the ureter. This may occur within a few hours or it may take several days; or colic may be intermittent.

Recovery is not always complete upon the evacuation of the stone. The previously retracted testicle may remain painful, and there are apt to be aching and soreness over the affected kidney and ureter.

In certain severe cases of mechanical irritation the symptoms of pyelitis, pyelonephritis with abscess, or hydronephrosis may be superadded. Anuria and uremia may result.

Nephrolithiasis as a *chronic affection* may exist for many years, with recurring paroxysms of renal colic. I observed a case for five years that had extended over a period of thirty years, until it finally came to necropsy. Between the attacks of colic the patient may be entirely comfortable, save perhaps an occasional burning in the urethra on micturition, owing to a highly concentrated, acid urine or to the passage of minute uric-acid granules. There are apt to be pain and tenderness over a kidney containing a large embedded stone. A smoky hued urine, due to slight hematuria, is also sometimes present in long-standing cases of renal calculus, particularly after exertion.

A *renal intermittent* fever may occur in nephrolithiasis, and is analogous to the hepatic intermittent fever of cholelithiasis.

Pyelitis—simple or purulent—with late involvement of the kidney parenchyma (pyelonephritis) is a frequent concomitant of chronic nephrolithiasis. The presence of pus in the urine is constant, with an absence of renal epithelium in cases of an abscess-cavity of the kidney. In ordinary pyelitis the pyuria is often intermittent.

The general health of patients with nephrolithiasis is, as a rule, remarkably good. Anorexia is not only seldom present, but such persons are habitually free and good liver. Persistent headaches with nausea, however, should warn one of uremia. Splenic and hepatic enlargement may be found with prolonged suppurative pyelonephritis, indicating amyloid disease.

Diagnosis.—This resolves itself into a study of the diagnostic characters of (a) the attacks of renal colic, (b) of the underlying systemic condition in general, and (c) the renal condition in particular that renders these attacks possible. The latter can be discovered only by a careful and continuous study of the clinical history and urinary manifestations as outlined in previous paragraphs.

Nephrolithiasis may be positively diagnosed in a case in which, after sudden, agonizing, colicky pain, referred to either lumbar region and radiating down the ureteral course to the testicle, a concretion is found to have passed with the urine. It is therefore necessary in a suspected case of renal colic to pour the urine through a fine sieve as soon as passed. The more recent improvements in the operative technic for producing the roentgen-rays enable us to detect renal calculi with accuracy as to their number, size, and relative position. The injection of collargol through an opaque sound, which has previously been introduced into the pelvis of the kidney, enables a roentgen-ray picture to outline the pelvis and calices.

Differential Diagnosis.—Renal colic must not be taken for *biliary* or

intestinal colic. The antecedent history is of great value in arriving at a diagnosis. In biliary colic there may be jaundice, and pain referred to the upper rather than to the lower abdominal zone, both of which symptoms are absent in renal colic; while in the latter the disturbance of micturition and the character of the urine, especially the hematuria, are characteristic.

In intestinal colic the griping pain is usually most intense in the umbilical region, is often relieved by pressure, and is associated with tympanites and constipation; it has usually a dietetic origin, while the renal and urinary symptoms are absent. The exclusion of *lumbodynia* and *lumbo-abdominal neuralgia* is not so difficult. The differentiation of the varieties of calculi from the symptoms is not positive. It has been suggested, however, that the oxalate stones usually cause the sharpest pains and the hematuria. Right-sided ureteral pain felt over the lower abdominal region may be confounded with *appendiceal colic*. Musser has found the pain of renal colic to be more paroxysmal and less uniform in location than in the latter. Early *renal tuberculosis* (*vide*), with its hematuria and pyuria, must be differentiated from renal calculus also. Cases of supposed stone in the kidney with most of the typical symptoms in which, however, no stone was found at operation (false stone), have been reported by James Tyson.¹ In all instances adhesions were found between the capsule and the kidney itself, and all were relieved by operation. In a case of *hypernephroma* under my care the blood coagula induced typical attacks of renal colic at intervals.

Prognosis.—This should always be guarded, owing to the possible dangers and complications that often attend nephrolithiasis. Thus the passage of gravel without marked symptoms tends to persist or recur—in both events an unfavorable tendency, since subsequent formations are apt to be larger and cause serious symptoms. An attack of renal colic may itself be fatal. Large latent calculi, of long standing, lead, in most instances, to such grave complications as pyelonephritis, pyo- and hydronephrosis, perinephric abscess, and uremia.

Treatment.—Paroxysms of renal colic call for prompt relief. This is best afforded by hypodermic injections of morphin and atropin, coupled with hot baths or fomentations applied to the loins. The free use of hot drinks, as lemonade, soda, or plain water, is also helpful in promoting the passage of the stone. Cases of excessive suffering require the inhalation of chloroform.

The treatment of the nephrolithiasis without or between attacks of renal colic is most important. First to be considered are the **hygienic and dietetic** measures, for in mild and uncomplicated cases much can be done to prevent the aggravation of the disorder, and at least the formation of larger concretions may be delayed. The patient should live a regular, calm, steady, and temperate life. Exercise should be so managed that it may be taken rather moderately in the open air, and with a view to preventing additional weight in persons of fair nutrition and to promoting a reduction of weight in the obese.

Overindulgence in food, particularly in meats (liver, sweetbread, and similar nuclear food), should be prohibited. Alcohol should not be taken. On the other hand, since the urine is apt to be scanty, the patient should be encouraged to drink freely of plain and alkaline waters. The value of various pure spring-waters as diluents is undoubted, the Buffalo, Londonderry, and Otterburn Lithia, the Saratoga, Bedford, and Poland waters, all being distinguished for their purity. More marked and more generally useful for their alkalinity are the Carlsbad, Vichy, and carbonated waters. In cases characterized by occasional hematuria the Rockbridge alum-water may be tried. Plain soda-water and lemonade may be used as adjuvants.

¹ *New York Med. Jour.*, May 26, 1906, p. 1106.

The **medicinal** treatment of nephrolithiasis is aimed to secure a solvent and disintegrating action upon the stones; it is symptomatic. It is extremely doubtful whether stones once formed in the pelvis of the kidney and remaining there are ever dissolved. Lithium citrate or carbonate in 5-grain (0.3) doses in tablet form, three or four times daily, has been generally employed. Sodium phosphate and the vegetable salts of potash, as the citrate, acetate, and tartrate, are useful. Much water, especially the carbonated, should be drunk, along with doses of the above, and in this way relieve, in a measure, the local distress and pain.

The reaction of the urine must be tested at stated intervals and kept faintly acid if the stones are composed of uric acid. Should the urine become alkaline, the alkaline treatment must be suspended for a while, or a secondary deposit of phosphates about the uric-acid stone may be induced. Naggling lumbar pains may be relieved by occasional doses of such analgesics as acetphenetidin, belladonna, hyoscyamus, codein, and indirectly by the sweet spirits of niter.

Efforts to acidify the urine are indicated when the calculus happens to be composed of phosphates or of calcium oxalate. This is more difficult of accomplishment than when it is necessary to reduce the acidity. Saccharin in 2- or 3-grain (0.13-0.2), and benzoic and boric acids in 5- to 15-grain (0.3-1.0) doses, in capsules, seem to be most useful for this purpose. It is claimed for calcium carbonate, again, that it diminishes the phosphates without making the urine alkaline.

The question of surgical interference must be decided in not a few cases; thus, it may be briefly stated that in protracted and obstinate cases of calculous renal disorder, with persistent local pain, a gradually decreasing capacity for work, and evidences of severe pyelitis, pyelonephritis, or, worse, of perinephric abscess, the surgeon must operate. In the simplest cases a nephrotomy or nephrolithotomy may be performed and the stone removed. Where the renal structure is much damaged it may be necessary to do a nephrectomy. To avoid the increased perils of the latter operation, however, it were better that a nephrotomy were done as early as consistent with the diagnosis of incarcerated pelvic stone and the condition of the patient.

ACUTE NEPHRITIS

(*Acute Bright's Disease; Acute Diffuse Nephritis; Acute Parenchymatous Nephritis; Exudative, Catarrhal, Tubal, Desquamative, and Glomerulonephritis of Acute Course*)

Definition.—An acute inflammation of the kidneys, more or less diffuse in nature. It may be either of a mild, severe, or grave character. Delafield describes three varieties of acute renal inflammation under the common synonym of acute Bright's disease, as follows: (1) *acute degeneration of the kidneys*, (2) *acute exudative nephritis*, and (3) *acute productive nephritis*. At present writing the three forms following are recognized by many writers: (a) Acute tubular; (b) acute glomerular, and (c) acute diffuse nephritis. The last-named variety manifests the symptoms of the first two. Moreover, it is not possible to recognize clinically either acute tubular or acute glomerular nephritis in many instances, but I shall incidentally give a brief description of the morbid changes and clinical features which they present.

Pathology.—From the very mild to the gravest cases of nephritis there is an intermediate series of continuously more marked pathologic changes in the renal tissues. These depend greatly on the amount of poisonous material circulating in the kidneys and eliminated by them.

In the mildest cases the *macroscopic* appearances of the kidneys may present nothing distinctly abnormal. As a rule, however, the organs are slightly enlarged, swollen, and somewhat softened. These conditions are more evident when the interstitial exudation is abundant and when inflammatory edema is evident. The kidneys may be reddened and congested and appear bloody on section, or they may be pale and mottled. In examples of the former, hemorrhages may be formed beneath the capsule (*acute hemorrhagic nephritis*), though it is more common to see red patches of hyperemia alternating with opaque, whitish portions on both the outer and cut surfaces of the kidneys. The cortex especially is swollen, turbid, and pale, or slightly congested in the mildest cases, and is deeply mottled (red and pale glomeruli) or hyperemic in severe instances. The pyramids usually show an intense redness. The surfaces are smooth and the capsule non-adherent.

Microscopically, in mild cases there is simply a cloudy swelling or a granular (parenchymatous) degeneration of the epithelium of the malpighian tufts, Bowman's capsule, and of the cortical uriniferous tubules (*acute tubular nephritis*). These changes may be almost exclusively limited to the glomeruli, as in some cases of scarlatina, and hence the term *glomerulonephritis* (*acute glomerular nephritis*). The cells are swollen, opaque, and irregular in shape, while the cell contents are granular (albuminoid or fatty). A further advance in the process is seen in cellular coagulation necrosis or disintegration, desquamation of the cells, and hyaline degeneration of masses of them in the tubules. Acute degenerative changes are frequently found in the acute infectious diseases or when inorganic poisons have been introduced into the body. In phosphorus-poisoning actual fatty degeneration of the epithelium may be found. A rapid necrosis of cells is also met with in severe cases.

True acute nephritis is not only characterized by changes of the renal epithelium (the parenchyma), described above, but the inflammatory exudate (serum, leukocytes, and erythrocytes) is found between the tubules. The kidneys show different stages of the process in different portions. In some places there is only a slight cellular infiltration of the intertubular tissues; in others, besides the desquamation of necrotic epithelial cells and the presence of hyaline casts in the tubules, the interstitial tissue is swollen by the coagulated serofibrinous exudate, abundant leukocytes, and some red blood-corpuscles. It should be stated that the inflammatory exudate collects also in the malpighian bodies and tubules. The epithelium lining the latter, especially the convoluted portion, is often flattened, and the tubules themselves may be dilated and choked with degenerated cells or, more frequently in the straight tubules, with hyaline casts. The white blood-cells that are found infiltrating the stroma of the kidney are not usually equally diffused, but are collected in foci in the cortex.

In most cases of diffuse exudative nephritis new epithelium appears, and a restoration of the glomerular function takes place. In the *productive variety* of acute diffuse nephritis, however, according to Delafeld, the lesions—consisting of a cellular growth in the capsules and of connective tissue around thickened arteries—are more permanent in character from the first, and hence the increased gravity of the disease. In the more intensely acute cases the new tissue between the tubules is largely cellular; in those of a subacute type it is relatively dense and fibrous.

Anasarca and pleural, pericardial, and peritoneal dropsy are also found in those dying of acute Bright's disease. Complicating conditions (lobar pneumonia, meningitis) are sometimes seen *postmortem*.

Etiology.—Acute nephritis may occur at any time of life, though it more often makes its appearance before than after middle life. Males are more

susceptible than females, and particularly when engaged in occupations requiring exposure to cold and wet. The habitual use of alcoholics is generally a predisposing cause of acute Bright's disease.

The principal exciting causes of acute diffuse nephritis are the following: (1) *Those acting on the skin*, as cold and dampness, extensive burns, and chronic skin diseases. In many cases it is difficult to estimate whether the influence of alcoholic intemperance predominates or the exposure incident to it. Thus, acute intoxication from beer-drinking itself may cause an attack of acute nephritis. The disease may also be attributed, at times, to exposure to cold and wet irrespective of alcoholic indulgence. It may be presumed with reason that in such cases there is some inherent or acquired weakness or a susceptibility of the kidneys, rendering them the weak links in the visceral or systemic chain. Watson¹ states that cold is a factor producing not acute nephritis, but the onset of acute symptoms in an already existing chronic nephritis.

(2) *Infectious Diseases*.—These embrace any of the acute infectious diseases, though in the majority of cases scarlet fever is the primary affection. Nephritis may supervene during the height of scarlatina, but more often it occurs in the second or third week of convalescence. Other infectious fevers may also cause acute nephritis (small-pox, typhus, typhoid, relapsing fever, epidemic influenza, tonsillitis, septic sore throat, cholera, diphtheria, yellow fever, measles, chicken-pox, erysipelas, septicopyemia, acute lobar pneumonia, cerebrospinal meningitis, dysentery, acute articular rheumatism, and tuberculosis: syphilis and malaria are rare causes). Acute infectious nephritis may also occur as a primary disorder, and the brunt of the affection may fall either upon the kidney rather than upon any other part, or upon the organism as a whole, as in the fevers.

(3) *Chemical Toxic Agents*.—Among the principal irritants of this class are turpentine, cantharides, carbolic and salicylic acids, iodoform, the mineral acids, potassium chlorate, and such inorganic poisons as phosphorus, lead, arsenic, and mercury. The excessive ingestion of highly acid, spiced, or adulterated foods (as from salicylic acid and lead chromate) may in certain individuals cause acute renal inflammation. White found lead in all of 5 specimens from trench nephritis; he suggests the possibility of the metal being derived from canned foods. On the other hand, most British observers ascribe it to a specific infection—"epidemic infectious nephritis." Ether anesthesia may induce acute diffuse nephritis.

(4) *Pregnancy*.—Here the nephritis (*gravidarum*) comes on in primiparæ, usually in the last months of pregnancy. It may be caused by renal engorgement due to mechanical pressure, as well as to nutritive disturbances in the kidney, owing to the altered blood condition, or to certain toxic products of metabolism.

(5) Latent and insidious *chronic nephritis* may be the cause of an onset of a manifest acute nephritis.

(6) Finally, traumatism to the kidney may cause acute nephritis, when the urine may contain hematoidin crystals.

Symptoms.—The *onset* varies with the cause of the nephritis, though generally it is rather sudden. Chilliness, nausea and vomiting, pain in the back, and, within twenty-four hours, dropsy, are seen in some cases. Children may be seized with *convulsions* (uremic), and adults are not less liable to them in severe attacks. Fever may be present, although it is neither constant nor high. The characteristic symptom is the early appearance of *edematous puffiness* of the eyelids and face, with pallor of the skin. Soon (and sometimes at first, even) a swelling is noticed about the ankles and legs, and in marked

¹ *Brit. Med. Jour.*, 1912, i, 822.

cases the whole body becomes dropsical, so that pitting on pressure may be observed pretty much all over the bodily surface. In such instances the scrotum and penis or the labia may become enormously distended, the skin having almost a translucent appearance.

Local symptoms, as pain and tenderness in the lumbar region, are often wanting and are never marked. There may be a desire to micturate often, accompanied by slight burning and vesical tenesmus, due to the concentrated urine. In very severe dropsy the tense, dry skin, as of the limbs, may be sensitive or even painful to the pressing finger. Movements of the body are often difficult, painful, and distressing in marked anasarca. Intense headache and backache may precede the onset of uremia. In mild cases the renal condition may be overlooked unless a urinary examination is made. The characteristics of the urine in acute nephritis are all important. The total quantity passed in twenty-four hours is diminished, and may be very scanty, sometimes amounting to not more than from 5 to 25 ounces (150–750 c.c.). Suppression occurs in some cases of toxic origin, when an acute degeneration or necrosis of the renal epithelium takes place, and in the most severe exudative inflammations. The *specific gravity* is increased to 1025 or more early in the case; later it may be as low as 1010 or 1015. The *color* is darker than normally, and is usually smoky red or reddish brown, according to the amount of blood passed. If the morphologic constituents are present in great quantity, a more or less abundant flocculent sediment appears on standing.

Microscopically, some red blood-corpuscles and renal epithelium are found along with the characteristic *blood*, *epithelial*, and *granular tube-casts* (Fig. 56). Typical casts may rarely be found without the presence of albumin. Chemically the urine is *acid*, and on boiling a *thick, curdy precipitate of albumin* forms. The percentage of the latter by Esbach's method varies from 1 to 1.5 per cent. The urea and gross solids are diminished. The molecular concentration or osmotic pressure of the urine is usually reduced (hyposthenuria), so that the freezing-point (cryoscopy) is 1° or less than 1° C. (instead of the normal 1.3° to 2.3° C.) below that of distilled water (0° C.) (A. O. J. Kelly).

Other symptoms may develop during the course of acute Bright's disease. If *great general edema* is present, physical signs of hydrothorax, ascites, and hydropericardium may be elicited. The first-mentioned condition is bilateral and causes dyspnea; the second increases the dyspnea by pressing the diaphragm upward; and the last impairs the heart's action. Strümpell describes a form of pneumonia—a "stiff inflammatory edema"—midway between lobar pneumonia and bronchopneumonia, that sometimes develops in severe cases of acute nephritis. Edema of the conjunctivæ, soft palate, and larynx may also occur. Recently Lapinsky reported a fatal case of acute parenchymatous nephritis in which severe bilateral sciatic neuritis was associated.

The *pulse* is often hard and tense, and, though slow at first, it may become accelerated later. Cardiac hypertrophy of a slight degree may be detected. The second aortic sound is accentuated. The arterial pressure is considerably elevated, varying according as the glomeruli or tubules are chiefly involved (Norris). Epistaxis is an occasional symptom and subconjunctival hemorrhages are sometimes seen as a result of uremic convulsions that may not have been witnessed. A very constant symptom is the dry, anemic skin. *Uremic manifestations* may ensue at any time during the course of the disease. They appear early in the most severe cases, with intense headache and backache, vomiting, and convulsions.

The *clinical course* in other cases differs somewhat from the above, which may be considered as the common form resulting from exposure. Acute

[L. Napoleon Boston.]

nephritis occurring as a complication of the infectious fevers, except scarlatina, may be characterized by the very slight degree, or even by the absence, of dropsy. Albuminuria, hematuria, anemia, and uremia supervene in the graver affections; this is the *acute tubular nephritis*. In *scarlatinal nephritis* we have an illustration of *acute glomerular nephritis*; anasarca is common, and slight edema at least is quite constant, while the blood-pressure is decidedly elevated. During the period of convalescence tube-casts (granular or fatty granular) may be found in the urine (Fig. 57). In mild affections simply a little albumin and a few hyaline casts reveal the parenchymatous degeneration. In cases of *degenerative nephritis* due to mineral poisoning the subsidence of the acute toxic symptoms may be followed by the *typhoid condition*. The *nephritis of pregnancy* is usually gradual in its onset, and the albumin increases from month to month. Some hyaline or faintly granular casts are found (Fig. 59), and erythrocytes rarely appear in the urine. *Danger of eclampsia* is constant until the albuminuria has subsided.

Acute productive nephritis (Delafield), in which there is a tendency to the formation of patches or wedges of fibrous tissue, is characterized by higher fever, by cerebral and circulatory disturbances of a typhoid nature, and by anemia, dropsy, and a highly albuminous urine, even though blood may be absent and casts may be few. The dropsy is most apparent in the legs. Dyspnea, vomiting, diarrhea, and a progressive and rapid loss of flesh and strength ensue until convulsions or coma, sometimes preceded by acute maniacal excitement, end in death. Milder cases, lasting from two to four weeks, apparently get well, albumin and casts persisting, however, until, after an interval of weeks or months, another and similar attack occurs. In short, the first acute attack is liable to chronic repetition until a fatal one takes place.

Diagnosis.—The condition cannot be overlooked when the urine is carefully examined both chemically and microscopically. The dreaded *eclampsia gravidarum* can, however, be recognized only by repeated urinary examination, especially during the last months of pregnancy. Acute Bright's disease should be suspected, and the urine examined in every case showing pallor of the skin and puffy eyelids, whether general prostration of the health is apparent or not. The characteristic symptoms of acute diffuse nephritis are the following: headache, restlessness, muscular twitching, dyspnea, nausea and vomiting, a tense pulse, moderate fever, dropsy, and anemia. Tube-casts and albuminuria are almost constant except in rare instances of puerperal eclampsia (J. Hirst). It should be borne in mind that slight albuminuria occurring in the course of pregnancy or during any of the acute specific fevers, *without casts*, is not a true nephritis, although a more or less remote consequence of the gradual degeneration of the renal epithelium associated with the febrile albuminuria. In addition to the presence of albumin and hyaline and cell-casts, however, a diminished quantity of sooty looking urine and the discovery of red and white blood-corpuscles will render the diagnosis positive. The history of the case and the causal factors are also to be taken into consideration.

The diagnosis of the particular subvariety is sometimes possible. Thus *acute tubular nephritis* commonly results from an intoxication, or more rarely from a severe infection or chilling. The urine is scanty, turbid, and often reddish brown in appearance, and the sediment is composed largely of renal epithelium and tube-casts. Edema is absent. The effects of the toxic agent on other viscera is shown by the presence of jaundice, myocardial weakness, and the like. In *acute glomerular nephritis* the urine is scanty, the amount of albumin large, but few if any tube-casts and renal cells are found. General edema is commonly present.

Trench nephritis begins with the occurrence of edema and the presence of dyspnea. The peculiarities of this subvariety have been epitomized by Sir John Rose Bradford¹ as "rapid subsidence of well-marked renal dropsy; frequent presence of bronchitis and dyspnea; severity and suddenness of onset of uremic manifestations, such as epileptiform seizures; rarity of occurrence of inflammatory complications, and an extraordinarily low mortality."

Prognosis.—The *duration* of ordinary exudative or tubal nephritis following exposure to cold and wet varies from a few days to three, four, or six weeks. The albuminuria steadily decreases, and with the casts finally disappears, while the daily quantity of urine increases, as does the excretion of urea. The prognosis depends much upon the primary disease or causative condition, and also upon the intensity and character of the renal inflammation. Scarlatinal nephritis is less likely to be recovered from than nephritis due to exposure to cold after alcoholic excesses. The acute parenchymatous degeneration that accompanies typhoid fever, diphtheria, and other infectious fevers, as well as pregnancy, is usually a mild affection and recovery takes place easily. But in acute yellow atrophy, yellow fever, cholera, and in severe phosphorus- or mercurial poisoning death may occur from the intense and wide-spread necrosis of renal epithelium. In favorable cases of ordinary exudative nephritis the dropsy and albuminuria gradually diminish, while the color of the skin and the quantity of urine and urea increase, so that in the course of from three to four or six weeks recovery is established. After the disappearance of the dropsy the albumin may persist for some time, and then slowly disappear; but rarely, in unfavorable cases, even when dropsy has disappeared, albuminuria may continue and the affection become a chronic parenchymatous nephritis.

Serious and often dangerous symptoms of acute nephritis are: severe general edema, dropsical effusions into the serous sacs (as hydrothorax), uremia (especially when beginning with cerebral manifestations, as coma or convulsions), and finally inflammation of the internal organs, as pleuritis, pneumonitis, pericarditis, peritonitis, and meningitis. In the absence of uremia recovery in cases of marked general dropsy is quite common. Suppression of urine, however, lasting more than twenty-four or forty-eight hours, is usually a fatal symptom. The prognosis is unfavorable also in cases in which the nephritis has a productive character. Life may, on the other hand, be prolonged for several years.

The various functional tests, according to Rowntree, are of little prognostic value on account of the rapidity with which marked changes in this respect occur. Such tests should be frequently repeated to get much information from them. An absence of phthalein for several days and a high blood urea concentration are grave prognostic findings.

Treatment.—I shall not include here the management of the primary affection of which the nephritis may be either a complication or consequence. Bland *foods* only should be allowed in the acute stage. Proteins should be limited. For this reason von Noorden gives thin gruels, fruit juices, and sugars, withholding milk for a week or two until the more acute symptoms have subsided. Salt is interdicted and water or fluids should be taken moderately, as they entail more work on the kidney, particularly if edema is present. Gradually the diet may be increased by adding milk, a quart in the twenty-four hours, junket, custard, vegetable purées, crackers, cocoa, and so on. Water can be given in increasing quantities when the urine is being freely passed. Fischer gives alkaline solutions (sodium chlorid, 14 gm.; sodium carbonate, 15 gm.; aqua dest., 1000 c.c.) by mouth, by rectum, or, in severe cases, intravenously, on the supposition that the nephritis is a manifestation of acidosis.

¹ *Jour. Amer. Med. Assoc.*, June 24, 1916, p. 2070.

Since the renal function is diminished by the congestion and inflammation, the first object in the treatment is to relieve these conditions and thus restore the excretory function. The single or combined use of diaphoretics and cathartics is practised, therefore, not that the skin and bowels should be made to perform the work normally done by the kidneys, but in order to restore the functional equilibrium by the antiphlogistic effect produced.

Absolute rest in a warm bed and in a warm room is of primary importance. Woolen underwear and blankets should be provided, so as to promote a constant free action of the sweat-glands. These hygienic measures should be carried out both in the mild and in the severer cases.

Local bloodletting, as by leeches or cupping over the loins, I seldom employ; in rare cases, however, when much pain is complained of, it may be useful, although hot fomentations may be more so. Diminution of the edema and the elimination of urea and other urinary constituents that may be retained in acute nephritis are best obtained by exciting a profuse perspiration. The hot-air or hot-water bath and the hot wet-pack may be used to accomplish these results, and in most cases the last-named method suffices. It is easily applied by wringing a blanket out of hot water, wrapping the patient in it, and then with a dry blanket, and finally a rubber-cloth cover, surrounding all. This furnishes a steam-bath in which the patient may remain until copious sweating has lasted an hour or so, according to the condition. Children suffering from scarlatinal nephritis may be treated thus, or quite readily also by immersion in hot water, for twenty, thirty, or forty minutes; the skin should then be lightly dried, and the child wrapped in warm sheets or blankets and warmly covered in bed. Hot vapor or air may be generated alongside the bed, and transferred under the raised or cradled bed-clothes by means of a tin funnel and pipe. The sweating will be aided by the drinking of hot lemonade or soda-water or of water containing spirit of *mindererus*. Should the skin fail to respond to these measures, as in uremia, perspiration may be started by a hypodermic injection of pilocarpin (gr. $\frac{1}{8}$ to $\frac{1}{6}$ —0.008–0.0108), after which it will continue to pour out on the application of heat. The heart and pulse should be watched after the injection of pilocarpin, as serious collapse sometimes attends its use. The sweatings should be repeated until the dropsy disappears and as often as the patient's strength will permit. The beneficial effects of sweat-baths are not due to the removal of nitrogen through the skin, but rather of sodium chlorid. A useful adjunct to the above is the administration of hydragogues, as the saline cathartics, elaterium, and compound jalap powder. Elaterium extract (gr. $\frac{1}{6}$ to $\frac{1}{4}$ —0.0108–0.0162) is prompt in action, and magnesium or sodium sulphate (5j—4.0), given in hot concentrated solution every hour, or a calomel purge, may be recommended. It may be necessary to aid in relieving the tension and distress of extreme edema by multiple punctures or by the use of a small trocar and canula, with a drainage-tube (Southey) attached to the latter after the trocar is withdrawn. Aspiration must be performed if either hydrothorax, hydropericardium, or ascites assumes serious proportions.

Uremic convulsions that do not soon yield to prompt diaphoresis and catharsis should be treated by venesection. As much as 1 or 2 pints (0.5–1 liter) of blood may be withdrawn and life saved thereby. Sometimes chloroform inhalations are needed to subdue the very violent convulsive seizures, as in eclampsia. Their return may be prevented by rectal injections of potassium bromid and chloral, consisting of 1 dram (4.0) of the former and $\frac{1}{2}$ dram (2.0) of the latter. Contraction of the arteries with increased tension and beginning muscular twitchings calls for the use of nitroglycerin, chloral hydrate, or, possibly, morphin.

Diuretics other than the simple diluent drinks mentioned have very little use in the therapy of acute diffuse nephritis, at least early in the disease. Later, as adjuvants to the diuretic properties of water, for two or three days at a time, potassium bitartrate or acetate, sodium benzoate, theocin gr. iij (0.2), caffein citrate gr. v to x (0.3–0.6), theobromin-sodium-salicylate gr. x to xv (0.6–1.0), and the infusion of digitalis, digipuratum, gr. iss (0.1), or strophanthin, if there is cardiac insufficiency, may be given, well diluted. Silvestri¹ states that epinephrin is a most valuable aid in acute nephritis, especially in children.

During convalescence care must be exercised that the patient does not catch cold. The diet must not be increased to solids too suddenly nor too rapidly, and particularly in the matter of meats. Light watery vegetables and fruits may be gradually added to the diet-list, although milk should be mainly used. Ferruginous tonics are indicated for the anemia, and Basham's mixture is an admirable preparation at this stage.

A change of locality to a warmer, drier, and more equable climate, and careful habits of dress, diet, and exercise are necessary in cases of recovery from the very serious forms of nephritis in which the renal parenchyma is shown to have been somewhat damaged by the persistence of slight albuminuria at intervals.

CHRONIC NEPHRITIS (EXUDATIVE)

(*Chronic Bright's Disease; Chronic Parenchymatous Nephritis; Chronic Diffuse Nephritis with Exudation; Chronic Tubal and Chronic Desquamative Nephritis; Chronic Glomerulonephritis; Large White Kidney; Secondary or Fatty and Contracted Kidney*)

Definition.—A chronic diffuse inflammation of the kidneys, attended with epithelial degeneration, exudation from the blood-vessels, and permanent connective-tissue changes in the stroma. According to Delafield, this is the *chronic productive (or diffuse) nephritis with exudation*—one of two varieties of chronic Bright's disease.

Pathology.—Although there are several types of pathologic kidney in this disease, the anatomic differences depend upon the causation and duration of the nephritis.

The first type of kidney to be mentioned is the *large white kidney* (without waxy degeneration). It is either enlarged or normal in size, and pale or yellowish in color. The surface is smooth, and the capsule is easily stripped off. On section the cortex is broader than normally, yellowish white throughout, or it may present opaque yellowish or whitish areas with mottlings of red. The pyramids are congested in some cases. Microscopically, the renal epithelium is swollen, hyaline, granular or fatty, and more or less disintegrated or flattened; the glomeruli are enlarged from the growth of the capsule-cells and of the cells covering the capillaries, and in some cases, owing to the connective-tissue thickening of the capsule, the tuft of capillaries is found to be atrophied. The interstitial tissue shows some thickening of the arterial walls and a moderate growth of connective tissue in patches around the glomeruli and tubules; the latter contain hyaline and granular casts.

The *small white kidney*, or secondary contracted kidney, in most instances is probably a later stage of the preceding, in which the degeneration of epithelium is more advanced and the growth of connective tissue and resultant cicatricial contraction are prominent features. The surface is slightly granulated, and the capsule is proportionally adherent. While this kidney is usually

¹ *Gaz. de. Ospedali e del. Cliniche*, Milan, September 1, 1915.

grayish or yellowish in color (*pale, granular kidney*), there may be some mottling due to red spots. The consistence is firm and the cut surface shows yellowish-white foci of the fatty degenerated epithelium in the narrowed cortex, "small, granular, fatty kidney." Under the microscope we find extensive degeneration and disintegration of the epithelium of the glomeruli and convoluted tubules, with atrophy of the parenchyma, and a corresponding increase of the interstitial connective tissue. Waxy degeneration may be associated.

Another variety is the *large red or variegated kidney of chronic hemorrhagic nephritis*. The organs are usually enlarged, swollen, red, and congested looking or mottled, and frequently "bumpy" or slightly bossellated. The capsule is slightly adherent to the depressions between the bosses. Red spots, due to small hemorrhages, may be noticed. The section shows also congested portions and gray or yellow spots corresponding to the anemic and fatty degenerated portions. Small cortical hemorrhagic areas or striations, brownish-red in color, are distinctive of the kidney. The microscopic appearances are those of the large white kidney plus those of acute nephritis. Or, there may be inflammatory edema and cellular infiltration of the intertubular tissue, and dilated tufts of capillaries with surrounding cellular hyperplasia.

Etiology.—The disease may follow either the acute diffuse nephritis, as of scarlet fever or pregnancy, or simple chronic congestion and chronic degeneration of the kidneys. Watson believes that acute nephritis is not a common disease, is usually due to the direct effect of some infection and that the majority recover completely. More often chronic parenchymatous nephritis arises insidiously, in a subacute manner and without any previous acute manifestation. Males are more frequently subjects than females. Children affected with the disease have usually had scarlatinal nephritis. Young adults are more commonly affected, however, with the usual variety, developing subacutely. Drinkers of beer and other malt and alcoholic intoxicants seem to be liable to the disease. It is not improbable that some toxic or infectious agency, acting slowly and persistently, may in the insidious cases be the cause of the nephritis, although manifestations elsewhere may be absent. I have observed it in certain individuals living in malarial regions. Persons working under exposure to cold and wet, and those living in humid and low, marshy localities are more liable than those who are better protected from climatic vicissitudes. Tuberculosis, syphilis (8 out of 84 cases—Stengel and Austin), and chronic suppuration may give rise to the "parenchymatous" form of chronic Bright's disease, and it is usually combined with amyloid disease.

Symptoms.—There may be a persistence, in a lesser degree, of the symptoms of an acute parenchymatous nephritis, particularly the anemia, dropsy, and the albuminuria, until the affection becomes chronic. In most cases, however, the disease develops slowly and gradually, in a *subacute* manner, though the earlier symptoms seldom indicate any renal derangement. There may be simply a general impairment of health and strength, loss of appetite, nausea, and attacks of indigestion, headache, dulness, and perhaps some pallor. Soon there is puffiness of the eyelids or swelling of the feet or ankles, or both, and the complexion takes on a blanched appearance. The *edema* gradually extends up the legs, and is often worse as the day grows, while on rising in the morning it may be found to have disappeared during the night's rest and recumbency. The *quantity of urine* is diminished in the majority of cases, though in the later stages it may be nearly or quite normal, and even slightly increased in long-standing instances or when absorption of the dropsy is taking place. Superadded acute nephritis may cause a very scanty or a suppressed secretion of urine. The specific gravity is, of course, increased in scanty urine,

and *vice versâ*. *Albuminuria* is often quite marked. The amount of albumin may be from one-fourth to three-fourths of the volume of the urine, or from 1 to 3 per cent. by weight. The nitrogen coefficient, *i. e.*, the relation of the urea to the total nitrogen, is reduced from the normal (80 to 82) to 60. The color of the urine is turbid, sometimes smoky yellow, and urates, casts, red and white blood-cells, epithelial cells, granular débris, and fatty granular cells are found in the usually abundant sediment. The *tube-casts* are of different varieties, but narrow or broad hyaline, fatty granular (Fig. 60), and epithelial casts are commonly observed.

The *edema* is prominent and persistent. It gradually extends all over the body, so that pitting can be obtained on the limbs, chest, abdomen, and back. The loose subcutaneous tissues, as of the penis, scrotum, and eyelids, are particularly distended. In chronic hemorrhagic nephritis only the edema may be absent or very slight. The *pasty, pallid complexion* and *anasarca* are most characteristic of chronic exudative nephritis, especially with large white kidney. The dropsy may be moderate and about stationary for several months; then, despite all treatment, it becomes insidiously worse, death ensuing in a month or two.

Dropsy of the serous sacs, with its attendant distressing symptoms, may be present in serious cases, and edema of the larynx and lungs may come on suddenly and cause death. Dyspnea may be toxic and nervous, as well as mechanical or cardiac in origin. *Cardiac dyspnea*, due to failure of the heart's action, as seen in many cases, is usually worse on lying down. It may be provoked by vasoconstriction, and is then a danger-signal of uremia. Catarrhal bronchitis may be associated with cough and expectoration.

There is *moderate hypertrophy of the left ventricle*, and later dilatation of both ventricles. As a rule, there is but little change in the blood-pressure, at least until the latter stages, when the glomeruli become involved, according to Volhard and Fahr.

Uremic symptoms are frequently manifested, except the convulsions which are common to chronic nephritis without exudation. Headache, vertigo, sleeplessness, nausea and vomiting, diarrhea, and stupor, coma, or delirium may develop and precede a fatal termination.

Albuminuric neuroretinitis, as evidenced by dimness of vision and field defects, occurs in quite a number of cases. The skin of the legs becomes subject to a red eczematous eruption in some cases of great dropsical distention. In the absence of complicating inflammations, such as pericarditis, endocarditis, pneumonitis, and ulcerative colitis, which are rare, the temperature is practically normal.

The **course** of chronic exudative nephritis may either continue from bad to worse, until death ends all in a year or two, or anemia, dropsy, and albuminuria may attack one who for years previous has had apparent good health, after a first attack the second proving fatal within a few months. Again, some patients, having a little pallor, urine of high specific gravity, with albumin, may complain of nothing for years, until decided attacks, lasting for several months, may occur, with intervals during which the dropsy, dyspnea, etc., may be absent, although some albuminuria persists. The average *duration* of the disease varies. The duration of chronic hemorrhagic nephritis may be somewhat longer (eight months to two or three years) than that of the large white kidney (six to eighteen months), but it is shorter than the secondary contracted kidney, which lasts from one and a half to three or even five years.

The **diagnosis** of the disease itself is not difficult, but of the stage or the variety of kidney it is almost impossible to tell correctly in some instances. The urinary examination, coupled with the symptoms of dropsy and anemia,

is sufficiently diagnostic of chronic diffuse nephritis (with exudation). The fact that, as shown by Czyhlarz and Donath,¹ methylene-blue is retarded in its elimination from the kidneys in nephritis, may have diagnostic value in some cases. The phenolsulphonephthalein output is uniformly low (Thayer and Snowden).

In cases of *large white kidney* the urine passed is, as a rule, less in quantity and is of higher specific gravity than in the small, pale, and contracted kidney. Edema is usually greater in the former also, while in the latter cardiovascular changes are more marked. The transition of the disease from the earlier to the later stage may be thus noted. The casts in the latter may be narrower and more darkly granular than in the large white kidney. The existence of *hemorrhagic kidney* may be inferred from the history of alcoholism and the persistent presence of erythrocytes and blood-casts in the urine.

Chronic parenchymatous is distinguished from chronic interstitial nephritis by the following points of difference:

CHRONIC PARENCHYMATOUS NEPHRITIS

Occurs in early or middle life.
There is a previous history of an acute attack, of scarlet fever, or perhaps of acute alcoholism.
The onset is gradual or markedly manifested.
Dropsy is a constant symptom.
Vascular changes and cerebral symptoms are comparatively uncommon.
Albuminuric retinitis common.
Marked albuminuria; many tube-casts, chiefly short, thick, granular.
Urine but little increased in quantity, often diminished; specific gravity is increased or slightly diminished.
Anemia occurs earlier and is marked.
Uremic symptoms are generally less severe—amaurosis, vomiting, diarrhea, headache.
Runs a shorter course—from two to six or seven years.

CHRONIC INTERSTITIAL NEPHRITIS

Occurs later in life.
A previous history of gout, chronic lead-poisoning, syphilis, excessive eating and drinking (spirits), nerve strain.
The onset is very slow, insidious, and indefinite.
Dropsy is rare.
Arteriosclerosis, cardiac hypertrophy, and cerebral symptoms are common.
Retinal hemorrhage and choking of disk.
Very slight albuminuria and few casts, chiefly hyaline (long, narrow).
Urine of very low specific gravity and excessive in quantity.
Anemia slowly progressive and less marked.
Uremic symptoms are generally severe—coma and convulsions, great dyspnea.
Has a more chronic course—seven to thirty years.

Prognosis.—This is invariably bad as to cure, though life may be prolonged in certain cases. In severe cases death may take place in from three months to a year, either from uremia, dropsy, cardiac dilatation, or complications. Cases of a year's duration almost never recover, and, *a fortiori*, those in which advanced secondary contraction of the kidney may be inferred are incurable, and may soon terminate fatally. Complete recoveries from the disease, particularly in children that have had scarlet fever, may occur but rarely. The prognosis depends greatly on the quantity of urine passed daily, the excretion of urea and total solids, and upon the amount and persistency of the albumin, as well as upon the degree of cardiovascular and retinal changes. Myers and Lough have shown that an estimation of the blood creatinin is of prognostic value, *e. g.*, over 5 mg. per 100 c.c. of blood having invariably terminated fatally in from a few days to two months, while figures from 3 to 5 mg. are to be regarded as decidedly unfavorable. The phthalein output decreases steadily up to the onset of uremia, "and is nearly or wholly suppressed from a day or two to a month before death." Mosenthal and Lewis²

¹ *Wien. klin. Wochen.*, June 15, 1899.

² *Jour. Amer. Med. Assoc.*, September 23, 1916, p. 933.

hold that the phenolsulphonephthalein excretion and Ambard's coefficient (*vide*. p. 935) are tests which enable one to follow most minutely the progress of renal disease. The response to water and the elimination of salt are functional tests of particular value in this type of nephritis.

Treatment.—The indications for treatment are similar to those in acute nephritis. The dropsy and uremia must be treated symptomatically, and the diet is of importance. Skimmed milk and buttermilk, or "zoölak," with dried bread, crackers, and zwieback, perhaps, should be depended on as much as possible when dropsy is pronounced. When dropsy is slight, more solid food, meats sparingly and vegetables, rice and other light cereals and fruits, and out-of-door life should be recommended. Until recently not enough protein food was allowed in chronic nephritis, but milk is still the best article. The reduction or complete absence of salt in the diet has a strong influence in reducing edema (Rovighi). The output of water and salt, however, should be recorded, and the intake of the latter restricted as indicated. Foster and Davis¹ have demonstrated that where there is no great amount of edema, we must allow considerable water, the while we diminish the protein intake, in order to eliminate the solids and retained nitrogen. A patient with edema should remain in bed. Residence in a warm, dry climate may aid in prolonging life. Woolens should be worn next to the skin, and severe exercise should be forbidden.

The infusion of digitalis, strophanthus, spartein, or convallaria may be needed in cardiac weakness, or nitroglycerin for contracted and tense arteries with a tendency to uremic twitchings. Unirritating diuretics, such as Trouseau's diuretic wine and Basham's mixture for the anemia, are useful. Theobromin-sodium-salicylate has also been tried lately, with favorable results. Von Hösslin states that sodium bicarbonate without much fluid reduces albuminuria. Arnoldi and Brückner have shown that calcium chlorid in small doses causes considerable diuresis in chronic nephritis. Silvestri, Borelli, Ercolani, and others call attention to epinephrin by the mouth in nephritis as a harmless and efficient method of treatment. Of a 1 : 1000 solution, 8 to 10 drops may be given four times daily.

CHRONIC NEPHRITIS (NON-EXUDATIVE)

(*Chronic Interstitial Nephritis; Chronic Bright's Disease; Primary, or Genuine, Contracted Kidney; Cirrhotic Kidney; Red Granular Kidney; Chronic Productive (Diffuse) Nephritis without Exudation (Delafield); Gouty Kidney*)

Definition.—A chronic diffuse inflammation of the kidneys, attended with a growth of connective tissue in the stroma, degeneration and atrophy of the parenchyma, and marked cardiovascular changes. "The destruction of the renal parenchyma is due to the circulation of noxious agents, but which is replaced by cicatricial fibrous tissue" (Weigert).

Pathology.—Four pathologic forms are recognized: (a) The primary form; (b) arteriosclerotic kidney; (c) the senile type, and (d) the secondary form (small white kidney), which was described under Chronic Parenchymatous Nephritis, of which it is a sequel.

(a) In the primary form, or true red granular kidney, these organs are often exceedingly small, and both kidneys together may not weigh over 2 to 4 ounces. The capsule is thick and very adherent, tearing the substance

¹ *Amer. Jour. Med. Sci.*, January, 1916, p. 44.

as it is stripped off, the surface reddish-brown in color, finely granular, and cysts may be numerous. The consistence is dense and resistant to the knife, the cut surface showing a thin atrophied cortex and sclerotic arteries. In the gouty kidney the pyramids show fine striations of sodium urate, or of uric acid or crystals representing uric-acid infarctions. The tubules show marked changes. Some are included in masses of connective tissue, so that there is compression atrophy and even total obliteration of the lumen. The inter-tubular connective tissue constricts the tubules in certain places, so that the lumen is elsewhere increased. The epithelium lining these tubules shows granular, fatty, or waxy degeneration, and may be either flattened, cuboid, or swollen. The tubes may contain granular or fatty débris and tube-casts.

(b) The arteriosclerotic kidney, like that of (a), is red and dense, but unlike the latter is not greatly reduced in size, and is often heavier than normal. The capsule is only slightly adherent, but little thickened, and the surface smooth. In certain cases circumscribed, depressed areas, red in color, due to localized atrophic changes, may be observed. The cut surface presents a reddish-brown color and arteriosclerotic vessels (obliterating endarteritis).

(c) The senile form is attended with reduction in the size of the kidney, with increase in the pelvic fat. The capsule is thick and adherent, the arteries sclerosed, and both the cortex and pyramids decidedly atrophied.

An almost constant accompaniment of chronic productive nephritis is cardiac hypertrophy. The degree of the latter depends upon the extent of the renal, and also of the general, arterial sclerosis. The whole heart may become so large that the term *cor bovinum* has been fittingly applied to it. In moderate enlargements the left ventricle only is hypertrophied.

Complicating lesions that may be mentioned are cerebral hemorrhage, cirrhosis of the liver, pulmonary emphysema, chronic endocarditis, chronic endarteritis, pericarditis, bronchitis, and gastric catarrh.

Two leading views on the question of the relation of the renal changes to the associated arteriosclerosis and cardiac hypertrophy: (a) The mechanical and (b) the chemical. Bright first suggested the mechanical theory, and since then Sir George Johnson, Senator, Traube, Cohnheim, Tyson, and others have advocated it. According to this view, the primary atrophic and degenerative changes of the renal parenchyma are compensated by a secondary rise of blood-pressure followed by cardiac hypertrophy and arteriosclerosis. Obviously, to compensate the loss of renal function due to the local lesion demands increased force on the part of the left ventricle, thus engendering hypertrophy and an exalted blood-pressure throughout the uninvolved portions of the kidneys as well as the general arterial system. The arteriosclerosis, however, may be primary, as in the arteriosclerotic kidney. Again, the vascular and renal conditions may develop independently of one another, although dependent upon a common cause.

(b) The *chemical theory* assumes the production, either by the kidneys or suprarenal glands, or both, of certain pressor substances, or the retention of toxic substances, which are capable of raising the blood-pressure, the latter in turn eventuating in hypertrophy of the heart and sclerosis of the arteries.

Etiology.—The cause of the slow diffuse degeneration, atrophy, and fibroid contraction of the kidneys is sometimes quite obscure. (a) In some cases it would seem to be “only an anticipation of the gradual changes which take place in the organ in extreme old age” (Osler)—the “senile kidney.” (b) *Heredity* undoubtedly plays a part in the causation of certain cases, even to the third or fourth generation. (c) *Age and Sex.*—The disease is more common in males; it is seldom manifested symptomatically until about fifty or sixty years of age, and is therefore an affection of advanced life. (d) Individuals

having a special tendency to sclerotic degeneration of the arteries, from whatever injurious influence, are more liable to chronic interstitial nephritis, although the prolonged irritation of deleterious (especially chemico-toxic) agents may give rise to the disease in those whose cellular nutrition is usually not defective. Thus, the disease has been attributed to the following causes: alcoholism and lead, giving rise to chronic poisoning. Chronic syphilis and chronic malaria probably are also causative factors. (e) Habitual overeating and drinking, owing to the imperfect metabolism of the substances ingested, cause a constant excretion of irritating products by the kidney, and no doubt frequently cause granular atrophy and sclerosis of the organ. The continuous and even moderate use of alcohol for many years, especially of spirituous liquors, is a wide-spread cause of the disease. It is equally likely that the excessive use of meats in the diet leads to the production of the renal disorder by deranging the function of the liver (Murchison). (f) Allied to the above is gout, which causes chronic Bright's disease. (g) According to Strümpell, severe acute articular rheumatism is sometimes followed by contracted kidney. (h) Chronic Bright's disease with renal sclerosis is favored in origin and development by the anxieties, worries, and high nervous tension connected with modern business activity and "social functions," the latter particularly acting their part among elderly ladies. Associated with these are usually overindulgence in rich foods and wines, and sedentary habits. (i) Emerson¹ has presented experimental evidence which shows the influence of repeated disturbance of the circulation as an accessory etiologic factor to the action of toxic substances. (j) The cold, moist climate of New England and the Middle States would seem, according to Purdy, to predispose to contracted kidney. (k) A chronic productive nephritis without exudation, though not the true "contracted and red granular" kidney, may be caused by hydronephrosis, chronic pyelitis, and chronic congestion of the kidney, as from heart disease.

Symptoms.—These may be latent for years, while the morbid productive changes in the kidneys are slowly effected. The first symptoms may not appear until late in life, although the kidneys may be in an advanced stage of degeneration. Or some complicating or intercurrent affection may set in, as pneumonia or pericarditis, and cause the development of grave or fatal renal symptoms. More commonly, however, there is an attack of *uremia*, with headache, stupor, or convulsions, dyspnea, nausea and vomiting, and a tense pulse. The attack may be recovered from. Then there is an interval of variable duration, during which the health is more or less impaired, and lassitude, drowsiness, disordered digestion, headache, failing vision, dyspnea, and frequent micturition are complained of. This is followed by another uremic attack, severer than the first, or perhaps fatal; if not fatal, the general health is still more reduced, and confinement to the house or bed is necessary until the vital forces can no longer compensate for the destruction of the renal parenchyma.

Spasmodic dyspnea (uremic; cardiac) is sometimes the first manifestation of contracted kidney. The gradual onset of periods of uncontrollable drowsiness during the day is often marked. Peabody states that an inefficient renal excretion leads to acidosis, through retention, causing dyspnea and other symptoms. An attack of hemiplegia may also be the first indication of renal disease. Sometimes progressive loss of flesh and strength, with a *dry, harsh, wrinkled skin*, may be from the beginning the only clinical features of the affection until death results from sheer feebleness and emaciation. The complexity and variability of the symptoms make it best to describe them under the heads of the various systems:

¹ *Arch. Int. Med.*, June, 1908.

Urinary System.—The daily *quantity of urine* is usually increased so much that patients are troubled with a desire to urinate frequently not only during the day, but two or three times during the night. This complaint may be aggravated by the hyperacidity of the urine and the irritability of the prostate (especially in advanced age) that are so often associated with cases of renal cirrhosis. The urine voided during the twenty-four hours may measure several quarts (2 to 4 liters) in well-marked cases of the disease. Early in the attack, when the incipient degeneration and destruction of the parenchymatous cells is taking place, the quantity of urine may be slightly decreased; but as the “blood-flow to the parts that remain must, *cæteris paribus*, be as great as it would have been to the whole of the organs if they had been intact,” excessive pressure is brought to bear within the capillaries by the compensating hypertrophy of the heart, and the secretion of the urine, especially of the watery elements, becomes more active. The *polyuria* may give rise to a suspicion of diabetes. The urine is clear and pale yellow in color, the *specific gravity* being seldom above 1010 or 1012, and it may be as low as 1002 or 1005. *Albumin* is found only in traces or it may be absent altogether (*glomerular atrophy*), especially in urine voided in the early morning. The urea is diminished, and there is little or no sediment. Widal classifies the cases of nephritis into those with retention of salts and those with retention of nitrogenous substances in the blood. He claims that the determination of urea in the blood, as contrasted with examination of the proportion of nitrogen in the urine, is more important clinically than the estimation of the percentage of albumin in the urine. A very careful microscopic examination may reveal a few, usually narrow, *hyaline* or *granular casts*, and rarely a few *erythrocytes*. In the later stages of the disease or upon the supervention of an uremic exacerbation or of a complicating inflammation the urine may be decreased, the albumin increased, and numerous casts be discovered in a more apparent urinary sediment. Hematuria is rare.

Circulatory System.—The freezing-point of the blood is lowered, due to the retention of products normally eliminated by the kidneys. It is to be recollected that the freezing-point in health is -0.56°C. , and in nephritis it may be found to be -0.58°C. or lower. The *physical signs* of cardiac hypertrophy are present. Symptoms referable to the heart are absent unless dilatation and feebleness, sudden arterial contraction, cardiac complications, or endocarditis occur. *Inspection and palpation* of the *hypertrophied heart* show apex-beat displaced downward and to the left, and an increased, heaving, and rather circumscribed apical impulse. These signs may be less evident in cases of coexisting emphysema. The left border of the deep cardiac dullness extends outside the nipple-line in the fifth or sixth interspace. The first sound of the heart is loud and may be duplicated. A distinctive auscultatory sign is the *accentuation of the aortic second sound*, indicating increased vascular tension. In quite a majority of the cases I observe, sooner or later, a mitral systolic murmur; it is due to relative insufficiency.

The *pulse* is increased in tension, and is hard, incompressible, and persistent, the duration of each pulse-wave being increased (*pulsus tardus*). The radial artery itself—and this is true of most of the palpable arteries—feels hard, thickened, and often tortuous, on account of the arteriosclerosis. The systolic blood-pressure is decidedly high, often exceeding 200 mm. Hg. As soon as compensation of the heart fails, symptoms of breathlessness (especially on exertion), palpitation, and the like, appear, and sometimes in paroxysmal attacks (“cardiac asthma”). The resultant stasis gives rise to transudation into the lungs (bronchorrhea; pulmonary edema), and later to edema of the extremities.

In a certain number of cases of chronic nephritis with marked changes in the intima of the renal arterioles the urinary symptoms are of but minor import. Functional tests are normal, and after death only occasional tubules and glomeruli show pathologic changes. The vascular changes include an extremely high blood-pressure, vascular and cerebral symptoms, signs of myocardial insufficiency, and, in fact, symptoms pointing almost entirely to the cardiovascular rather than the renal system. The high pressure may persist for years without urinary symptoms. When death occurs it is usually a cardiac or vascular death, and only from 10 to 15 per cent. of the patients die with marked renal symptoms. For this type of disease Janeway has proposed the name "cardiovascular hypertensive disease." Volhard and Fahr call this type of nephritis the pure arteriosclerotic kidney and the hypertension "benign." Allbut has proposed the term "hyperpiesis" for hypertension cases without demonstrable renal, vascular, or cardiac disturbance. It is presumed that this latter condition precedes organic hypertension.

Respiratory System.—Epistaxis may be a serious symptom. Sudden edema of the larynx may also occur, and is always grave. Transudations into the pleural sac (hydrothorax), as well as into the lungs (*vide supra*), may precede death. Dyspnea, which is either cardiac or uremic, is usually worse at night, and a true orthopnea, together with Cheyne-Stokes breathing, may be observed associated with uremic stupor and coma.

Nervous System.—Symptoms referable to the nervous system are very important, since they are usually indicative of grave uremia. Cephalalgia is frequent, and neuralgic pains throughout the body, and insomnia, may be complained of. Later great *drowsiness* is often a premonition of uremic coma. Convulsions may be preceded by muscular twitchings, which should attract attention to the imminent danger of the former. Cerebral apoplexy with hemiplegia may be the first symptom of contracted kidney. It is especially apt to occur in cases of marked hardening and weakening of the arteries. There may be a hemorrhagic pachymeningitis, as well as a hemorrhage into the brain substance. The hemiplegia may persist until death; or it may disappear in a short time, and be followed by subsequent attacks at intervals ("shifting paralyses"). *Formication*, *numbness*, and pallor of one or more fingers (the "dead finger") I believe, with Dieulafoy, to be sometimes the earliest symptoms of chronic Bright's disease.

Of the **special senses**, *nephritic retinitis* is often the earliest evidence of chronic Bright's disease. The patient may or may not have had slight dimness of vision (mistiness) prior to the ophthalmoscopic examination. The loss of vision affects both eyes, and is usually partial (*amblyopia*). Sudden and complete blindness may come on in grave cases—*uremic amaurosis*—the condition being due to neuroretinitis. The optic papilla is swollen, and surrounded by retinal hemorrhages or by white dots and streaks ("feather-splashes"). Exophthalmos without thyroid enlargement has occasionally been noted (Barker and Hanes, Gordinier). Tinnitus aurium, deafness, and *vertigo* are not uncommon.

Digestive System.—Anorexia, nausea, and annoying dyspepsia are often complained of. T. F. Reilly calls attention to the bad taste on arising in the morning and disappearing after breakfast as an early symptom. Severe vomiting may usher in a uremic attack. Catarrhal gastritis may exist for some time, the tongue being coated and the breath heavy and urinous. *Uremic diarrhea* may also occur.

The Skin.—Edema is usually absent in renal sclerosis; when it does occur, however (as in the ankles and limbs), it is due to dilatation and failure of the heart. The skin is dry; a certain degree of pallor is noticed, and often it has

a cyanotic tinge. *Pruritus* and troublesome eczema are frequently present, and *muscular cramps*, occurring especially in the calves of the legs and at night, may also be associated. The general nutrition gradually fails, so that in advanced cases the debility and emaciation are extreme.

Uremia may come on at any time during the course of the disease, and may be the first symptomatic manifestation; it may either be sudden and severe in its onset (acute uremia), or mild, insidious, and gradual (chronic uremia). Moderate fever may attend a uremic attack, or the temperature may be normal; in chronic uremia, with prostration, coma, delirium, and feeble pulse, it may be even subnormal.

Among the **complications** that may occur are the following: pneumonia, either lobar or lobular; pleuritis, pericarditis, bronchitis, gastritis, enteritis, peritonitis, meningitis, endocarditis, emphysema, phthisis, acute dermatitis exfoliativa (Duckworth), and hepatic cirrhosis.

Diagnosis.—This depends in great part upon the physical, chemical, and histologic examination of the urine. Both the morning and evening urine should be examined repeatedly for albumin and casts, since one examination—and especially that of the morning urine—may give negative results, owing both to the scarcity of these two pathologic elements and to the fact that one or both may be altogether absent in some instances. The mere discovery of a trace of albumin or of a few casts is not always positive evidence of chronic Bright's disease, as both may exist in other conditions. But the age, habits, and symptoms of the patient must be studied in connection with frequent urinary examinations; and a persistent slight albuminuria, with casts, and the passage daily of large quantities of clear, pale urine of low specific gravity, afford sufficient grounds for making the diagnosis. The test-meal for renal function (*vide* p. 934) probably gives the earliest indication of diminished kidney efficiency (Mosenthal and Lewis).

Contracted kidney should be suspected in all cases in which, during middle life, either one or more of the following symptoms and signs may be noticed: frequent headache, congestive disorders, repeated epistaxis, vertigo, dimness of vision, intractable conjunctival irritation (Alleman), impaired strength, dyspneic attacks, gastro-intestinal dyspepsia, noises in the ear, itching of the skin, cramps in the calves, muscular twitchings, growing mental dullness, increasing pulse-tension, and rigidity and tortuosity of the temporal and radial arteries. Sudden coma, convulsions, amaurosis, apoplexy, vomiting, or dyspnea in persons in the middle period of life, with or without a history of polyuria should create the suspicion of chronic Bright's disease. It will be found in such cases that there has been a diminution in the urinary flow before the attack. Persons of gouty, rheumatic, or alcoholic habits, with evidences of cardiac hypertrophy, an accentuated aortic second sound, and a hard pulse are often readily diagnosed as subjects of contracted kidney when an examination of the urine is made.

If the first examination of the patient is made during a sudden uremic or apoplectic attack, catheterization should be done if necessary, and the detection of albuminuria will then clear the diagnosis. To determine accurately the permeability of the kidneys, Schapira¹ recommends the hypodermic administration of phloridzin or indigo carmin, followed by ureter catheterization.

In order to differentiate between primary renal affection with secondary cardiac hypertrophy and *primary heart disease with a secondary congested kidney occurring late in the case*, the general features, course, symptoms, and signs must be carefully and judiciously balanced. Prominent cardiovascular changes would indicate an arteriosclerotic kidney. The presence of a diastolic

¹ *Jour. Amer. Med. Assoc.*, January 15, 1910.

murmur would tend to exclude primary contracted kidney of toxic origin; on the other hand, an albuminuric retinitis would point to a primary renal complaint. The symptoms of ordinary non-inflammatory *senile kidney* may not be unlike those of chronic interstitial nephritis, though not so severe; and yet, from excessive eating and drinking at times, uremic attacks may supervene to cloud the diagnosis.

Prognosis.—The *duration* of chronic interstitial nephritis varies. In uncomplicated cases it may last for five, ten, twenty, or possibly thirty years. Complications or intercurrent affections may, however, shorten the duration very much. Janeway, in a study of 122 private patients whose records extended over a long period of time found that 60 died as a result of gradual cardiac insufficiency; 46 of uremia; 29 of cerebral apoplexy; 10 of angina pectoris; 7 of pulmonary edema; 13 of complicating acute infectious disease; the remainder of various infrequent complications or accidents. The *postmortem* examination may show the characteristic kidneys in one who during life had no symptoms indicating renal disease, and whose death was caused by some intercurrent disease. The gradual destruction of the renal parenchyma and its replacement by scar-tissue cause irreparable damage to the organs. On the other hand, the fact that the process is usually a slow one and its duration long is compatible with the preservation of life for many years, and with comparative comfort, even, in many instances. The prognosis in a given case depends very much upon the general constitutional condition, the cardiovascular state, and the presence or absence of uremia and inflammatory complications. Cardiac dilatation and insufficiency indicate a not far distant end. It is in the prognosis of these cases that the various functional tests, as previously described, are of so much value. In the early stages of the disorder salt is excreted fully in the twenty-four hours, but the urine is of a low specific gravity and low salt concentration. Water excretion is accompanied by polyuria, nocturia, and a low specific gravity. As the renal insufficiency progresses the phthalein elimination becomes decreased, the non-coagulable protein of the blood increases, and there is an increasingly high constant of Ambard. In the terminal stages phthalein may not be eliminated, the blood nitrogen reaches extremely high figures, salt is retained as well as lactose, and the specific gravity of the urine is fixed and constant. The blood creatinin may rise to over 5 mg. per 100 cubic centimeter of blood as death threatens. Convulsive and apoplectic seizures are often fatal, and hemorrhages, persistent vomiting, and diarrhea, *retinitis nephritica*, coma, and delirium render the prognosis as to further systemic tolerance of the degenerated kidneys exceedingly grave.

Treatment.—An early recognition of the disease and the steadfast practice of careful hygienic measures will prevent, to a considerable degree, the advance of the cirrhotic changes. Noxious substances entering into the etiology of the affection must be avoided and removed as far as possible. Alcoholics must be interdicted, and lead—when the cause of the condition—must be kept from further poisoning the system by a change of occupation. By diminishing these irritants the heart and blood-vessels are also conserved—a point of vital importance.

The **hygienic treatment** must embrace a regulation of all the habits of body and modes of life. The patient must be treated, and not his malady, since that is incurable. A dietary that is suitable for each individual case must be made out; it must be the aim to maintain the nutritive equilibrium of the patient without producing irritation of the renal epithelium. Vaughan holds that a salt-free diet protects the kidneys by decreasing their labor. Saundby's rule is a good guide: "Eat very sparingly of butcher's meat; avoid malt liquors, spirits, and strong wines." Red meats are no more injurious than white

in their effects in this disease. An exclusive milk diet may be necessary for short periods when gastric irritation is present. Tervoert and van Lier claim that their experiments and clinical experience indicate that restriction to a milk diet in cases of nephritis with retention of urea is decidedly harmful. Von Noorden urges that milk contains, on the whole, too much protein, and recommends that it should be restricted to 3 pints a day, to which 1 pint of cream should be added. Vegetables, greens, fruits, and light, well-cooked farinaceous articles may also be partaken of, and cocoa may be drunk. The use of natural mineral waters aids in the renal circulation and keeps the kidneys flushed. In general, a mixed diet will be of advantage; the nitrogenous and carbohydrate elements (sugars and starches) are used in limited amounts, while pure fats and fruits (raw or cooked) are to be recommended. I would add that whole milk, diluted, should make up a considerable portion of the diet, that meats be allowed in small quantity once daily, as a rule, and that we should draw largely upon the vegetable kingdom for aliment. Stout persons and those leading sedentary lives should have less food than those taking exercise, and gastric disorder requires the elimination of all but soft, bland foods, or a liquid diet until digestion is restored. As elsewhere stated, it is impossible to lay down a dietary that would be suitable for all cases on account of the peculiarities presented by the individual cases. The effect of a given diet is to be noted by a careful observation of the bodily weight and by oft-repeated examination of the urine and blood. Extremes of bodily and mental activity should be avoided, and physical exercise should be moderate, regular, and taken in the open air, provided the latter be warm and dry.

A change of residence to a warm, mild, and dry climate is often of service. The variability and humidity of temperate climates, particularly during winter, aggravate this disease, while a sea voyage or a sojourn at some southern, western, or European resort, where the soil is dry and sandy and the climate equable, may be very beneficial.

The indications for **medicinal treatment** are principally as follows: The bowels should be kept free by the aid of laxatives (*e. g.*, trituration elaterini, gr. $\frac{1}{4}$ to j—0.016–0.065) or laxative alkaline mineral waters. Bitter tonics are useful in some cases in which a furred tongue and indigestion are troublesome. Acids or alkalies, according to special indications, may also be used simultaneously. An increased vascular tension, such as to place a serious strain upon the heart; the other extreme, of a very low tension, that induces dropsy; and complications, usually uremic (convulsions, dyspnea, headache), also call for therapeutic assistance. High tension is to be met by the cautious use of nitroglycerin in gradually ascending doses, beginning with 1 minim (0.065 every three hours. Headache, vertigo, and the so-called renal asthma (dyspnea) are also often relieved by this drug. A too great reduction in the arterial tension is undesirable, being attended with danger of uremia and serous effusions, owing to insufficient urinary excretion.

Low tension, with signs of cardiac dilatation, scanty albuminous urine, and edema, requires heart tonics and stimulants, in conjunction with purgatives. Digitalis (preferably in infusion) has good effects, especially when combined with strychnin nitrate. The salines should be given for the dropsy.

Uremic symptoms should be treated as in acute Bright's disease by causing profuse sweating and free catharsis, and in some cases by phlebotomy. Inhalation of amyl nitrite or chloroform, or, what is often a useful and necessary measure, the hypodermic injection of morphin (gr. $\frac{1}{6}$ —0.0108), may be tried in convulsions, severe headache, or dyspnea. White and Wilcox¹ have shown that morphin does good in nephritis by diminishing the oxidizing functions

¹ *Internat. Clin.*, vol. ii, 20th Series.

of the body metabolism. Le Fevre extols chloral for its more lasting action than chloroform.

Contracted kidney of a probable malarial or syphilitic origin may be benefited somewhat by the use of arsenic cautiously and the iodids respectively; but no drugs can possibly restore the destroyed renal parenchyma or transform connective-tissue cells into secreting kidney cells.

Certain recent writers (Rose, Ferguson, Wolff) had observed the disappearance of casts and albuminuria after the operation of nephropexy in which a portion of the capsule had been removed. In 1898 Edebohls first proposed the cure of chronic nephritis by operation—decapsulation. He reports 18 cases thus treated, and in each operation (except 2) stripped off about one-half of the capsule. The beneficial and curative effects indicated by an increased flow of urine and the disappearance of dropsy tube-casts and albumin, do not show themselves usually before the tenth day. It is not a helpful operation in advanced cases and its precise value as a therapeutic measure in chronic nephritis has not as yet been determined. While the majority of the cases treated surgically belong in the category of chronic interstitial nephritis, decapsulation is quite as appropriate in suitable cases of the parenchymatous variety.

PYELITIS

(*Pyelonephritis; Pyonephritis*)

Definition.—Inflammation of the pelvis of the kidney. The compound terms above represent inflammation of the kidney structure as a result of, and combined with, pyelitis.

Pathology.—In the mildest varieties of pyelitis (the catarrhal) the morbid changes consist simply of a reddened, swollen, and turbid mucous membrane, covered with an exudation of viscid mucopus and desquamated epithelium. Ecchymoses are sometimes seen. The urine in the pelvis of the kidney is also turbid from the admixed pus-corpuscles and pelvic epithelium. In calculous pyelitis purulent inflammation and ulceration prevail, and the kidney structure is also involved by extension (pyelonephritis). Renal abscesses are thus formed, and small dark calculi may be found mingled with the pus in small abscess cavities; or, perhaps, as noted before (*vide* Nephrolithiasis), one large abscess cavity may replace the destroyed renal parenchyma (*pyonephrosis*).

A diphtheritic inflammation, with the formation of a false membrane and sloughing of the pelvis, sometimes follows the severe acute infections. Marked hemorrhagic areas may be seen also. In tuberculous pyelitis there is usually an association of nephritis with areas of tuberculous softening and ulceration, and later pyonephrosis. In very chronic cases the pyelitis may be followed by an infiltration of the kidney structure with cheesy masses that may become the seat of calcification.

Persistent obstruction leading to pyelitis is associated with dilatation of the pelvis from retention of urine or of pus (pyonephrosis). This, in turn, from prolonged pressure, causes marked atrophy of the secreting structure of the kidney. There is also an increase in the interstitial tissue. The so-called *surgical kidney* is found when an acute bilateral pyelitis, following a severe cystitis, has excited an acute suppurative inflammation of the kidney. Acute suppurative or interstitial inflammation of the kidney due to metastatic or miliary abscesses is considered under the heading *Pyemia* (*vide* p. 164).

Etiology.—Pyelitis rarely is primary or independent in origin, as after

exposure to cold and wet. The principal organisms concerned are the *colon bacillus*, *streptococcus*, *staphylococcus*, and *gonococcus*. The secondary causes of pyelitis are as follows: (1) renal calculi (the most frequent); (2) extension upward through the ureteral lymphatics of the organisms causing urethritis or cystitis; (3) retention of decomposed urine in the pelvis of the kidney; (4) renal affections, as tubercle, carcinoma, and acute nephritis; (5) specific fevers; (6) foreign bodies, other than stone in the pelvis; (7) irritating diuretics. To point out briefly certain additional facts bearing upon the causation of pyelitis in the order named, it should be mentioned that *calculous pyelitis* may result from the irritation of the constant presence and passage of small stones ("gravel"), or even of uric-acid "sand," as well as from the large dendritic concretions that send offshoots into the calyces. Extensions of inflammation to the pelvis from lower portions of the urinary tract may occur in protracted cases of such affections as gonorrheal urethritis and puerperal and calculous cystitis. The preponderance of right-sided pyelitis has recently been explained by the finding of a direct lymphatic connection between the colon and the right kidney (Franke). *Obstructive pyelitis* sometimes follows the impaction of renal calculi or of other foreign bodies in the ureter when there is pre-existing inflammation of the tract, or when, as usually happens, there is chemical irritation from the decomposition of the accumulated urine. There may be obstruction in the bladder and urethra, as from enlarged prostatic tumors, stricture, phimosis, and paralysis of the sphincter vesicæ, or as in paraplegia. Under the consideration of tuberculosis and carcinoma of the kidney is included the involvement of the pelvis by these conditions. *Infectious pyelitis* may result from small-pox, diphtheria, typhoid fever, and scarlatina, and it depends upon the presence of the organisms in the blood-stream. It is usually associated with more or less nephritis (pyelonephritis). Parasites, such as the echinococcus (hydatids), distoma, strongylus, and filaria, may give rise to pyelitis. Cantharides, cubebs, copaiba, turpentine, and diabetic urine even, may rarely excite a pyelitis in association with pyogenic bacteria.

Symptoms.—These are frequently overshadowed by those of the primary causative condition: they are varied also for the same reason. The clinical manifestations of a simple catarrhal pyelitis are slight pain and tenderness in the region of the affected kidney or kidneys, mild fever, with a *turbid urine of acid reaction*, showing a few pus-cells, a little mucus, rarely some red blood-corpuscles, and a trace of albumin.

In the severer varieties, as in calculous pyelitis, especially when there are attacks of renal colic, the urine frequently shows to the naked eye the presence of *blood* and a marked amount of *pus*, some *mucus*, and at times the transitional *caudate epithelial cells* from the middle layers of the mucosa. In obstructive pyelitis the urine sometimes flows freely and normally for a while, until the developing pain over the inflamed kidney ends in relief by the expulsion of the obstacle and the passage of purulent urine. This *alteration of normal with pyoid urine* is indicative of a unilateral pyelitis. *Ammoniacal urine* is met with in *cystopyelitis*. *Albuminuria* is decidedly shown according to the degree of *pyuria*.

In chronic suppurative pyelitis or pyelonephritis the *pyuria* is variable both in quantity and constancy. *Intermittent pyuria* may be due to the temporary blocking of the ureter by a stone (*vide* Obstructive Pyelitis). The pus is seldom mixed with epithelium in chronic purulent pyelitis. The associated intermittent fever may be like that of tuberculous pyelitis, and marked prostration, anemia, and emaciation are concomitants. Evidences of amyloid change may be revealed in long-standing chronic cases.

In severe pyelitis the *pain* is often acute, coursing *down the ureters*. The

fever is moderate, and there are present the common symptoms described under Nephrolithiasis (*vide* p. 946).

The fever in purulent pyelitis (pyonephrosis) and pyelonephritis takes on a *hectic* or *typhoid* type. Paroxysms of rigors or chills, followed by a rapid rise in temperature and ending in perspiration, may be observed; or there may be marked prostration and feebleness of circulation, delirium, and stupor. The temperature-curve runs an irregular course, with marked remissions, in pyemic cases.

Distinct *enlargement* and *fluctuation* of the diseased kidney may be determined in some cases of pyonephrosis. This may also be intermittent, being detectable while there is obstruction to the flow of pus, and *vice versa*. According to A. H. Smith, at the menstrual periods pyelitis may be subject to marked exacerbations, simulating renal colic. In chronic pyelitis with atrophy of the kidney the onset of uremia may terminate the case.

Dagnosis.—This embraces the discrimination from other affections, and the possible detection of the variety—etiologically considered—of the pyelitis. It is most important to pay attention to the clinical history of any case with a view to the discovery of the cause; also the urinary condition must be carefully studied. In the very nature of this affection it is often impossible to exclude other affections of the urinary tract, as *nephritis*, *cystitis*, and *urethritis*.

Epithelium from the pelvis of the kidney cannot be distinguished from transitional bladder cells; but, given the indications of a pyelitis, its calculous cause is at once made clear upon the passage of the characteristic uratic or oxalatic concretions. It may happen that the urine from one kidney is prevented from flowing by the impaction of a stone in the ureter. The urine may now flow clear from the other and vicariously acting kidney until, the stone having given way, it suddenly increases in quantity and changes in character, owing to the return of the morphologic elements of the pyelitis (corpuscles, desquamated epithelium, crystals, and débris).

Catheterization of the ureters and renal pelves, as described and practised by Pawlik and Kelly, is a most certain method of determining in doubtful cases from which side the purulent urine arises. Urine from the diseased kidney freezes at a point higher than does that from the healthy organ.¹ Palpation of the ureters through the lateral and anterior fornix of the vagina will sometimes reveal thickening and tenderness in cystopyelitis, and ureteral distention sometimes may be felt in pyelitis calculosa.

Castes and albumin are usually present when the kidney structure is involved by extension of the pyelitis, while marked pain in the region of the kidney indicates predominant pyelitis, though it does not exclude the possibility of coexisting nephritis. Marked vesical irritability points to associated cystitis, but in intense pyelitis with much pus and an acid urine vesical tenesmus may also be troublesome. Tuberculous can be discriminated from calculous pyelitis by finding tubercle bacilli in the pus. Tubercle bacilli were found by Flick and Walsh in the urine in 73.3 per cent. of consumptives, though lesions of the kidneys were often wanting. The presence of a fluctuating tumor in the lumbar region is significant enough of pus; but it may be difficult to determine whether it is due to pyonephrosis or perinephric abscess, although pyuria and the previous history of pyelitis, as well as the more circumscribed and less edematous character of the swelling of the former, are important distinguishing points.

Differential Diagnosis.—The *hemorrhagic pyelitis* of Senator, Delafield, and others, described as occurring in milder forms, and particularly in girls of neurotic types, may be distinguished by the intermittent hematuria and the

¹ Tinker, *Johns Hopkins Hosp. Bull.*, June, 1903.

occasional lumbar pain, lasting but a few days or a week, and followed uniformly by recovery.

Based on a thorough analysis of a considerable number of non-tuberculous renal infections, Cabot and Crabtree¹ state that, if with clinical evidence suggesting a renal infection, freshly drawn urine shows cocci in abundance with a small amount of albumin, a few red blood-corpuscles and many leukocytes or a little pus, together with a renal function at or near normal limits, a diagnosis of coccus infection of the kidney is justified. If, on the other hand, a similar examination shows many bacilli, a little albumin and much pus, with a markedly diminished kidney function, a diagnosis of colon bacillus infection of the kidney is unavoidable.

Difficulty is sometimes experienced in diagnosticating pyelitis when co-existent with cystitis—*pyelocystitis*. These affections will not be confounded, however, when it is recollected that their histories differ. There is pain in one lumbar region in the former, and in the bladder in the latter.

According to Rosenfeld: (1) an alkaline reaction is not found in uncomplicated pyelitis; (2) the limit of albumin in the urine, even with severest cystitis, is 0.1 per cent. (maximum, 0.15). Stress is laid upon the relation of the albumin contents, which is from two to three times greater with pyelitis than with cystitis.

Prognosis.—Renal complications always make the pyelitis a serious affection. Catarrhal cases recover. Calculous pyelitis tends toward chronicity. Pyelonephritis and pyonephrosis are apt to end fatally from exhaustion or uremia. Perforation and the discharge of pus into the peritoneal cavity, pleural sac, intestine, and bronchi even, may precede death. The gravity of all cases of pyelitis depends upon the causes and upon the tendency to consecutive suppuration.

Treatment.—This varies according to the cause: the latter needs to be removed, its effects counteracted, and its return avoided. The treatment of calculous pyelitis is essentially the treatment of nephrolithiasis. Primary inflammation of the lower portions of the urinary tract must be combated; causes of retention of decomposed urine, as a urethral stricture or enlarged prostate, must be diminished; infectious fevers must be judiciously handled and irritating diuretics withheld.

Local measures are of value in all forms of pyelitis. Hot-water bags, fomentations, poultices, and dry cupping are often of great service. Internally, the use of diluents is to be recommended, especially the alkaline mineral waters, flaxseed tea, barley-water, skimmed milk and buttermilk, and lemonade.

Hexamethylenamin is the most valuable drug to counteract the infection of the pelvis of the kidney and the associated cystitis, but is of value only when the urine is acid in reaction. Surgical intervention is necessary in severe purulent pyelitis, pyelonephritis, and pyonephrosis.

HYDRONEPHROSIS

Definition.—An obstructive accumulation of urinary fluid in the pelvis and calyces of the kidney; it may cause dilatation, pyelitis, or inflammation and atrophy of the renal structure.

Pathology.—Hydronephrosis is usually unilateral. The pathologic changes consist of a dilatation of the pelvis of the kidney, associated with a degree of atrophy of the renal tissue depending upon the degree and persistence

¹ *Surg., Gyn., and Obst.*, 1916, xxiii, 495.

of the pressure. The accumulated fluid causes flattening and atrophy of the papillæ, and gradually of the tubules and glomeruli, as the dilatation and distention increase, until in extreme cases remnants only of the renal structure remain in the walls of the hydronephrotic cyst. The mucous membrane lining the pelvis and calyces first becomes thinned, and later thickened, by the growth of connective tissue, thus forming the dense sac wall. There is also a growth of connective tissue in the renal parenchyma, medullary and cortical, a chronic nephritis with degeneration and atrophy of the renal cells being set up.

A *nephrydrotic cyst* may be very large, containing as much as several gallons of liquid. Sometimes in medium-sized sacs the external appearance of the walls may be lobulated; the interior, however, usually shows only partial septa projecting from the wall into the cavity of the sac. According to the seat of obstruction one or both ureters may also be dilated. If one kidney is affected, its fellow is often hypertrophied.

The fluid contained in the sac varies in composition, but usually is a clear, thin, yellowish, watery urine. The specific gravity is low, and the reaction is often slightly alkaline. Traces of albumin, urea, uric acid, and salts are found. Turbidity may be present owing to admixture with pus, blood, or epithelium, but only in instances in which previous inflammatory conditions, as a calculous pyelitis, or subsequent complications of like nature have existed.

Etiology.—Hydronephrosis—or, better, *nephrydrosis*—is in most instances secondarily produced by diseases—congenital or acquired—that cause occlusion of the ureter. Probably from 20 to 35 per cent. of cases are congenital (Roberts). In these cases the causal condition is one of stricture due to obstruction caused by a defective development or malformation in the urinary passage of one or both sides, usually the latter. Thus, there may be a valve-like formation or a very acute insertion of the ureter into the kidney. Peacock¹ reports a case with multiple ureters and primary obstruction in the posterior urethra. The dilation has occasionally become so great in the fetus as to cause considerable mechanical difficulty during labor.

Among adults, women are more often subject to hydronephrosis than men, and especially women who have borne children. The condition may be bilateral, as from a stricture low down and due to gonorrheal urethritis, but more often it is unilateral. The causes of these acquired cases are as follows: (1) Impacted calculi in the ureter or renal pelvis. (2) Disease of the ureteral walls, as inflammatory thickening and cicatricial stenosis from ulcers. (3) Flexion and twisting of the ureter, as from movable kidney. (4) Pressure upon the ureter from without, as by tumors and constricting bands (pelvic adhesions). The gravid and retrodisplaced uterus, uterine and ovarian neoplasms, enlarged and prolapsed spleen, and similar conditions causing compression or traction and obliteration of the lumen of the ureter, are found in this class. (5) Calculus of the lower portion of the ureter. (6) Diseases and tumors of the bladder that involve the ureteral orifices, particularly carcinoma and papilloma, or that cause retention, as prostatic enlargement. (7) Urethral stricture. (8) According to Fenwick, 16 per cent. of all cases are the result of pressure on the ureter by aberrant renal vessels.

Symptoms.—These depend somewhat upon the cause and extent of the hydronephrosis. Marked bilateral disease, when congenital, may render the fetus unviable. The unilateral variety may be overlooked for years, and no symptoms may point to the trouble until a tumor can be made out by inspection and palpation, or until the ureter of the remaining kidney may become obstructed and symptoms of uremia supervene. The latter are more apt to come on, and earlier too, in double hydronephrosis.

¹ *Jour. Amer. Med. Assoc.*, April 8, 1916, p. 1088.

Locally, the patient may complain of frequent and severe *pains* that shoot about the affected loin and downward toward the thigh. Sensations of weight and a dragging discomfort are common. Anorexia, nausea and vomiting, eructations, and irregularity of bowel action are associated sometimes. In large hydronephrotic cysts a continuous dull, aching pain only may be felt, or, as is not infrequently the case, the tumor may be absolutely painless. Obstinate constipation may result from compression of the colon, or in moderate enlargements diarrhea may occur from the pressure irritation.

Usually a swelling is detected in the renal region. It gradually increases in size, and in marked enlargements distinct bulging may be visible in the hypochondriac and lumbar regions. *Palpation* reveals a rounded, firm, yet somewhat elastic and sometimes fluctuating tumor. There may be slight tenderness. Dulness on percussion is found over the mass except where the colon overlies it, when tympany is elicited; this is a characteristic sign of kidney tumors. Moderate enlargements generally do not descend during inspiration.

The *intermittent* form of hydronephrosis (Landau) is interesting from the variations that occur in the size of the tumors. A *marked diminution* is coincident with a more or less sudden increase in the quantity of urine passed; and, on the other hand, as the tumor gradually enlarges the flow of urine decreases. These cases are in most instances due to movable kidney. *Colicky pains* often usher in the periods of greatest distention preceding the sudden increase in the flow of clear urine. This variety of the affection occurs most frequently in women that have borne children. The *general symptoms* scarcely amount to more than a certain loss of flesh incident to the associated worry and anxiety. The filling of the nephrydrotic cyst, the distention, and the pain and discharge, with subsidence of the tumor, recur with variable frequency. Violent exercise inflicting a sudden jar may precipitate the attacks. The tumor may continue to develop in size for several days after the pain has disappeared. The latter may last from several hours to a day. During the intervals, and after the urine has increased in quantity, gradually or quickly, the patient may feel tolerably comfortable for weeks or months. For obvious reasons the tumor is rather mobile in intermittent hydronephrosis.

The occurrence of chills, fever and sweats, nausea and vomiting, abdominal distention, and rapid pulse usually indicates suppuration and pyonephrosis. The urine will then be cloudy and reveal pus, following both discharge and aspiration. A lowered specific gravity and the presence of albumin will be noted when a chronic nephritis has been set up. The functional kidney test which is most practical is that by the employment of phenolphthalein. Increased arterial tension and symptoms of acute febrile or chronic afebrile uremia may be added.

Hydronephrosis paraplegica is a form of the disease in which paraplegia develops as a complication.

The *course* of nephrydrosis is usually chronic, with variations and exacerbations depending upon the cause of the affection.

Diagnosis.—This is obviously very difficult in cases in which the accumulation of liquid is small. Characteristic signs are the gradual development of a tumor in either flank, as described above, with diminution in the urinary flow, followed by a more or less sudden free discharge and the subsidence of the tumor, with recurrences (as in the intermittent variety). Ureteral catheterization is of great value as a diagnostic criterion. If the ureteral catheter can be passed up to the renal pelvis, the tension promptly disappears and a much larger quantity of urine is passed through the catheter of the affected side than from the normal side, or if fluid is injected into the pelvis of the kidneys, the pelvis of the affected side has a larger capacity than the unaffected

or the normal pelvis. The injection of opaque substances, such as collargol or thorium, through the catheter into the pelvis and ureter of the side suspected to be diseased and then roentgenogramming the kidney region will yield a beautiful picture, revealing fully the extent of the kidney involvement, the degree of the pelvic dilatation, and so on. On account of the ease with which a diagnosis may be made by the aid of the roentgenologist and the gynecologist it is unwise to attempt to make or sustain the diagnosis by means of aspiration because of the possibility of infection.

Differential Diagnosis.—The nephrydrotic sac must be distinguished by exclusion from an *ovarian cyst*, *cystic kidney*, and *tumors of the spleen, liver, and gall-bladder*. Very large cysts may be mistaken for *ascites*. Assurance of the presence of the colon over the tumor is diagnostic, and a chemical examination of the fluid obtained by the use of the exploring needle will suffice in most cases. It should be remembered, however, that a slight amount of urea is sometimes found in ovarian cystic fluid. The presence of pus-cells in abundance in the aspirated fluid, with symptoms of suppuration, is significant of pyonephrosis. Segregation and catheterization of the ureters may elicit decisive evidence during the existence of the tumor.

Prognosis.—This is generally unfavorable, though in unilateral hydro-nephrosis evidences of compensation on the part of the unaffected kidney should render the case guardedly favorable, particularly if the cause be a movable kidney. The bilateral affection is always grave owing to the danger of uremia. Infection of the cyst with pus-organisms is usually a fatal complication. Recovery may ensue in rare instances in which a spontaneous discharge of the liquid takes place. Rupture of the sac is unlikely.

Treatment.—The removal of the cause is seldom feasible. Symptomatic treatment only is required in mild cases, though sometimes gentle massage over the sac, properly directed and cautiously applied (to avoid rupture), may cause a reduction in the size of the tumor. Most often surgical measures only are of use. These procedures, however, are undertaken only when successive reaccumulations of the fluid follow those measures first mentioned.

PERINEPHRIC ABSCESS

(*Perinephritis*)

Definition.—Suppurative inflammation of the connective tissue surrounding the kidney.

Pathology.—The suppuration attacks the lax adipose tissue or the fatty capsule in which the kidney is embedded and the adjacent retroperitoneal tissue. The starting-point of suppuration is usually behind the kidney. There may be several small abscesses at first, but more often a single large abscess is found. The walls may be soft and shreddy, or in more chronic cases thickened and fibrous. A bulging externally over the affected lumbar region is not infrequent, particularly in large and extensive accumulations of pus. The latter has a tendency at a given point to burrow into the surrounding tissues, and especially downward toward the iliac fossa, pointing in the groin near Poupart's ligament. It may extent backward and open upon the skin surface. Sometimes the pus perforates the diaphragm and discharges through the pleural cavity and lungs, or the colon, vagina, bladder, or peritoneum may be perforated. The pus is occasionally quite offensive, and may be ichorous from an admixture of infiltrated urine. Perirenal abscess due to calculous pyonephrosis may contain calculi that have ulcerated through pelvic or renal

walls. Thickening of the adjacent peritoneum is often found. In certain cases of perinephritis, which usually gave no symptoms during life, the *post-mortem* examination has revealed fibrous adhesions and a firm and thickened and fatty capsule, stripped with difficulty from the true capsule of the kidney.

Etiology.—Perirenal abscesses, when not traumatic in origin, develop most frequently as a result of purulent pyelonephritis or pyonephrosis. Hence they are *usually secondary*. Other primary conditions that may cause perirenal suppuration are the following: extension of inflammation from the ureter or pelvis of the kidney, pelvic abscess, appendiceal or hepatic abscesses, spinal caries (psoas abscess), and empyema. Sometimes tuberculous processes in the kidney and suppurating new growths, as carcinoma and cysts (including the echinococcus), are complicated by perirenal abscess. More rarely such severe infectious diseases as typhus fever, small-pox, and pyemia lead to purulent perinephritis. Finally, there are cases for which no cause is discoverable.

Symptoms.—Subjectively, there is noted a *dull, throbbing pain* over the affected region that is increased by motion; sometimes, when the abscess is large and presses on the large nerve-trunks, the pains may become shooting in character and be felt in the leg on the same side. *Numbness* may also be felt. Pain and tenderness on palpation are common. The patient is prostrated, weak, and often quite emaciated, and flexure of the thigh on the affected side is frequent. The characteristic fever of suppuration is present in the deeply remitting or intermitting type, with alternating chills and debilitating sweats. Pus is found in the urine only when the kidney is involved. Sooner or later evidences of a *tumor* are seen; the areas can be palpated, and a gradual bulging in the lumbar area, increasing slowly, with smoothness and glistening of the skin and pitting (edema), may be observed. *Fluctuation* is frequently apparent in advanced cases, and in favorable cases signs of “pointing” appear. There is an associated polynuclear hyperleukocytosis.

Diagnosis.—Should the abscess tend to burrow downward, the condition may be somewhat obscure on account of the absence of distinct local symptoms. Indeed, involvement of the psoas may give rise to symptoms of coxitis, as pain referred to the knee-joint. The diagnosis is usually easy, and when in doubt as to whether the tumor is an abscess or a hydronephrosis or solid mass, the exploring needle should be used.

Differential Diagnosis.—An important point in differentiating perinephric abscess from suppurative pyelitis or pyelonephritis alone is the fact that in the latter the quantity of urine is usually diminished, while in the former there is less apt to be any interference with the renal secretion. Again, while in the latter the urine usually contains blood and pus, in the former the urine is free from blood, though not necessarily from pus, and casts are apt to be absent here.

Prognosis.—This is guardedly favorable if the abscess points externally in the lumbar area. Of course, rupture into the peritoneal cavity, bladder, bowel, and groin is always a serious occurrence.

The **treatment** is surgical, consisting in free incision and drainage.

CYSTIC KIDNEY

(Renal Cyst)

Pathology.—Congenital cystic kidneys are in reality collections of cysts, varying in size from a pea to a marble, and separated from each other by septa of compressed renal or fibrous tissue. Either one, or frequently both, kidneys

may be affected with what is sometimes termed *congenital cystic degeneration of the kidneys*. There is considerable enlargement of the organs, and during intra-uterine life they may attain an enormous size. In mild cases the affection may be tolerated for some years after birth. The cystic fluid may be either clear, turbid, reddish-yellow, or dark brown in color, acid in reaction, and holds in solution urinary salts, blood, cholesterin, and sometimes uric acid and urea. A single layer of flattened epithelial cells lines the cyst walls. The cysts themselves seem to be dilatations of the renal tubules and of Bowman's capsules, due, in some instances, to an obliteration of the tubules of the papillæ or to stenosis of some portion of the urinary tract.

The cystic kidneys usually met with in adult life (acquired) are of several varieties: (1) One or perhaps a few cysts may be present, larger usually than those in the congenital cystic kidney, which seem to cause no interference with the normal renal functions. Sometimes a reddish-brown colloid material is contained in these cysts.

(2) Small and often quite minute cysts frequently accompany the chronic nephritic kidney that is small, contracted, and cirrhotic. These result from dilated tubules and capsules when the former are narrowed by the hyperplasia of fibrous tissue.

(3) Cystic kidneys in adults may have the pathologic characteristics of the congenital variety—a mere aggregation of cysts containing clear or colored serum or a cloudy, dark, thick, colloid liquid. This condition is sometimes associated with similar cystic disease of the liver and spleen. It may be a late manifestation of mild congenital defects. The kidneys have been found converted into cysts in cases in which the presence of calculi (uric acid) in the tubules has probably started the cystic degeneration.

(4) Solitary cystic adenoma rarely occurs. It is in the form of a globular tumor projecting from the surface (usually the anterior) of the kidney. It may be as large as an orange, and may be enclosed in a distinct capsule. On section the mass is found to be composed of various-sized cysts separated by septa of fibrous tissue lined with cuboid or columnar epithelium. The remainder of the kidney appears to be quite healthy.

Symptoms.—These may be absent in adults until the sudden development of uremia. Ordinarily, the clinical picture is similar to that of chronic interstitial nephritis. There is an increase in the quantity of urine, which is of low specific gravity. Slight albuminuria may be present. On *palpation* a large, rounded, and *sponge-like* mass may be felt in either hypochondrium or on both sides. Cardiac hypertrophy and increased arterial tension, as in chronic nephritis, are also frequently met with in cystic degeneration of the kidneys. Parker reports a case which was followed by exfoliative dermatitis.

The **diagnosis** can only be made upon the presence of the above symptoms and the discovery of the clear physical signs of the tumor. It should be pointed out that a possible complication of perinephric abscess, due to rupture of one or more of the cysts (as has occurred—Osler), would, of course, render a diagnosis wellnigh impossible.

Prognosis.—Bilateral cystic disease of the kidney must eventually prove fatal, due to uremia or cardiac failure. Solitary cysts give a tolerably favorable outlook under proper surgical interference.

Treatment.—The unilocular cysts just referred to above may be removed, capsule and all, and the kidney sutured. Bilateral disease cannot be operated upon for obvious reasons; unilateral cystic degeneration may be treated by nephrectomy, with narrow chances of success.

NEW GROWTHS OF THE KIDNEY

The most common tumors of the kidney are those belonging to the class of adenomata (benign) and those that are either sarcomatous or carcinomatous (malignant).

Adenomata may be congenital or acquired. They grow in the cortex of the kidney in the form of small nodular masses, which in some cases may increase to a considerable size before any symptoms are produced. A cystic growth may be combined with adenoma (*cystic adenoma*), and *lymphadenoma* is also occasionally seen as a secondary growth. Other benign tumors that may affect the kidney are *angioma*, *fibroma*, and *lipoma*. Very large vascular adenomata may become malignant. Grawitz, Lubarsch, Kelly, and others have described a variety of tumor (*hypernephroma*) derived from aberrant adrenal tissue misplaced in the kidney. In 32 cases Fraser found morphologic evidence indicating that the tumors were derived from renal adenomata.

Symptoms.—The important points in the diagnosis of hypernephroma are hematuria at long intervals, pain and tumor, the latter giving rise to pressure symptoms. Roentgen-ray plates are of value in differentiating the hematuria of stone (Moffitt).

Sarcoma and **carcinoma** may be either primary or secondary. *Sarcoma* is frequently congenital in origin, and may have an admixture of striped muscular tissue. The presence of the latter in the kidney points to developmental disturbances during embryonic life as the cause of a variety of tumor known as *rhabdomyoma*. Alveolar sarcoma is also met with. Renal sarcoma is not uncommon in children.

Renal carcinoma is probably of less frequent occurrence than sarcoma; it may, however, be found in children as well as in aged persons, the two extremes of life. Carcinoma of the kidney is usually of the soft medullary or encephaloid variety. As a primary affection it probably originates in the renal tubules. Secondary carcinoma of the kidney, although probably more frequent than the primary form, is seldom of clinical importance. Renal carcinoma may occur as a diffuse infiltration or in nodular masses, one kidney usually being affected in primary carcinoma. The tumor sometimes reaches an enormous size, and instances are recorded in which nearly the whole abdomen has been filled, and in which the growth weighed as much as 31 pounds (14 kgms., Roberts). Rhabdomyomata do not, as a rule, attain a very large size, though sarcomata may grow quite large. Softening and hemorrhage within these malignant growths may occur. The pelvis of the kidney may be invaded, and metastatic areas may form in the liver or the lungs, though this occurs in the case of primary renal carcinoma less readily than from carcinoma in other organs. The renal parenchyma is either partially or wholly destroyed, the pyramids being attacked later than the cortex.

Symptoms.—*Lumbar pain* on the affected side is often an early symptom, and may persist throughout the course of the disease. It may be paroxysmal, and be felt extending down the thigh, or it may be dull, dragging, and limited in character. Pain is not, however, a constant symptom in a certain proportion of the cases.

Hematuria may occur early or late, and often appears before any tumor is palpable. The blood may be in a fluid state or in clots, the latter not seldom taking the form of pelvic or urethral casts, the passage of which may give rise to colicky pains. Casts of the ureter sometimes resemble lumbricoid worms. The hemorrhage may be excessive and cause marked weakness and a symptomatic anemia, superadded to the cancerous anemia that is usually present; on the other hand, it may be so slight as to be discoverable only microscopically.

It recurs at irregular intervals of days or weeks. Large clots may accumulate in the bladder and cause vesical irritability. The urine from the healthy kidney may be quite normal, and may be secured for observation by ureteral catheterization. *Anorexia, nausea and vomiting, progressive loss of flesh and strength, increasing pallor, and the concomitant symptoms of the cancerous cachexia* are seen to develop.

Physical Signs.—These may not be sufficient to reveal the presence of the tumor for some time after the above symptoms have been observed. The appearance of a palpable tumor in either flank is a definite aid to diagnosis. It is felt between the ribs and pelvis latero-anteriorly, and at first, when small and on the right side, it may be movable. Both sarcoma and carcinoma of the kidney may assume enormous sizes. The tumor feels dense and hard (except rapidly growing tumors, as encephaloid), either smooth or lobulated, and, when not too large, may retain the natural position and form of the kidney. The growth extends downward and inward, and in the very large malignant renal tumors of childhood the abdomen shows considerable enlargement, along with an abnormal pulsation and a prominence of the veins. Usually the tumor does not move with respiration. Percussion gives dullness over the mass, although in small and moderately large tumors the overlying colon may cause a tympanitic note to be heard.

Diagnosis.—The presence of a tumor, when not too large and distinctly occupying the lumbar and lower lateral abdominal region, together with hematuria, pain of a local nature, and progressive failure of nutrition, may be looked upon as diagnostic of a malignant type of renal tumor. The relation of the colon to the tumor and immobility of the latter during respiration are also diagnostic.

Differential Diagnosis.—This is a very difficult subject. Affections such as hydronephrosis, paranephritic cyst,¹ pyonephrosis, cystic kidney, hydatids, ovarian, splenic, and hepatic tumors and (particularly in children) retroperitoneal sarcoma must be differentiated from renal growths. Careful bimanual palpation will aid in the diagnosis, but the exclusion of other lumbar enlargements must be made by close attention to the history and to the development and course of the symptoms. Hematuria alone, in aged persons, is suggestive of carcinoma when no tangible cause for the presence of the blood is at hand. Hepatic and splenic tumors are usually movable during deep breathing, while renal tumors are not so. In cases of hepatic growths also the area of dullness extends higher, while in renal growths on the right side a tympanitic area generally lies between the liver and the tumor. The characteristic notch and edge of the spleen, and the absence of the overlying colon tympany, are points that distinguish splenic enlargements from those of the left kidney. Pelvic growths (ovarian and uterine) enlarge from below upward, and are readily detected by vaginal examination. In children Lobstein's cancer (retroperitoneal sarcoma), if very large, is easily mistaken for a renal tumor, except that it is usually more centrally situated and more firmly fixed.

Prognosis and Treatment.—The termination in cases of renal carcinoma is inevitably fatal, and children succumb more quickly than adults. The disease may last from a few months to sometimes a year to two.

If the kidney be removed while the growth is still small, the prognosis is fairly good; but if large or if metastatic tumors have formed, the prognosis is always bad. Bloch warmly advocates in some cases the removal of small sections of kidney substance, to avert the necessity of a nephrectomy by proving the non-malignancy of the growth. The *treatment*, aside from early surgical measures, is entirely symptomatic and supportive, and obviously it is unsuccessful.

¹ *Jour. Amer. Med. Assoc.*, June 27, 1903, p. 1775.

ful. Renal colic, excessive hematuria, and a gradually lowered vitality may be met by the use of palliatives, tonics, and by nutritious and easily digestible diet.

II. DISEASES OF THE BLADDER

CYSTITIS

Definition.—Inflammation of the mucous membrane of the bladder. It may be either *acute* or *chronic*, the latter being clinically the much more frequent condition.

ACUTE CYSTITIS

Pathology.—Cystoscopic examination performed according to Pawlik's or Kelly's method, hereafter to be described, reveals an intensely hyperemic condition of the vesical mucosa, which is puffy, edematous, and of a bright red color; this may be more intense at points, especially in the vicinity of the trigone. The membrane is bathed in a thick, tenacious mucus, and here and there may be noted denuded areas, the exfoliated epithelium often hanging in shreds from the bladder wall. Hemorrhagic effusions may be observed. In the severer grades of the disease the intense general hyperemia causes a disappearance of the blood-vessels that are to be seen in the normal condition. Occasionally small patches of ulceration, due to abscess formation (*phlegmonous cystitis*), may be observed, and in rare and fatal instances the entire bladder wall is involved in a necrotic process.

Etiology.—Cases of acute cystitis may be grouped according to their origin into four main classes, as follows:

(1) **Catarrhal.**—Like other mucosæ, the vesical epithelium is very responsive to systemic circulatory disturbances. Thus, sudden exposure to extremes of cold or heat or violent atmospheric changes, thereby abruptly suppressing the action of the skin, may be potent influences in the etiology of the disease. An intense acute catarrhal inflammation may follow retention of the urine in the bladder, with or without its subsequent decomposition; it may also be the result of pressure from an enlarged prostate or other tumor, and may follow cystocele, urethral stricture, or paresis of the bladder wall. In overdistention of the bladder, with the accumulation of a gallon (4 liters) or more of urine, the so-called acute *exfoliative cystitis* may result, in which the entire mucous membrane of the bladder may be shed, and the symptoms of grave uremic intoxication supervene. The prolonged retention of urine is followed by decomposition of the fluid, and this, by its irritant action, always excites a cystitis that soon assumes the chronic type.

(2) **Septic.**—This may result either from the direct introduction of pus-producing germs into the bladder or from the systemic transmission of these micro-organisms to the organ. This is known as the *bacterial origin* of cystitis. Under the first class may be mentioned the passage of an unclean catheter or sound; this is a cause of cystitis in puerperal women, and in men who are the subjects of minor grades of urethral stricture, and who have been subjected to gradual dilatation by means of bougies. *Gonorrheal cystitis* is also to be included under this heading. There is a condition known as *febrile cystitis*, which constitutes the second class of septic cases. This comprises the vesical inflammation that is present in the various febrile conditions, and which is probably a direct result of the presence in the urine of the causal bacilli or their toxins (Fitz). Thus, in all of the infectious diseases and fevers

(typhoid and the other exanthemata, rheumatism, diphtheria, tuberculosis) there is noted a cystitis of varying degrees of severity that can be accounted for only by the local irritant action of the specific germ of the associated disease, or its eliminating toxins. It does not necessarily follow, however, that organisms in the urine will cause a cystitis. The *Bacillus typhosus*, for example, is very generally found in the urine of individuals sick with typhoid, though rarely does a cystitis develop.

(3) **Toxic.**—Certain drugs when introduced into the system manifest an irritant action upon the vesical mucosa, and promptly excite a severe grade of acute cystitis. Prominent among these may be mentioned cantharides and other irritants of the urinary tract—cubebs, copaiba, and sinapis. Workers in coal-tar dye-stuffs are sometimes affected with acute cystitis.

(4) **Traumatic.**—Traumatic inflammation of the bladder follows the improper and careless use of the catheter, sound, or other instrument; the presence in the bladder of calculi or other foreign bodies; and the pressure of the fetus in parturition, or of large masses of impacted feces.

(5) **From Adjacent Inflammation.**—Irritation with consequent inflammation may result from the extension of an inflammatory process from surrounding structures either by continuity or contiguity of tissue. Thus, a cystitis may follow a urethritis—gonorrheal or otherwise; it may result from an extension downward of a ureteritis, or it may be consequent upon a vaginitis, a malignant neoplasm of an adjacent viscus, a salpingitis, pelvic peritonitis, or pelvic abscess in the immediate vicinity of the bladder, as in the vesico-uterine pouch.

The **symptoms** of acute cystitis are very marked. *Pain, vesical irritability, vesical and rectal tenesmus, frequency of micturition, fever, and urinary changes* are all pronounced. Prominent among these is *pain*, which may be most intense and is the earliest and most persistent manifestation of the disease. Its seat is the suprapubic region, whence it may radiate to the sacral region, the perineum, the end of the penis, or the upper portion of the thighs; it is most constant, but is worst just before micturition, by which it may be alleviated. It is considerably relieved by the recumbent posture, and is aggravated by pressure over the bladder.

With the pain, and probably ranking second in severity, is the *rectal and vesical tenesmus*, or *strangury*. There is an almost constant desire to urinate. The *urine* may be opaque or highly colored. It is often bloody (in very acute cases the vesical contents may consist of a small quantity of pure blood only), is of a specific gravity varying from 1005 to 1030 (in the febrile cases), and contains pus-corpuscles, mucous flakes, shreds of disintegrated and exfoliated epithelium (bladder), and micro-organisms. Thomas R. Brown,¹ in a bacteriologic study of 26 cases, found the exciting causes as follows: *Bacillus coli communis*, 57.7 per cent.; *Staphylococcus pyogenes albus*, 19.2 per cent.; *Staphylococcus pyogenes aureus*, 7.7 per cent.; and *Bacillus pyocyaneus*, *Bacillus typhosus*, and *Bacillus proteus vulgaris* (Haiser), each 3.8 per cent.

Gonorrheal infection may invade the vesical mucosæ when mixed or pure cultures of this organism are recoverable from the urine; fungous mycelial threads and yeast-cells have even been found in certain cases (*mycotic cystitis*). The urine is commonly acid in reaction, though Brown found it alkaline where the excitant was the *Bacillus proteus vulgaris*. It may become less acid or alkaline should the condition become modified. More or less albumin will be noted, and on standing a dense sediment forms in the bottom of the flask, which is composed of all the foregoing substances, as shown by chemical and microscopic examination. The total quantity of urine voided in the twenty-four hours may be normal in amount or even slightly in excess of the normal.

¹ *Johns Hopkins Hosp. Bull.*, January, 1901, p. 4.

On the other hand, if exfoliation of the mucous membrane takes place, there may occur partial or even total suppression of the urine.

Fever, with or without an initial rigor, persists throughout the attack, but is not of a severe type, save in the septic and malignant (diphtheritic) forms of the disease, when it may reach 103° to 105° F. (39.4°–40.5° C.).

Abscesses may form, and betray themselves by localized pain, tenderness, and, in some cases by a circumscribed induration requiring surgical treatment.

In the variety associated with extreme exfoliation of the vesical mucosa *grave uremic manifestations* follow. These include all the features of the typhoid state (dry, brown tongue, mild delirium, nervous and muscular twitching; headache; gastric disturbances; and coma). There is also some degree of malaise and anorexia.

It must not be forgotten that acute cystitis may represent an acute exacerbation in the chronic form, and at times may assume a severe type of the disease.

Diagnosis.—Cystitis should be readily recognized from the history of the case and the frequency of the two almost pathognomonic symptoms—suprapubic pain and vesical tenesmus. An examination of the urine will reveal the characteristic clinical features. The percentage of albumin is usually much larger in nephritis than in irritability of the bladder. The differentiation between cystitis and vesical irritability will be noted under the latter condition. Urethritis may be excluded by means of the two-glass test. For example, if urination into two glasses reveals pus in both, after carefully washing out the urethra as far as the compressor urethræ muscle, it is “very positive proof that cystitis or some inflammation further up the canal is present” (Greene and Brooks).

The **prognosis** of the milder grades of cystitis is good; the septic and malignant cases offer a much graver outlook. Extension of the process upward toward the kidneys is always serious.

The **treatment** of acute cystitis includes prophylactic, hygienic, and medicinal measures.

Prophylactic.—Most important is the prevention of the disease, and this includes, in addition to the usual care of the body, the observance of thorough asepsis during catheterization.

Hygienic.—The cause of the disease, if evident (calculus, external pressure), should be sought and removed. The patient should at once be placed absolutely at rest in the recumbent posture. The *diet* must be regulated, and all irritating, highly seasoned articles of food must be interdicted. Alcohol in any form is prohibited. An absolute milk diet will be most beneficial. The patient should be instructed to drink freely of water and other diluent drinks. The free action of the skin may be secured by friction and warm bathing.

Medicinal.—The drugs to be employed are the saline laxatives and the various mild diuretics and urinary antiseptics. The reaction of the urine will indicate the variety of antiseptic to be employed. If it be acid, hexamethylenamin is the drug that is indicated. It may be given in doses up to 60 grains (4.0) a day. In alkaline conditions of the urine probably the most valuable drugs are benzoic and boric acids and salol. Benzoic acid is best administered in the form of ammonium benzoate, which may be given in 10-grain (0.6) doses thrice daily. If possible it is best to acidify the urine by giving acid sodium phosphate or some such drug and then give hexamethylenamin. Hot applications and hot local bathing (sitz-baths) will do much to relieve the pain and tenesmus; if these be severe, a rectal suppository of opium and belladonna or an enema of chloral hydrate will generally give prompt relief. Tincture of cannabis indica, administered internally, may answer if opium be contraindicated. Under such a course as the preceding a

cure may be expected within eight or ten days. It is prudent to advise the patients to wear flannel or silk binders over the abdomen, to avoid chilling of the surface and subsequent acute attacks.

CHRONIC CYSTITIS

Pathology.—The vesical mucosa is not so hyperemic as in the acute variety, but is of a peculiar muddy or grayish-blue (slate) color, dotted here and there with patches of erosion or of actual ulceration. Slight hemorrhages may and do occur. Owing to the slow course of the disease there follows an immense thickening of the bladder wall from hyperplasia, conjoined with more or less edema, of the tissues. The result is a contraction of the wall with a proportionate diminution in the vesical capacity. The mucosa may become polypoid in spots, and there rarely follows obstruction of the ureteral orifices, with consequent dilatation of the ureters and renal pelves from a damming back of the secretion. In the majority of cases, however, the changes will be found on cystoscopic examination to be limited to the lower portion of the bladder. The urinary changes are about as in the acute form, save that the reaction is alkaline and the amount of mucus and pus is proportionately greater.

Etiology.—Chronic inflammation of the bladder may be the result of a neglected or oft-repeated acute attack. It may occur from the persistent action of an exciting cause, as the presence of some irritating substance (calculus) in the bladder, or of some excitant external to that viscus, as a localized inflammation or a displaced uterus. The tuberculous variety and that due to neoplasms are insidious in development.

The **symptoms** and **diagnosis** differ but slightly from those of acute cystitis, although the pain and tenesmus are less intense. Oppositely, the *amount of albumin* in the urine is comparatively large. The same remark applies to the *quantity of mucus* and *pus* (*vide* Pathology); indeed, the last-named ingredient often forms a thick gelatinous mass in the standing urine that tends to adhere to the receptacle. According to Brown's researches bacterial flora contribute liberally toward chronic cystitis: *Bacillus coli communis* was present in the urine in 55.2 per cent. (50 per cent. in pure culture, and once combined with *Bacillus tuberculosis*); *Staphylococcus pyogenes aureus*, 10.3 per cent.; *Staphylococcus albus*, 6.9 per cent.; *Bacillus proteus vulgaris*, 3.4 per cent. The reaction of the urine is often neutral or alkaline where infection is due to the three last-named organisms. An alkaline reaction exists in 80 to 90 per cent. of cases. The cystoscope is an invaluable aid to the recognition of chronic cystitis. Chronic cystitis is accompanied by debility and emaciation, which, however, are of slow development.

The **prognosis** is always serious, and the course of the disease is, at the best, protracted.

Treatment.—Very generally, the treatment set down for the acute disease will not answer in the chronic form. Undoubtedly, there will follow more or less amelioration of the symptoms, but the tendency is toward a prolonged chronicity. In such cases, after the removal of the ascertainable causes so far as practicable, we are compelled to resort to local treatment of the bladder. This includes—(1) Vesical irrigation; (2) topical applications; (3) permanent drainage of the bladder.

Vesical irrigation is secured by means of an aseptic soft-rubber catheter which is connected with a graduated glass funnel: a siphonage is produced by the alternate elevation and depression of the funnel, which contains the irrigating fluid. The latter may consist of plain sterilized (boiled) water, sterile normal salt solution (40 to 60 gr. to the pint—2.5–4.0 per $\frac{1}{2}$ liter), or a weak solution of mercuric chlorid (1 : 50,000–100,000). The irrigation should be done

slowly, and not more than twice or thrice daily in severe cases, and much less frequently in ordinary cases, according to the exigencies of the condition.

Vesical medication may be secured by means of the funnel after irrigation, the medicating substances being dissolved in a pint of water and allowed to flow slowly in and out of the bladder. The drugs that may be used in this manner are silver nitrate or zinc sulphate (1-5 gr. to the ounce—0.065-0.3 to 30.0) or a saturated solution of boric acid. If the salts of zinc or silver are used, not more than an ounce of the solution should be allowed to enter the bladder, and much less than this amount will generally suffice. In cases in which there exist patches of ulceration the application must be made directly to these areas through the endoscope or cystoscope. Stronger solutions may now be employed, as silver nitrate, 20 to 30 gr. (1.3-2.0) to the ounce. This application should be followed by a slight irrigation of the bladder.

When this local medication fails to effect a cure, permanent drainage of the bladder must be secured—in the male by a suprapubic or perineal incision, and in the female by the establishment of a vesicovaginal fistula. This places the bladder absolutely at rest, and gives the inflamed mucosa a chance to heal under proper medication.

As to internal remedies, various agents that possess a local stimulating effect upon the genito-urinary tract are advised by most authors, but I think little is to be gained from their employment as compared with the results achievable from topical treatment. Most efficacious among internal remedies are oil of sandalwood, terebene, hexamethylenamin if the urine be acid.

NEOPLASMS OF THE BLADDER

Primary new growths of the bladder are exceedingly rare, occurring, however, with greater frequency in males in about the proportion of 3 to 1; they may be either benign or malignant. On the other hand, secondary neoplasms, particularly carcinomata, are relatively common. The most frequent variety of new growth encountered is carcinoma, particularly the so-called villous or papillomatous carcinoma, Williams finding in 20 women affected with bladder tumor, carcinoma in 16. Other growths are sarcomatous, fibromatous, cystic, and papillomatous in nature.

The **symptoms** are the same for all varieties, and include, first and most commonly, *hemorrhage* (which is both persistent and free), together with pain, frequency of micturition, and occasionally the discharge of detached fragments of the growth. In carcinomatous cases of advanced standing cachexia will be marked. By means of the cystoscope the nature of the complaint is disclosed. In the case of secondary growths the primary tumor may often be detected.

The **prognosis**, of course, will depend upon the nature of the growth.

The **treatment** is purely surgical.

VESICAL HEMORRHAGE

Hemorrhage of the bladder has been mentioned as a symptom of various affections, both general and local, among the former being leukemia and malarial hematuria, and among the latter nephrolithiasis and tuberculosis and carcinoma of the bladder. It is also a prominent manifestation in stone in the bladder, and not infrequently appears in pregnancy (late). Independently of the opera-

tion of all of the above-mentioned etiologic factors, hemorrhage has been known to occur from the bladder, and recent precise methods of exploring the viscus (endoscopic examination) have shown it to be due to a hemorrhoidal state of the vessels or to ulceration. The hemorrhage may be profuse, and, rarely, even fatal in its effects.

The **diagnosis** is based in part upon the absence of the more obvious causes of hematuria and the presence of free bleedings, but chiefly upon the result of a careful cystoscopic exploration of the bladder.

The **prognosis**, so far as my experience extends, is eminently favorable, though a few fatal cases have been reported.

Treatment.—This is mainly local. The bladder may be irrigated with an astringent solution (1 per cent. tannic acid, $\frac{1}{2}$ per cent. alum), and this may be alternated with an antiseptic solution (3 per cent. boric acid, 1 per cent. salicylic acid).

NEUROSES OF THE BLADDER

IRRITABILITY OF THE BLADDER

Definition.—By this term is meant a condition of the bladder in which there exists a hyperesthesia of the organ, especially of the neck—that portion surrounding the urethral and ureteral orifices (*vesical trigone*)—without the presence of any tangible cause therefor. This must be distinguished from the irritability that is associated with true organic disease of the bladder itself, as in the presence of calculi, tumors, or fissure of the neck, or with disease of the surrounding structures.

Pathology.—Cystoscopic examination of the bladder may reveal a slight increase in the vascularity of the mucous membrane. The condition of irritable bladder in women, which has previously been held to be a purely functional derangement, is now regarded by Dacheux and Zuckermandl as a localized hyperemia, especially at the *bas fond*, and less often at the beginning of the urethra.

Etiology.—While in many instances no well-defined causal relations can be determined, it is very generally true that the patients who are the subjects of vesical irritability are individuals of a neurotic temperament, very often manifesting strong hysteric tendencies. They are generally ill-nourished, fretful, irritable, peevish, suffering almost constantly from vague neuralgic attacks in different portions of the body (cephalgia, tic douloureux, lumbosacral pain), and in a chronic condition of physical prostration. Frequently they eventually develop a true hypochondriasis or melancholia. In others there may be found a history of extreme mental and physical tire, overwork, business anxiety, overindulgence in venery, menstrual irregularity, dysmenorrhea, ovarian or uterine disorders, long-continued gastro-intestinal disturbance (dyspepsia), improper hygienic surroundings, improper regimen, indulgence in late hours, and a general lack of will-power. It must, however, be remembered that subjects of chronic malarial intoxication very often manifest all the symptoms of vesical irritability, marked, it may be, by a feature of more or less periodicity. The condition must commonly, however, be regarded as belonging essentially to the large group of neuroses.

In a certain percentage of cases the bladder trouble is a reflex manifestation of some disease of an adjacent organ, as the urethra, ureter, vagina, rectum, anus, or the internal organs of generation. These are not, however, to be looked upon as cases of true neurotic vesical irritability.

The **symptoms** of irritable bladder are mainly extreme painfulness and frequency of micturition, associated with marked vesical and rectal tenesmus. The dysuria is not always or altogether relieved by micturition; indeed, the pain may be just as severe, or even worse after, than before, the voiding of the urine. Especially is this true when there coexists a more or less spasmodic muscular action of the bladder walls, the hypersensitive mucosa then being squeezed, and the patient suffering at times to such an extent as to be thrown almost into a state of collapse. There is usually a sense of weight or pressure in the pubic region, which is largely relieved when the patient assumes the recumbent posture. Urination is often performed spasmodically, or there may be a *spasm* of the urethra and neck of the bladder resulting in an utter inability to perform the act. The *urine* may be normal in appearance and amount. Very often it is increased in quantity (*hysteric polyuria*), and at times the opposite may be true and more or less suppression be noted.

Diagnosis.—Very frequently will simple vesical irritability be confounded with true cystitis. The points of differentiation, however, are as follows:

IRRITABLE BLADDER

The patient is of a neurotic temperament, and generally gives no history of organic bladder disease nor of operations upon the bladder.

Pain is severe, and often worse after micturition.

The constitutional symptoms are those of nervous depression.

Never results fatally.

The urine does not present any marked alteration in its physical or chemical qualities. It may show hyperacidity, or extreme concentration, or dilution.

The appearance of the mucosa is negative in true neurosis.

The duration is always protracted.

CYSTITIS

May occur in any individual, irrespective of temperament. It frequently follows catheterization, sounding, or other traumatism.

The pain is usually much relieved by micturition.

The constitutional symptoms are not marked, save in grave cases.

May result fatally.

There are always present marked and characteristic alterations in the physical and chemical qualities of the urine.

Cystoscopic exploration reveals the angry and diseased mucosa, and may show the cause (calculus, tumor).

The duration of acute attacks may be short.

Prognosis.—Good as regards life; doubtful as regards the ultimate cure of the patient.

Treatment.—Since the condition is largely one of neurotic origin, the attention of the physician must be directed mainly toward a betterment of the state of the nervous system. Absolute rest, physical and mental, must be insisted upon, and the patient must be subjected to a course of strict moral suasion whenever this may be deemed necessary. Any cause of reflex irritation must be removed, and a careful search should be instituted for some such condition as cervical stenosis, uterine displacements, anal fissure, hemorrhoids, stricture of the rectum, vaginitis, urethritis, tuberculous infection of Skene's glands of the urethra, chronic gastro-intestinal catarrh, and the like. The habits of the patient must be inquired into, and late hours, the eating of improper and unwholesome articles of food, masturbation, or the reading of sensational and trashy literature corrected. In many instances the pronounced neurasthenic condition demands a course, more or less protracted, of the Weir Mitchell rest treatment (*vide* Neurasthenia, p. 1164). The urine should be carefully examined for pathologic features, and by an appropriate course of treatment it should be rendered as bland and unirritating as possible. Large drafts of diluent drinks may be of benefit, and if these be combined with the prolonged administration of nerve sedatives and antispasmodics, a marked amelioration of the patient's condition may be secured. In cases associated

with spasmodic muscular contraction it may become necessary to employ an occasional suppository of opium and belladonna, or an enema of chloral hydrate. Change of air and scene, regulation of the diet, the institution of a proper course of gymnastics, mental and physical, and the observance of a happy and cheerful atmosphere will generally do much to improve the patient's condition. The administration of tonics (strychnin, iron) and the prevention of constipation are very essential. Especially must it be remembered that in all these cases of simple vesical irritability physical exploration of the bladder is absolutely contraindicated. The patient's mind must be directed away from the bladder in order to secure good results.

NEUROSES OF MICTURITION

1. **Incontinence of Urine** (*Enuresis*).—An inability to retain the urine. This may arise from a number of causes. Frequently it is the result of some lesion of the spinal cord involving the sphincteric center of the bladder; this is known as *paralytic incontinence*, and is to be recognized by a constant dribbling, alternating with spurts of urine when voluntary or involuntary muscular action is brought into play, as in the act of coughing, sneezing, or bending forward of the body. It may be the result of a general bodily weakness or after prostrating diseases (typhoid, late stages of pulmonary tuberculosis). Again, it may result from some local condition in the bladder or urethra. Here may be mentioned paralysis of the urethra from overdilatation or from traumatism, or that due to pressure of the fetal head in a prolonged labor; imperfect vesical innervation; overdistention of the bladder, producing a paresis of its walls; or from some temporary obstruction at the urethra or base of the bladder, such as a tumor or a sharply retroflexed uterus. It may be a result of overdistention of the bladder, with partial paralysis of the sphincter, the bladder remaining overfilled, while there is a constant escape of a few drops of urine (*incontinence of retention*). It may follow some local causes of irritation, as the presence of vesical calculi, pressure from an anteverted uterus upon the fundus of the bladder, cystitis, and parasites. The condition known as *spasmodic incontinence* is that due to an overaction of the compressor muscle of the bladder, as a consequence of which there is a diminution of the vesical capacity, the urine being forcibly and involuntarily ejected at irregular intervals. Finally, *nocturnal enuresis* is that variety which is so common in young, delicate, and often neurotic children: this is usually noticed in the early hours of sleep, and is often the result of some local irritation acting upon a hypersensitive organism, such as the presence of oxyurias, an elongated prepuce, contraction of the urethral meatus, or masturbation. Bierhoff¹ is of the opinion that the essential or ultimate condition is hyperesthesia of the deep urethra or sphincter from hyperemia or inflammation. Nocturnal incontinence may be a manifestation of nocturnal epilepsy or of incipient cerebral or spinal disease (Fitz). Adenoid vegetations may bear an indirect causative relation to the condition, and it may be a symptom of thyroid hypoplasia. In the female, urethral papillomata and caruncles have been assigned as causes. The hyperacidity of the urine associated with podagra may also excite enuresis. The constant escape of urine in the parietic cases is apt to result in extensive excoriation of the parts.

The *treatment* varies according to the cause. The enuresis of children, if left alone, will eventually cure itself as the age and strength of the patient increases, though obvious exciting causes, if present, should be removed if not impracticable. Good hygiene, systematic evacuation of the bladder, elevation of the hips on a pillow in bed, plenty of out-of-door exercise, a change

¹ *Phila. Med. Jour.*, May 26, 1900.

to the seashore or mountains, an abundance of suitable and strengthening food, mainly vegetable, so that a large proportion of the fluid output occurs by way of the intestines, with a minimum of water, and milk, especially late in the day, and the administration of tonics (iron, cod-liver or olive oil, and strychnin), will generally effect a cure. The fluidextract of *rhus aromatica* in 5 to 15 drop doses, thrice daily, has been very beneficial in children. Excellent results often follow the administration of minute doses of atropin or tincture of belladonna.

In very delicate or feeble children suffering from enuresis I give a motor tonic and stimulant (tr. nucis vom.). In cases showing marked hyperacidity the alkalies or alkaline mineral waters, with careful rearrangement of the diet, are indicated. Klotz advises to raise the foot of the bed and make the patient sleep on his side. Again, the little sufferer may be wakened prior to the hour for the occurrence of the incontinence.

Spasmodic action of the vesical compressor may be relieved by the cautious use of the motor depressants, while its converse, paresis, demands the exhibition of full doses of strychnin or tincture of nux vomica. The judicious and careful use of the catheter, followed by the administration of strychnin, will promptly effect a cure in the incontinence of retention not caused by an organic obstruction such as an enlarged prostate. Any local cause of vesical irritation must be removed. Galvanism in the parietic cases, applied both to the bladder and to the urethra, may be of service. Forchheimer uses the faradic current; in girls one pole is introduced into the vagina, in boys into the rectum, while the other pole is placed over the region of the bladder. The current must not be of too great strength, and he begins with the weakest induction current, which is gradually increased. In the female Sanger suggests massage of the urethra. Vibratory massage has proved successful in a few cases. Should excoriation occur, bland ointments, as of zinc oxid and lanolin, should be used. Removal of adenoid vegetations has been recommended in cases in which they produce conditions of malnutrition. For cases caused by thyroid insufficiency, the use of thyroid extract will relieve the enuresis and also bring about marked improvement in the general physical and mental condition.

2. **Retention.**—Nervous retention of the urine is occasionally encountered in hysteric and highly neurotic individuals. Its most common manifestation is an inability to urinate in the presence of others. It is also occasionally noted after childbirth, when it may be due to nervous reaction, to edema and tortuosity of the urethra, or to a temporary inability of the bladder walls to contract upon their contents, thereby permitting a longer retention of the vesical contents, and even favoring overdistention of the organ. If the urine be allowed to remain for too long a period in the bladder, fermentative changes follow and a secondary cystitis will result. Under these circumstances an exfoliation of a portion or even of the entire bladder epithelium may be noted.

The *treatment* consists in the administration of strychnin and other nerve tonics, in building up the general constitution, and in affording a change of air and recreation. In that variety following childbirth the patient should be urged to make voluntary efforts at micturition, and these may be seconded by the firm application of an abdominal binder and compress, or of hot, moist flannel cloths, kept up for twenty minutes or a half-hour. The sound of running water, as when pouring water from a pitcher into the basin, often causes a contraction of the bladder and excites the flow of urine. It may become necessary, the foregoing methods failing, to resort to catheterization, the usual antiseptic precautions being observed.

PART IX

DISEASES OF THE NERVOUS SYSTEM

THE central nervous system is generally divided into two parts—the brain and the cord. The *brain* consists of the cerebral hemispheres, the basal ganglia, the cerebellum, the pons, and the medulla. The cerebral hemispheres are joined together by the corpus callosum and the anterior and posterior commissures. They are united to the pons by the crura cerebri, and the pons is continuous with the medulla, which in turn is continuous with the spinal cord. The surface of the cerebral hemispheres is divided by sulci or fissures into various regions, known as the frontal, parietal, temporosphenoidal, and occipital lobes. The superior longitudinal fissure separates the two hemispheres; the fissure of Sylvius is between the frontal and parietal lobes above and the temporosphenoidal lobe below. The fissure of Rolando divides the frontal from the parietal lobe, and the parieto-occipital fissure the latter from the occipital lobe. The continuation of the last-named fissure upon the median surface forms the upper boundary of the cuneus, the lower boundary of which is the calcarine fissure. The hippocampal fissure separates the fascia dentata from the hippocampal gyrus, and by its extension inward produces an elevation in the lateral ventricle known as the hippocampus major. Each lobe is subdivided by secondary fissures into a number of lobules. The topography of the hemispheres is important because it is now possible to map out with considerable accuracy the regions in which various motor impulses originate, and with less accuracy the regions in which various sensory phenomena are perceived.

The central nervous system is composed practically of two elements—the neuroglia, or supporting substance, and the neurons. The neuron is the active part, and consists of a cell body containing a nucleus which, in turn, contains a nucleolus; a number of processes arising from the cell body which are similar in structure to it—*i. e.*, protoplasm—and known as dendrites or dendrons; and a process of different structure which arises either from the cell body or a dendrite, known as the axon or axis-cylinder process. Each neuron is an independent nerve unit and probably has no anatomic connection with any other neuron. The axis-cylinders, however, arising from certain cells may divide into a brush-like tuft of fine fibers which surrounds the cell bodies and dendrites of other neurons. In this way there is a physiologic connection, and such combinations form the various motor and sensory tracts. Axis-cylinders which arise from the cells in the gray matter of the pons, medulla, and anterior horns of the spinal cord end in the so-called motorial end-plates in the muscles. The function of a cell body may be to either originate motor impulses, to control muscle tone, to modify impulses received from another neuron, to act as reflex centers, exercise a trophic or nutritive influence on muscles, bones, skin, etc., or to receive and recognize sensory impressions. Certain cells may combine several of these functions, thus, the cells in the anterior horns of the spinal cord receive motor impulses from the cortical

cells, and by means of their axis-cylinders (the peripheral nerves) transmit them to the muscles, act as reflex centers, and control the nutrition of the muscles.

Cells are found in the gray matter, and the axis-cylinders constitute the white matter of the brain and cord. Each axis-cylinder is surrounded by a myelin sheath. They conduct either efferent or afferent impulses which are always away from the cell body, while the dendrites convey only afferent impulses from the periphery to the cell. Thus axis-cylinders compose the motor portion of the peripheral nerves, while the sensory portion is composed of dendrites.

A group of cells which together control some function of the body is known as a center. Either from or to these the various tracts run. Certain centers originate movements of the muscles (motor centers), others receive sensory

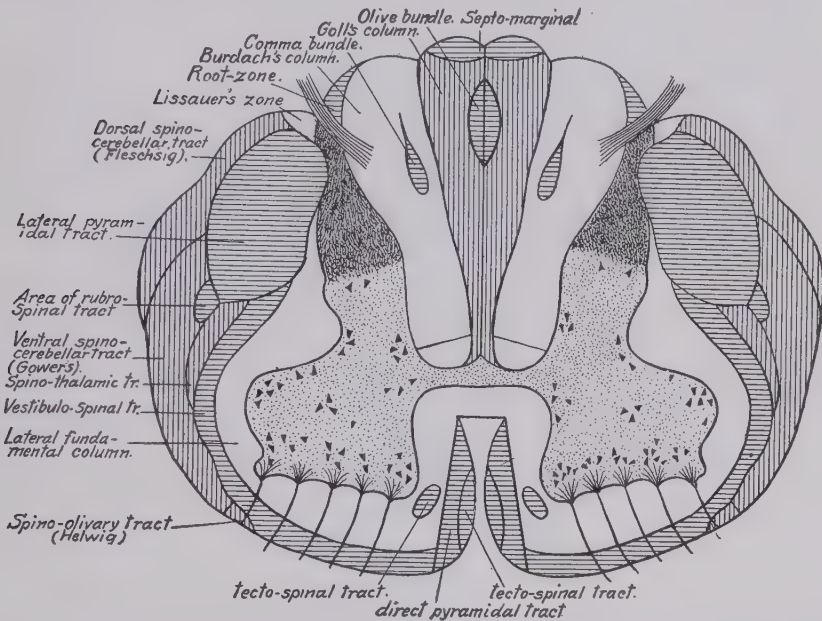

Fig. 62.—Showing the tracts and columns of the spinal cord. Descending tracts are indicated with the horizontal ruled lines; ascending tracts are indicated with the vertical ruled lines. The vestibulo-spinal is not as extensive as indicated and lies mainly in the ventral column. The rubrospinal tract is not as sharply defined as indicated (modified from Dana's "Text-Book of Nervous Diseases").

impressions (sensory centers), others combine certain combinations of movements, sensations, and perceptions, such as are employed in certain functions, as speech, writing, and other more or less complicated combinations of muscle contractions, as playing musical instruments, etc. (association centers). Those fibers which connect cortical centers (p. 995) with either the cells of the basal ganglia, the nuclei in the pons and medulla, or gray matter of the spinal cord are termed "projection fibers." They form the pathways by which motor impulses are sent from the cortical centers to the cells in pons, medulla, and anterior horns of the cord, and by which sensory impressions are brought from certain groups of cells in the medulla and base of the brain to the cerebral cortex. Other tracts connect different centers with each other either in the same or opposite side of the brain. These are known as association fibers or tracts.

The most important tracts are the motor and sensory. The first consists of two neurons, the *upper* or *central* and the *lower* or *peripheral*. The cell bodies of the former are in the ascending frontal or precentral convolution (p. 995); from these the axons converge to the internal capsule, where they occupy the posterior limb. They pass from here through the crus, pons, and medulla, in the lower part of which most of them decussate and cross to the opposite side, passing down the cord in the posterior portion of the lateral column of the spinal cord (crossed pyramidal tracts) (Fig. 63). The small portion which do not decussate pass down in the anterior columns (direct pyramidal tracts) (Fig. 63). The terminals of these fibers surround the cells either in pons and medulla, which constitute the nuclei of the cranial motor nerves or those in

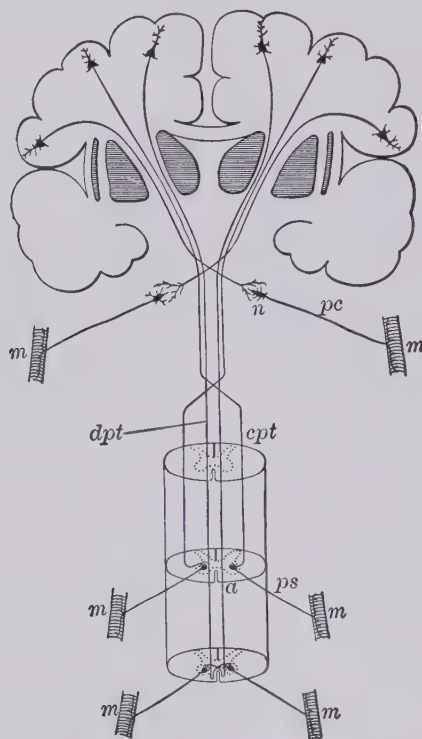

Fig. 63.—Diagram of the direct or voluntary motor tract, showing the center of the motor impulses from the cerebral cortex of the voluntary muscles (Van Gehuchten): *m*, Muscles; *n*, cells of nuclei of motor cranial nerves in pons and medulla; *a*, motor cells in anterior horns of spinal cord; *dpt*, direct pyramidal tract; *cpt*, crossed pyramidal tract; *pc*, peripheral cranial nerve; *ps*, peripheral spinal nerve.

the anterior horns of the spinal cord. These cells are the beginning of the peripheral neuron and their axons form the motor cranial and the motor portion of the spinal peripheral nerves (Fig. 63).

In connection with the motor tracts the *extrapyramidal tracts* are of importance; their exact course is not definitely known. According to Mills, they probably begin in the cortex anterior to the motor area (midfrontal region). From here the axis-cylinders go to the corpus striatum, especially the lenticular nucleus (p. 999), and then to the red nucleus and cerebellum. He believes that from here afferent fibers pass to the parietal lobe, and from there to the motor cortex. Afferent fibers also pass from the cerebellum to the red nucleus. Mills has called this the "tonectic apparatus." The functions of the central

neuron or the pyramidal tract are as follows: The cells originate motor impulses which pass through the axis-cylinders to the cells in the anterior horns of the gray matter of the cord. It also probably conveys impulses received from the extrapyramidal center and tract that control muscle tone (*infra*). The cells of the peripheral neuron receive the motor impulses from the central neuron and send them to the muscles through the peripheral motor nerves (cranial and spinal). They also control the nutrition of the muscles (trophic centers) and act as reflex centers, that is, they act as the center of a reflex arc, receiving sensory impulses from the sensory nerves and sending out motor impulses through the motor nerves (p. 1005).

The extrapyramidal tracts are thought to influence muscle tone and possibly control it. Lesions in its course cause increased tone, as shown by spasticity and tremor (p. 999). Lesions which partly destroy the pyramidal tract, owing to the fact that tonic innervation will be irregular and aberrant in its manifestation, also cause spasticity or hypertonicity, and usually increase of the tendon or deep reflexes, as these depend upon muscle tone for their presence. If, however, the pyramidal tract is completely destroyed, as when the spinal cord is divided, there is hypotonicity and flaccidity of the muscles with loss of the tendon jerks. This is due to the inability of the tonic impulses to reach the muscles.

Owing to these facts certain symptoms are characteristic of a destructive lesion partly destroying the upper motor neuron or pyramidal tract, and of a lesion interfering with the functions of the peripheral neuron. They are shown in the following table:

TABLE SHOWING SYMPTOMS DUE TO CENTRAL NEURON DESTRUCTIVE LESION AND THOSE DUE TO PERIPHERAL NEURON LESION

	<i>Lesion of upper neuron.</i>	<i>Lesion of peripheral neuron.</i>
Muscle tone.	Increased more or less. Complete destruction causes flaccidity.	Diminished or lost. Flaccid paralysis.
Reflexes.	Tendon jerks or deep reflexes usually increased. Babinski reflex present.	Diminished or lost (both tendon and skin (p. 1006). Babinski reflex absent.
Nutrition of muscles.	Good. Sometimes slight atrophy from disuse, and if the lesion occurred in childhood, lack of growth of the entire limb.	Muscles more or less wasted.
Electric reactions.	Same as the normal muscle.	Changed. Either a diminished response or the reaction of degeneration.

The *sensory tracts* comprise several different pathways conducting different forms of sensation. The cells of the first neuron are situated in either the posterior root ganglia or those of the sensory cranial nerves, as the case may be. From each cell there arises a long dendrite which goes to the periphery and ends as an end-organ in either the skin, mucous membranes, muscles, or joints. If a spinal nerve, the axis-cylinder enters the spinal cord, where it divides into a long ascending and a short descending branch. Many of the former go to form the *posterior columns* (Goll and Burdach) (Fig. 64) and end in the nucleus gracilis and nucleus cuneatus respectively. The cells of these nuclei are the beginning of another neuron the axis-cylinders of which form the lemniscus or fillet. Here the fibers decussate and pass to the optic thalamus of the opposite side, in the cells of which another neuron begins, whose axis-cylinders pass through the posterior part of the posterior limb of the internal capsule (Fig. 71), and hence to the parietal region of the cortex. In a

similar way cranial sensory nerves enter the pons and medulla and join the fibers from the spinal cord.

Sensations from the muscles are largely and tactile sensations partly conducted by this path (Fig. 64). While there must be other pathways for tactile impressions, they are not positively known.

Others of these fibers enter the gray matter of the cord by the posterior horns, in the cells of which a new neuron begins, whose axis-cylinders cross to the other side through the anterior commissure. They then pass up in the anterolateral columns through the pons, and by way of the superior cerebellar

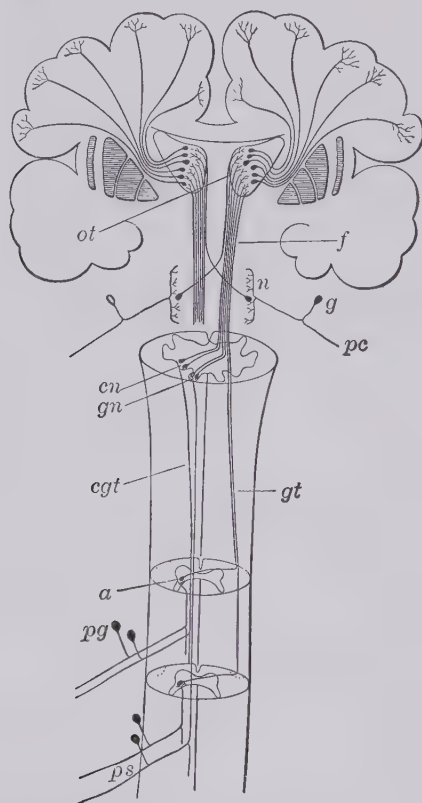

Fig. 64.—The direct sensory tract: *ps*, Peripheral spinal nerves; *pg*, ganglion on posterior roots of spinal nerves; *gt*, Gower's tract; *cgt*, columns of Goll and Burdach; *cn*, nucleus cuneatus; *gn*, nucleus gracilis; *a*, cells in posterior horn; *pc*, peripheral cranial nerve; *g*, ganglion on cranial sensory nerve; *n*, cells of cranial sensory nerves in medulla; *f*, fillet; *ot*, optic thalamus.

peduncles reach the cerebellum (Fig. 64). This is known as *Gower's tract* (Fig. 62). It has been believed that its function is to conduct pain and temperature sensations (heat and cold), but many believe that the tractus spinothalamicus and spinotectalis, which lies next to it, performs that function (Fig. 62). Still other fibers go to the cells of the posterior vesicular column of Clarke, the axis-cylinders of which form the *direct cerebellar tract* (Fig. 65), which pass up in the lateral column and through the inferior cerebellar peduncles to the cerebellum. They also conduct sensations from the muscles.

The peripheral nerve-fibers which conduct *sensations of pressure* from the skin, muscles, tendons, fasciæ, and periosteum run in the motor nerves, and

this must be remembered in testing for absence of tactile sensibility, and substances used that make the least pressure possible.

To summarize: Sensations of *touch* are conducted in the posterior columns and others not definitely known. Some pass up on the same side of the cord until they reach the pons, when they cross to the other side; others possibly cross to the other side in the cord. Sensations of *pain, heat, and cold* are conducted by the tractus spinothalamicus and spinotectalis and possibly by Gower's tract. They pass to the other side shortly after entering the cord. *Muscle sensations* are conducted by the posterior columns and direct cerebellar tracts, the fibers of which do not decussate.

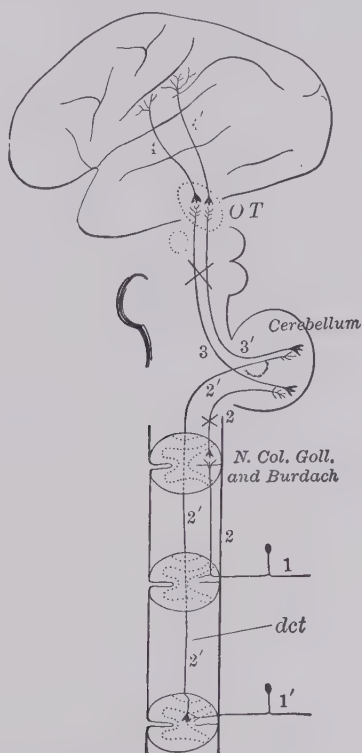

Fig. 65.—Indirect sensory tracts (Van Gehuchten): *dct*, Direct cerebellar tract. The numbers represent the different series of neurons.

The so-called *vegetative nervous system* is of great importance. It is a system of efferent fibers which supply those organs whose action is not under control of the will, *i. e.*, those containing involuntary and smooth muscle-fibers, as the viscera, blood-vessels, musculature of the skin and iris; certain organs containing striated muscle, as the heart, esophagus, genito-urinary, and the various glands. It is composed of the *sympathetic nervous system* and some cranial nerves—viz., pneumogastric, oculomotor, chorda tympani; and some spinal nerves arising from the lower sacral segments, which are known as the *autonomic system* (Fig. 66). As the sympathetic system is in close relation with the spinal nerves and cord, it can readily be seen that diseases affecting these parts may cause various vasomotor and secretory symptoms.

In addition to the knowledge of the course and functions of the tracts

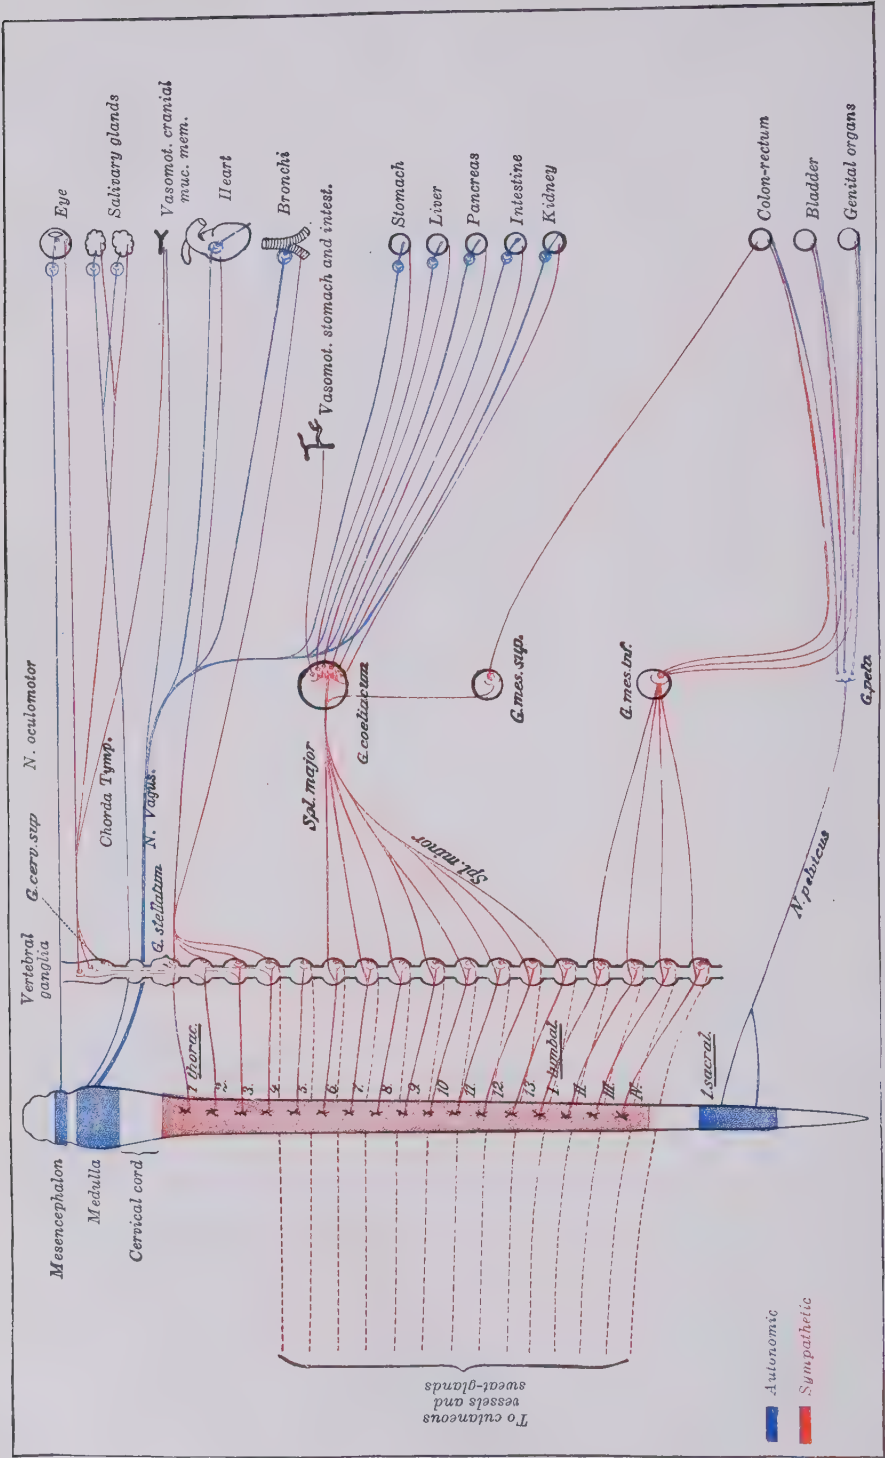

Fig. 66.—Diagram of vegetative nervous system. (From "Pharmacology," by Meyer, Gottlieb, and Halsey, J. B. Lippincott Co., Publishers.)

just described, which enables us to determine the location of lesions in the cord (p. 1005), the function and location of many centers are known, a know-

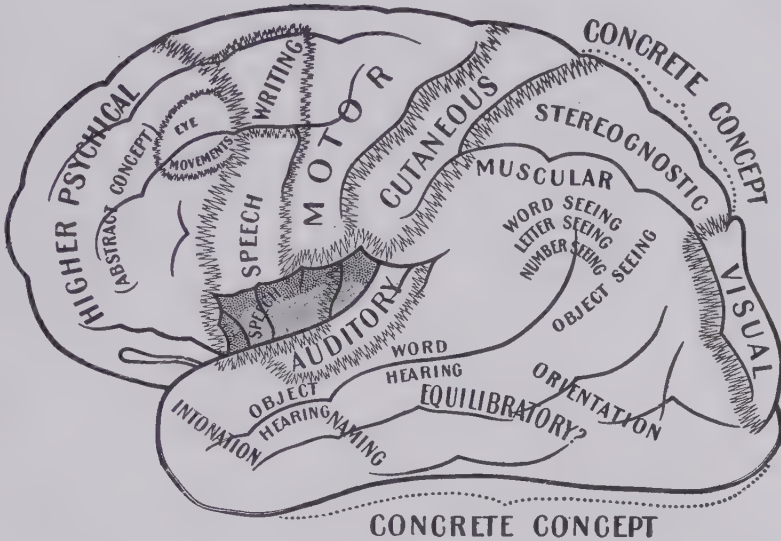

Fig. 67.—Side view of human brain, showing localization of functions (Charles K. Mills).

ledge of which often enables us by a study of the symptoms to determine which part of the brain is affected (Figs. 67, 68).

CEREBRAL LOCALIZATION

In applying this knowledge it must be borne in mind that symptoms may be due either to irritation or destruction of these parts (p. 1012), and that similar symptoms referable to neighboring centers and tracts may be due to pressure upon them by the lesion. This is especially the case with tumors. Such lesions, also, if they cause much increase in the size of the brain may distort it so that nerves are pulled upon or pressure made on parts some distance from the lesion. This is especially the case with the sixth nerve.

Frontal Lobes.—That part of the frontal lobe just in front of the motor region (prefrontal region) (Fig. 67) is the seat of the higher mental functions, as memory, judgment, reasoning, attention, etc. Many believe that in right-handed people the left lobe is the active one, and *vice versa*. In front of this area (midfrontal region) Mills has placed his center for muscle-tone. Lesions in this area cause a symptom known as either *tonic perseveration* or *tonic innervation*. It is manifested by inability to immediately let go of an object after it is grasped, in other words, to relax innervation in a muscle group or groups. The symptom occurs on the side opposite the lesion. It is usually associated with some degree of motor paralysis and must not be confounded with either myotonia (p. 1186), clonic perseveration, or intentional perseveration (p. 1004). Lesions in this region on the left side have caused apraxia (p. 1004). In the third frontal on the left side is situated the center for motor speech, memories, and probably in the second frontal that for the muscular movements essential for writing (see Aphasia).

Motor Region.—The centers which originate voluntary motor impulses are in the entire ascending frontal or precentral convolution (Figs. 67, 69), partly

in the second frontal, and in the paracentral lobule. In the latter region and the upper part of the ascending frontal the centers for leg movements are located. Those for movements of the lips, tongue, larynx, etc., are in the lower part of the convolution, while between the two are the centers for the arm, hand, and shoulder. The symptoms occur on the side opposite the lesion. These may be either increased or diminished function, or both combined, as the lesion is either irritative or destructive, or both.

Symptoms of irritation usually occur when the lesion involves the meninges and hence irritates the cortical cells. They are known as Jacksonian epilepsy. This consists of periodic attacks of clonic spasm either first occurring in or limited to the muscles supplied by the particular part of the motor area irritated. In this connection it must be remembered that individual muscles are not represented in the cortex, but that groups of muscles representing certain movements are. Consciousness is usually retained, but in some cases after the localized spasm is present for an appreciable time a general convulsion with

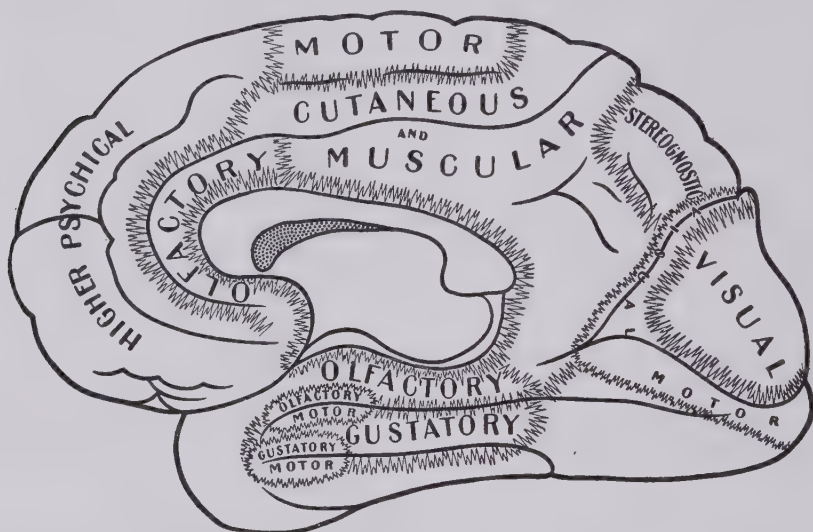

Fig. 68.—View of the mesial surface of human brain, showing localization of functions (Charles K. Mills).

loss of consciousness may develop (p. 1135). Irritation of sensory cells also causes peculiar attacks (p. 997, 998). If the nerve-fibers are irritated (subcortical) by an acute lesion there may be tonic spasm for a time, which soon passes off (p. 1094).

A destructive lesion causes impairment of function, indicated by more or less motor weakness. As the lesion is in the central neuron the characteristic symptoms are as described on p. 991. Such symptoms confined to either one limb (monoplegia) or the muscles of the face, tongue, and larynx, indicate a lesion in or near the cortex, as only here is there space enough for one center to be involved without involving the others (Figs. 69, 70). A lesion much below the cortex or in the internal capsule will cause weakness of the opposite arm and leg and lower part of the face (hemiplegia). Therefore, paralysis occurring first, to be followed some time later by Jacksonian attacks, indicates a subcortical lesion which has grown toward the surface; the opposite indicates a lesion either involving the meninges or infiltrating the cortex as a glioma. An acute lesion, as an apoplexy, causes paralysis of all the muscles on the opposite side,

but it has been shown that muscles which habitually act together, as those of respiration, swallowing, speech, closing the eyes, and facial expression, may be innervated from either side of the brain, and if one side is disabled the other side will take up the work. Muscles which control the functions mentioned, therefore, sooner or later regain their power. If, however, the association fibers are cut off or a similar lesion occurs on the other side, function does not return (pseudobulbar palsy, p. 1066).

Postcentral Convolution.—In this, also known as the ascending parietal convolution, are probably located the centers for *cutaneous sensation* (Fig. 67).

Parietal Lobes.—In the upper part is situated the center for the *stereognostic sense*. By this is meant the ability to recognize an object, without seeing it, by its peculiar shape, weight, hardness, etc. (see p. 1004).

In the lower part is an area for memories of *muscular movements*. A lesion here causes irregularity of such movements, (ataxia) and loss of the sense of position. The former is indicated by inability to make fine movements, such

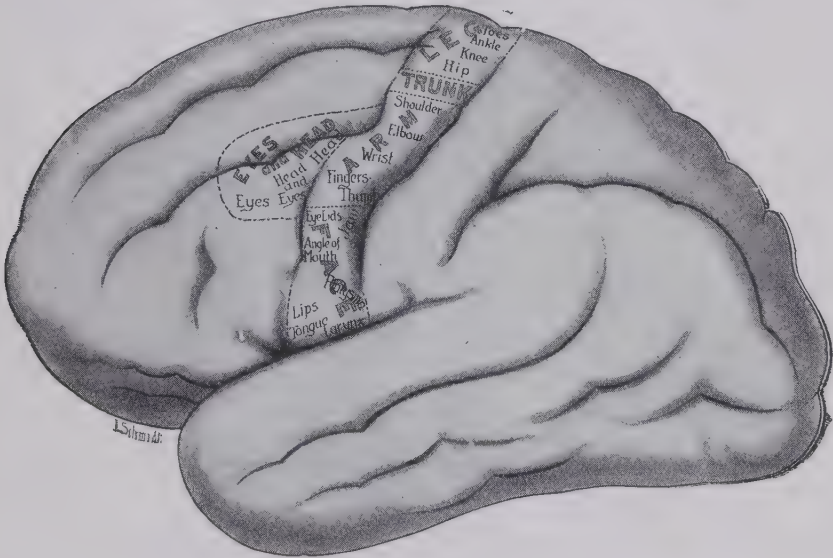

Fig. 69.—The subdivisions of the motor cortex (Mills and Frazier).

as touching the end of the nose with the finger (finger-to-nose test), the eyes being closed, or to place the heel on the opposite knee (heel-to-knee test), smoothly and regularly. When attempted coarse irregular tremors result (see Asynergy, p. 1000). By the latter is meant inability to recognize the position of all or part of a limb with the eyes closed. On the left side is located the center for memories of written and printed words (see Aphasia). Lesions on the left side have also caused apraxia (p. 1004).

Occipital Lobes.—These are important as the secondary visual centers, which are located in the cuneus, about the calcarine fissure (Figs. 67, 68).

Irritative lesions may cause visual hallucinations, as flashes of light. Such phenomena may also occur in migraine (p. 1138), but if due to an organic lesion, such as a tumor, impairment of function will sooner or later occur, which is manifested by lateral homonymous hemianopsia (p. 1029).

Temporal Lobes.—Destruction of one lobe causes some slight impairment of hearing in the opposite ear. In the first temporal convolution of the left side

is situated the center for auditory word memories. The second temporal of this side may be the so-called naming center (Fig. 67) (see Aphasia).

In the uncinate gyrus are located the centers for *smell* and *taste*. Irritative lesions here cause hallucinations of these senses (p. 1027). Destructive lesions cause impairment or loss. Lesions here may also cause attacks consisting of taste auræ, chewing movements, and a dreamy or stuporous state. Hughlings Jackson termed these "uncinate fits." They are epileptiform. The center which has to do with vertigo may also be in this lobe (p. 1041).

Centrum Ovale.—Destructive lesions may cause either motor or sensory symptoms. If near the cortex, paralysis of either the monoplegic or the hemi-

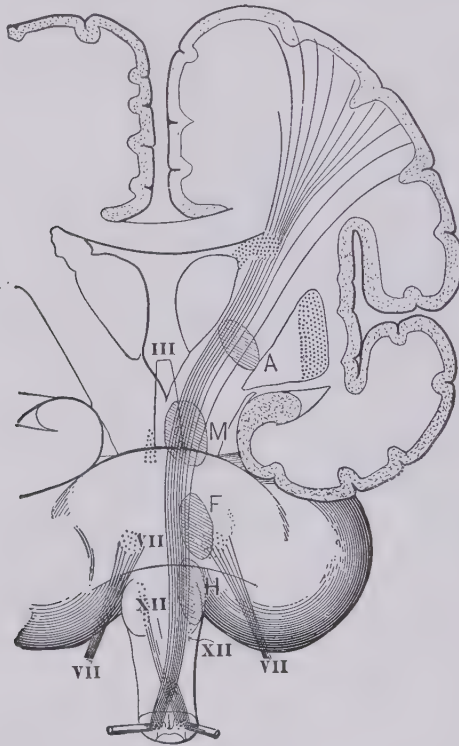

Fig. 70.—Showing the mechanism of alternate hemiplegias. A lesion at *A* causes complete hemiplegia by destroying the motor tract. One at *M* causes paralysis of the third cranial nerve (motor oculi) by destroying its nucleus or root on the same side, and paralysis of the arm and leg on opposite side. A lesion at *F* causes facial palsy on same side; hemiplegia on opposite side. In a lesion at *H* the hypoglossus would be affected on one side, with hemiplegia on the other. (Potts, "Nervous and Mental Diseases," modified from Edinger.)

plegic type (p. 996) occurs (Fig. 70). If near the internal capsule, the symptoms resemble those of a lesion there.

Corpus Callosum.—This contains the association fibers which connect the two sides of the brain. A lesion located there causes paralysis of an irregular type (see p. 1109). Apraxia of the left hand and arm has been observed.

Internal Capsule.—Through its posterior limb pass the motor fibers on their way from the cortex to the spinal cord. In the posterior part of the posterior limb are sensory fibers (Fig. 71). Destructive lesions cause hemiplegia in the opposite side, and if the sensory fibers are involved, loss of sensation on that side (hemianesthesia) (see p. 1159).

Crus Cerebri.—As the third cranial nerve passes through the crus near the pyramidal tract, a symptom group characteristic of a lesion here is hemiplegia of the side opposite the lesion and a third nerve palsy (p. 1032) on the same side (syndrome of Weber). Hemianesthesia will occur if the tegmentum is involved, and interference with the functions of the red nucleus causes either tremor or athetoid movements (p. 1102). As the optic tract crosses the crus it may also suffer, and if so, lateral homonymous hemianopsia will occur (p. 1029).

Corpus Striatum.—This is part of the extrapyramidal tract system (p. 990). and evidently exercises a controlling or inhibitory influence upon muscle tone. Lesions of the *lenticular nucleus* cause spasticity and tremor without motor paralysis and the Babinski reflex (pp. 1103, 1109). Causeless emotionalism may also occur, and Mills believes that if the emotions are painful there is a lesion of the *caudate nucleus*. Other symptoms which may be present are due to disorder of the vasomotor and secretory systems, which causes disturbances of pulse, respiration, temperature, and glandular activities. (See also Marie's *Theory of Aphasia*, p. 1004.)

Optic Thalamus.—This is part of the sensory tracts (p. 991) and is also connected with special sense paths. Together with the anterior corpora quadri-

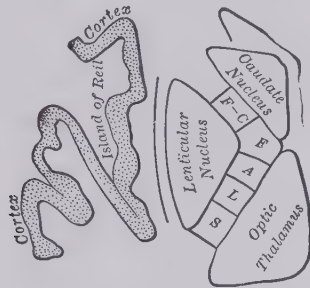

Fig. 71.—Diagram of horizontal section through the basal ganglia and internal capsule (left side), showing the position of the chief tracts in the internal capsule. The region of the capsule marked by the letters *L A F* is occupied by motor fibers: *L* corresponds to the leg fibers, *A* to the arm fibers, *F* to the face fibers (including fibers to face muscles and tongue). The region *F-C* contains the frontocerebellar tract (intellectual tract). The region marked *S* contains the general sensory tract from the opposite side and the fibers from the optic and olfactory nerves of the opposite side, sometimes called the "sensory crossway." (Potts, "Nervous and Mental Diseases.")

gemina and external geniculate bodies, the pulvinar forms part of the primary optic centers (p. 1029). Pure thalamic lesions have caused hemianesthesia, pains, hemiataxia, and choreiform movements involving the affected side, paralysis of the facial muscles when used to express the emotions, with preservation of voluntary motion, causeless laughter, and crying. Hemianopsia of the lateral homonymous type may be present (p. 1029).

Corpora Quadrigemina.—The anterior tubercles form part of the primary optic centers (p. 1029). The posterior tubercles with the internal geniculate bodies are connected with the auditory nerves and cerebellum. Lesions of this part cause diminution of hearing and inco-ordination of the cerebellar type (see p. 1109).

Pons.—The most prominent symptom indicating a lesion here is *crossed or alternating paralysis*. By this is meant weakness of the arm and leg on the side opposite the lesion, with paralysis of cranial nerves on the same side (Fig. 70). The cranial nerves which may be so affected are the facial, the paralysis being of the peripheral type (p. 1039), sixth, eighth, and fifth, both motor and sensory divisions. When either the sixth nucleus or the posterior longitudinal bundle is involved there is loss of lateral conjugate movement of the eyes to the side of the lesion (p. 1033). This distinguishes sixth nerve palsy due to this cause from

involvement of the sixth nerve trunk at the base of the brain. In the latter case the palsy will be limited to the sixth nerve of the affected side, and loss of lateral associated movement will not occur. If the sensory tracts are involved, hemianesthesia occurs. If the lesion is below the upper third, this is crossed. When the middle cerebellar peduncles are involved, inco-ordination of the cerebellar type occurs. Hyperpyrexia may occur in acute lesions.

Medulla.—This contains the nuclei of the ninth, tenth, eleventh and twelfth cranial nerves, and motor sensory tracts. A lesion here causes bulbar symptoms (p. 1065), which develop either suddenly or gradually as the disease is acute or chronic. There may be weakness of the arm and leg, which may be on either the same or opposite side, depending whether it is above or below the decussation of the pyramids. Pressure on the fourth ventricle may cause polyuria and glycosuria.

Cerebellum.—The principal function of this part of the brain is the controlling of *synergy* or *synergia*. By this is meant "the power or faculty by which movements, more or less complex, but functionally definite, are associated in a special act or acts. It is motor association being carried out in movements of different parts of the same limb or in synchronous movements of the limbs and trunk" (Mills and Weisenburg). Every co-ordinate movement of the body and limbs is dependent upon the synchronous action of a number of muscles, the contraction of which must be accurately timed. If this is not so, the movement is performed in an irregular or inco-ordinate manner, which is termed *asynergy* or *asynergia*. For this purpose sensations travel to the cerebellum from the muscles, joints, tendons, and possibly to some extent from the skin by way of the peripheral nerves, posterior columns, and direct cerebellar tracts (p. 993).

Lesions in these parts will also cause inco-ordination, but of a different type (pp. 1022, 1128).

It is believed that the upper part of the vermis controls movements of the shoulder-girdle and upper part of the trunk, and the lower part controls those of the pelvic girdle and lower part of the trunk.

Base of the Brain.—Lesions here cause different symptoms according to their location and the structures pressed upon or involved. More or less paralysis of cranial nerves occurs, the pituitary body may be involved, or the crura or cerebellum suffer from pressure. (See section on Cranial Nerves and pp. 1109, 1110.)

Centers Controlling Speech and Allied Functions.—Those controlling written and spoken speech are the third frontal, possibly the second frontal, the first and second temporal, and the angular gyrus, all of the left side in right-handed people. Interference with the function of any or all of these centers causes what is known as aphasia. Disturbance of allied functions and the centers controlling them will also be discussed during its description.

APHASIA

Definition.—By aphasia is meant either a partial or complete loss of the power of either expression or comprehension (or of both combined) of any of the usual signs of language, not dependent upon lesions of the peripheral nerves or organs, but upon lesions of the cortical centers concerned in speech, or the tracts connecting them.

Etiology.—Aphasia, in most cases, and practically always, if permanent, is due to a destructive lesion of either the centers or tracts above mentioned.

Usually this is either caused by a cerebral hemorrhage or acute softening (*vide* apoplexy), and is, therefore, frequently associated with hemiplegia. It may, however, be caused by any organic lesion, as tumor, encephalitis, or abscess. Transient aphasia may be caused by so-called functional disturbances. It may follow severe fright, anger, hemorrhage, and exhaustion; occur as a symptom of migraine, or be caused by toxemias, as uremia, gout, vegetable and mineral poisons, and infectious diseases.

The Genesis of Speech and Location of Centers.—To properly understand the development of the symptoms of aphasia, some knowledge of the evolution of language is essential. The child learns to understand language before he can utter it. Through the different senses he perceives the different characteristics and appearance of an object. These percepts are stored away in the brain, and gradually the child learns to associate the name that he hears applied to a certain object with that object. The memory of the sound of this word is stored in the center for word memories, which is in the first temporal convolution of the left side in right-handed persons, and *vice versa* in those who are left handed. Whenever this word is used, the various characteristics of the object are at once brought into consciousness by a stimulation of the different centers where the memories of these characteristics are stored. Eventually the child learns to make the various co-ordinated muscular movements necessary to pronounce the word. The memory of necessary movements of the lips (tongue, larynx) required to pronounce a word are also stored in a center, which in right-handed persons is the foot of the third left frontal convolution (Broca's convolution psychomotor center, glossokinesthetic center of Bastian). The exciting of one of these centers excites the others; thus, if we hear the ringing of a bell, a mental image of the other characteristics of the bell is formed, and the proper word designating that image comes into consciousness by stimulation of the center for word memories. If it is desired to pronounce the word, an impulse is sent from this center to Broca's convolution, which starts in motion the various movements of the organs of speech necessary to pronounce the word.

Even if a word is not audibly pronounced, mental images of words enter into thought processes, as do also the muscular movements necessary to pronounce the word. This is constantly being done in silent thinking, when the sounds of words are mentally recalled without visible movements of the muscles necessary to pronounce the word being made. This has been termed the *internal language*.

We learn to read by associating the visual appearance of certain symbols with the sound previously acquired of the respective letters and words. These so-called visual memories are also stored in the cerebral cortex, probably in the angular gyrus and its vicinity. When one reads aloud, the words are first recognized by the visual center, which calls up the corresponding sound in the auditory center, from which the motor speech center is stimulated, and the memory of the required muscle-movements necessary to articulate the word is called up. Then through the centers for these muscles in the foot of the precentral convolution (Fig. 99) the word is pronounced. When we read silently, the same process takes place by means of the internal language.

In learning to write the visual perception of the letters is associated with certain muscular movements of the fingers and arms necessary to make them. These memories are kept in the second frontal convolution of the left side (in right-handed people). This center has been termed the writing or cheiro-kinesthetic center. As in writing, each letter is self-dictated by means of either the spoken or internal language, the other centers involved in these

processes are first excited. Reference to Fig. 72 will show the location of the centers mentioned and their probable connections.

From the foregoing it will be seen that while each center has certain functions, these are more or less dependent upon each other. It has been observed that a lesion developing suddenly in one center causes more or less interference in the function of the others; this is especially the case soon after the onset; later, permanent symptoms more closely related to the affected center remain. These early symptoms have been explained by von Monakow¹ to be due to a lowering of functional activity in a more or less distant part of the speech mechanism, due to the upsetting of the balance between the several parts of this mechanism produced by the destruction of one of the integral parts by the lesion. He termed this *diachsisis*.

Classification.—Based on whether the receptive or emissive function is affected, aphasia has been divided into sensory and motor. Sensory aphasia

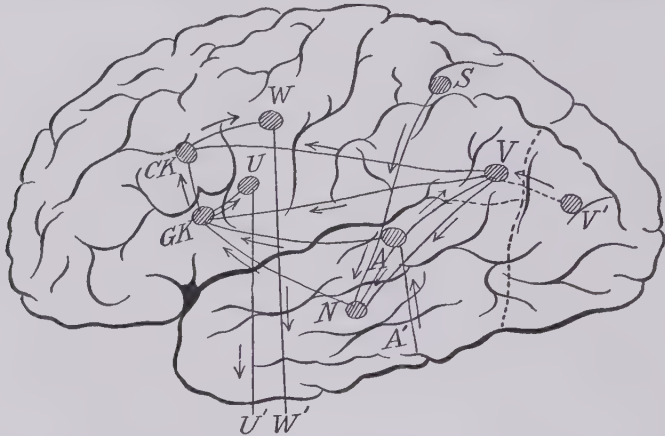

Fig. 72.—Diagram showing probable pathways of nervous impulses concerned in speech and writing:² A, Center for auditory word memories in first temporal convolution; V, center for visual word memories in angular gyrus; G K, glossokinesthetic center (Bastian), or psychomotor center, at foot of third temporal convolution; U, centers for muscles involved in articulation at foot of central convolution; C K, probable centers for memory of muscular movements involved in writing (cheirokinesthetic center of Bastian); W, centers for controlling muscles of arm and hand in central convolutions; A-A', tract from cortex of temporal lobe (auditory centers) to center for word memories; V-V', tract from cuneus to center for visual memories; W-W', tract from arm and hand centers to cells in anterior horns of cord and peripheral nerves controlling these muscles (pyramidal tract); U-U', tract from centers for muscles of articulation to centers in pons and medulla and nerves controlling those muscles (pyramidal tract). In speaking, impulses travel from A-G K-U-U'; in reading aloud, from V-A-G K-U-U'; in silent reading, from V-A-G K; in writing spontaneously, V-A-G K-W-W'; in writing from dictation, A-V-G K-C K-W-W'; in copying, V-C K-W-W'; N, naming center (?); S, center for stereognostic sense in parietal lobe (Potts).

(Wernicke) is present when, the peripheral apparatus being intact, the patient is either unable to understand the language which he has been accustomed to use or is unable to recognize the meaning of the symbols, either written or printed, with which he was once familiar. In other words, he hears, but the once familiar sounds are to the patient as a foreign language; he sees them, but they look to him as those of a foreign language, and he cannot read understandingly. The former is known as *word-deafness* or *auditory aphasia*, the latter as *word-blindness*, *alexia*, or *visual aphasia*.

Closely related to this is one termed *optic aphasia*, in which the patient when shown an object with which he was once familiar is unable to call up its

¹ *Neurol. Centralblatt*, November, 1906, p. 1026.

² In right-handed persons these centers and tracts are situated in the left side of the brain; in left-handed persons they are situated in the right side of the brain.

name. He is, however, able to pronounce the name when he hears it. This symptom is termed *anomia*, and is probably due to a lesion in the center N (Fig. 72) or one of the tracts, SN, VN, or AN, for the reason that naming an object depends upon the recognition of its visual, auditory, or tactile characteristics. Another is the form known as mind or psychic blindness, in which, in addition to loss of the power of reading, there also is inability to distinguish between objects and persons and to know the proper use of things. This last is known as apraxia (p. 1004). Mind-blindness, therefore, is word-blindness plus apraxia.

Motor aphasia (Broca's), or aphemia, is present when the patient, the peripheral speech apparatus (lips, tongue, larynx) being intact, is unable either partly or completely to give utterance to his thoughts. Loss of the power of writing, not dependent upon paralysis of the muscles, is termed *agraphia*. It is usually associated either with motor aphasia or word-blindness.

When a patient is able to speak and read several languages he may, in some cases, only be aphasic for one of them. He may be able to read letters when he cannot words; printed symbols, when he cannot written ones; figures and not letters, and *vice versâ*.

Related to speech is gesture. Loss of the power of understanding or employing gesture is known as *amimia*. Sometimes, either with or without defects of ordinary speech, there is loss of the power in those who once possessed it to either produce or comprehend musical sounds. This is termed *amusia*.

In some cases the patient may be able to speak, but he skips words and uses wrong ones. This is termed *paraphasia* or *conduction aphasia*, being due to a lesion in the tract A-GK, Fig. 72. Aphasia is also divided into cortical and subcortical; the symptoms of each follow:¹

Cortical Auditory Aphasia.—The lesion is at A. There would be loss of the power of understanding spoken words; words could not be repeated or written from dictation. Stimulation of this center being necessary to activate GK, spoken speech would be defective, wrong words used, and paraphasia result. The internal language also being interfered with, the power of reading and writing is defective (tracts V-A-GK, Fig. 72).

Subcortical Auditory Aphasia.—The lesion is in the tract A-A', the center A being intact. The patient is unable to understand spoken words. Reading and writing from dictation are not well performed. Some paraphasia is present, as the patient, when he pronounces a word, is unable by hearing to recognize its correctness. The internal language is intact and word memories can be recalled (A); hence silent reading and writing are not interfered with (tract V-A-GK, Fig. 72).

Cortical Visual Aphasia.—Lesion in center V. There is inability to read (alexia) aloud or silently, to write spontaneously, from dictation, or to copy understandingly. Speech is not interfered with.

Subcortical Visual Aphasia.—Lesion in tract V'-V, loss of ability to read and copy understandingly. Through the tract V'-CK he can copy mechanically. The center V being intact, visual memories can be recalled; hence he can write imperfectly, as one with his eyes closed.

Cortical Motor Aphasia.—Lesion in center GK. Spontaneous speech, repeating words, and reading aloud are either completely or partially lost. Owing to the loss of the internal language, the power of silent reading and writing is also lost (V-A-GK, Fig. 72). Language is understood.

¹ As a matter of fact, lesions cannot be as definitely localized as here described. The principle of diaschisis (p. 1002) must be borne in mind in studying aphasics. The subdivision here given seems valuable, however, for purposes of study.

Subcortical Motor Aphasia.—Lesion in tract GK-U. Spontaneous speech, repeating words, and reading aloud are lost. The internal language being intact (A and GK), silent reading and writing are not interfered with. Language is understood.

Two or more of these centers or their connecting tracts may be diseased, and then a combined motor and sensory aphasia will result. See also p. 1002.

Marie's Theory of Aphasia.—The above is a presentation of the commonly accepted views upon this subject. In 1906 Marie¹ denied the truth of these views and advanced those entirely different. While these in their entirety have not been generally accepted, a brief mention of them should be made. He denies that the third frontal convolution has anything to do with speech. He believes that the only speech center is the zone of Wernicke, which consists of the supramarginal and angular gyri and the posterior part of the first two temporal convolutions. This region is not one, however, in which sensory images or memories are stored up, but is a purely intellectual center. A lesion in this region causes the symptoms described above, under Sensory Aphasia, and termed by him Wernicke's aphasia. He denies the existence of either pure word-deafness or pure word-blindness, and of cortical and subcortical varieties. What is generally termed motor aphasia is the above form plus anarthria. Anarthria occurs when the lesion involves the lenticular zone, which is an area comprised between a line passing in a transverse direction from the anterior fissure of the island of Reil to a corresponding point in the lateral ventricle, and a line in a similar direction from the posterior fissure of the island of Reil to a corresponding point of the lateral ventricle. Within this are situated the caudate and lenticular nuclei, the external capsule, the cortex of the island of Reil, and the internal capsule. The anarthria or aphemia of Marie is characterized by loss of speech, with preservation of the understanding of words, of reading and writing. It is an interference with the co-ordination of movements required for phonation, without motor paralysis. As has been previously stated, what is commonly termed motor or Broca's aphasia is this, plus a lesion of Wernicke's zone, which produces the symptoms usually known as sensory aphasia.

Closely related to aphasia are *apraxia* and the *stereognostic sense*.

Apraxia has been divided into sensory and motor or dyspraxia.² In the former, also known as *agnosia*, there is inability to recognize a heretofore familiar object by any one of the senses, and hence there is inability to name it. Thus, if an object is not recognized by sight, there is visual apraxia, or agnosia, by hearing, auditory apraxia, or agnosia, and so on. Visual agnosia is also known as mind-blindness (p. 1003). In the latter the object is recognized, but the patient has forgotten how to use it in the proper way; thus a pencil is recognized and named, but the patient does not know how to use it. These symptoms are usually due to lesions of the left hemisphere in right-handed people. Motor apraxia has been frequently observed when the lesion was either in the first and second frontal convolutions on the left side, parietal lobe, or in the corpus callosum. Variations of this symptom are *parapraxia*, in which the patient when asked to make certain movements, makes others; the *intentional perseveration of Liepmann*, in which he performs the first act requested correctly, but when asked to perform a different one, repeats the first; and the *clonic perseveration of Liepmann*, in which he continues to perform an action for some time after being told to stop. *Stereognostic sense* is the name given to memories preserved in the cerebral cortex (parietal lobe, Fig. 67) of the char-

² Wilson, *Brain*, 1908, p. 164.

acteristics of objects by which we are enabled to recognize them without seeing them. Thus, when a person who is blindfolded recognizes that an object placed in his hand is a dollar, he does so by his memory of the peculiar shape, hardness, weight, etc., of previous dollars. The sense depends upon a correlation of tactile, pressure, muscle, and temperature perceptions, and its interpretation by the higher psychic centers (parietal lobe). Loss or diminution of any one of the above forms of sensation causes loss of this sense, which has been termed *astereognosis*, or tactile agnosia. Lately it has been proposed to restrict this term to inability to recognize the shape and consistency of objects, while inability to recognize them has been termed *asymbolia*.

Diagnosis of Aphasia.—This depends upon the presence of the symptoms detailed above, the peripheral apparatus being intact. This will serve to differentiate it from speech defects due to paralysis of the muscles concerned in speech, such as occurs in bulbar and pseudobulbar palsy. Motor aphasia is more common than sensory. The condition is usually associated with a right-sided hemiplegia, due to a lesion (thrombosis) in the middle cerebral artery, but may be due to any destructive lesion, as tumor, encephalitis, etc.

Prognosis.—The younger the patient, the better the outlook for some return of speech. Improvement may continue for a considerable time, and eventually fair power return. Many, however, never improve.

Treatment.—This consists of re-education by the same methods as in teaching children to speak, read, and write.

SPINAL LOCALIZATION

This depends upon a knowledge of the location and function of the tracts described on pp. 990-992, and of the location of the reflex centers and cells in the anterior horns which control certain muscles (p. 1008). A knowledge of the reflexes is very important.

These depend upon the integrity of what is known as a reflex arc. This consists of a sensory nerve, certain cells in the anterior horns, and a motor nerve (Fig. 73). If any part of this arc is functionally interfered with, the corresponding reflex is either diminished or absent. Muscle tone also has considerable to do with reflex action, especially the so-called deep reflexes, as when it is excessive they are increased, and diminished when it is decreased (p. 991). In this connection it should be remembered

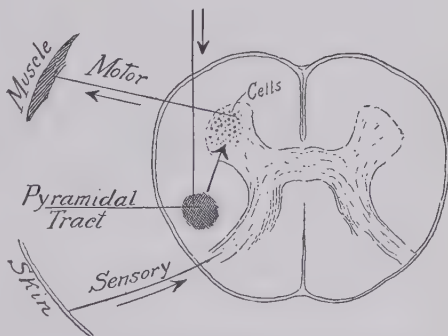

Fig. 73.—Diagram of a reflex arc and course of inhibitory impulses through the pyramidal tract.

that sensory impulses from the muscles are essential to muscle tone, and when they are not received by the brain, as when there is a lesion of the posterior or sensory nerve-roots, muscle tone is diminished. This is especially seen in *tabes dorsalis*. Reflexes are divided into *skin* or *superficial*, *tendon* and *muscle*, or *deep* and *visceral*.

SKIN REFLEXES

These are caused by pinching or otherwise irritating the skin, when involuntary muscular contractions occur. This is often an effort to escape from the irritation, and is then known as a "defense reaction." The more important ones are:

The *plantar reflex*, which is brought out by irritating the sole of the foot. Normally under these circumstances the leg is drawn more or less actively toward the body and the toes plantar flexed. In lesions involving the pyramidal tract the toes, especially the great toe, are separated and dorsal flexed. This is known as the *Babinski reflex*. In children under two years of age this phenomenon is normal.

Cremaster Reflex.—The testicle is drawn up when the skin on the inside of the thigh is scratched.

Abdominal Reflex.—When the side of the abdomen is scratched there is contraction of the rectus muscle. The upper quadrants may react when the lower will not, and *vice versa* (p. 1011).

Pupillary Skin Reflex.—This is caused by pinching the skin on the side of the neck, when dilatation of the pupil will occur.

Pharyngeal Reflex.—This is shown by gagging and elevation of the soft palate when the back of the pharynx and pillars of the fauces are irritated.

DEEP OR MUSCLE AND TENDON REFLEXES

Sometimes these may be absent owing to mechanical reasons, as ankylosis of a joint or excessive spasticity of the muscles.

Knee-jerk or Patellar Tendon Reflex.—This is brought out by striking the patellar tendon while the leg hangs loosely at right angles with the thigh. By so doing a contraction of the quadriceps femoris takes place, causing more or less extension of the leg on the thigh. Either its increase, diminution, or absence are indications of disease. Very rarely it is absent in normal people. When greatly increased, *patellar clonus* may occur, meaning by this rapid clonic contractions of the quadriceps muscle either when the tendon is struck or the patella pushed downward. When absent from functional causes it may be often elicited by causing the patient to make some muscular effort, as clasping the hands or pulling on something. This is known as *reinforcement by Jendrassik's method*.

Tendo Achillis or Ankle-jerk.—If the tendo achillis is struck while the foot is slightly dorsal flexed, contraction of the soleus muscle will occur with more or less plantar flexion of the foot. If this is considerably increased, *ankle-clonus* may occur. By this is meant a rapid to-and-fro motion of the foot when it is suddenly dorsal flexed, due to clonic contractions of the soleus. True ankle-clonus practically always means disease of the pyramidal tract. *Pseudo-ankle-clonus* may occur in functional diseases, as hysteria, and in toxic and cachectic states, as uremia, septicemia, arthritis, etc.¹ It differs from the true in that contractions of both the soleus and gastrocnemius muscles occurs, and, as a rule, it is not so persistent.

Triceps Jerk.—Tapping the triceps tendon above the elbow while the forearm hangs at right angles with the upper arm causes contraction of the triceps muscle and some extension of the forearm.

Biceps Jerk.—If the biceps tendon is struck while the forearm is partially flexed on the upper arm, contraction of the biceps muscle with some flexion of the forearm will occur.

¹ *Amer. Jour. Med. Sci.*, July, 1913, p. 1.

Jaw-jerk.—This is always pathologic and is elicited by striking the chin while the mouth is partly open. If present, contraction of the masseter muscles occurs.

VISCERAL REFLEXES

Reflexes of the Eye.—By the *direct light reflex* is meant contraction of the pupil which should occur when the eye is exposed to light, to be followed by dilatation when the light is removed (p. 1029). Modifications of this are *hippus* and the *rebounding pupil*. In the former the pupil, after contracting, will dilate again, doing this alternately a number of times. It may be normal, but usually is seen in mania, meningitis, hysteria, and neurasthenics. The latter consists of contraction followed, while exposed to the same light, by dilatation.

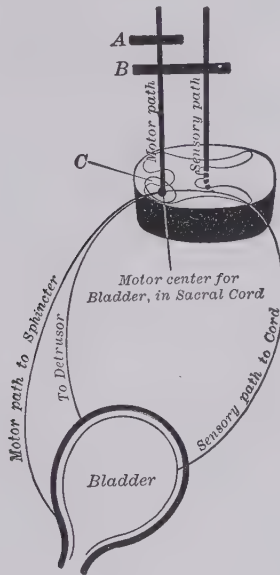

Fig. 74.—Diagram illustrating the innervation of the bladder and the effect of lesions in various parts of the spinal cord upon the function of micturition. A lesion, A, which interrupts the voluntary path to the bladder center in the sacral cord causes incontinence of urine. When a sufficient quantity of urine accumulates in the bladder there occur a reflex contraction of the detrusor and a relaxation of the sphincter. The sensory path from the cord to the brain being uninvolved the patient is conscious of the process, but cannot exercise voluntary control over it. With a lesion, B, which involves also the sensory path, the patient is unconscious of the filling and reflex emptying of the bladder. A lesion, C, which causes destruction of the sacral reflex center of the bladder causes continuous dribbling of urine, and not its automatic expulsion at intervals (Herter).

This is said to indicate retrobulbar neuritis. By the *convergence* or *ciliary reflex* is meant the pupillary contraction which should occur when looking at a near object, and dilatation when looking at a distant one. Loss of the light reflex with preservation of the convergence is known as the *Argyll Robertson pupil*. This is usually seen as a symptom of tabes dorsalis and paresis. Rarely the phenomena may be reversed. The *pupillary skin reflex* is described on p. 1006.

Reflexes of the Bladder, Rectum, and Sexual Apparatus.—The reflex arc for urination and defecation consists of the pudendal plexus and the third and fourth sacral segments of the cord. These nerves are also connected with the hypogastric plexus and sacral ganglion of the sympathetic system, and this system probably has some influence and may compensate to some extent for loss of function in the arc. When anything interferes with the action of the

inhibitory part of the mechanism (pyramidal tracts), voluntary control of urination and defecation is lost; in other words, so soon as the bladder is full, the contents are expelled automatically, just as is normally the case in the infant. If there is weakness of the muscles concerned in urination, a certain amount of residual urine is left which gradually accumulates until the bladder becomes overfull, the sphincter muscle is overcome, and dribbling of urine occurs. This is known as the *incontinence of retention*. It may occur also in retention due to mechanical causes, as enlarged prostate. When the centers in the cord are involved or the nerve-trunks, there is constant dribbling without previous retention. In this condition also the anal sphincter will be relaxed and the *anal reflex*, which consists of contraction of the sphincter when the

finger is introduced into the rectum, will be lost. When there is merely weakness of the muscles concerned in these functions, there will be difficulty in starting the stream of urine or obstinate constipation. If the sensory tracts of the cord are involved, the patient will not have the sensations peculiar to a full bladder or rectum (Fig. 74). Damage to the reflex arc governing the sexual functions causes loss of the power of erection. Loss of inhibition may cause priapism.

For the purposes of localization of lesions in the spinal cord it is assumed to be composed of thirty-one divisions called segments. Each segment contains reflex, trophic and vasomotor centers, and cells which give origin to motor peripheral nerves supplying certain muscles, and receives peripheral sensory nerve-fibers that receive sensation from certain areas of the skin, etc. Through them also pass the motor tracts conveying impulses from the brain and exercising an inhibitory influence upon the reflexes and sensory tracts conveying sensory impulses to it. The segments are named according to the peripheral

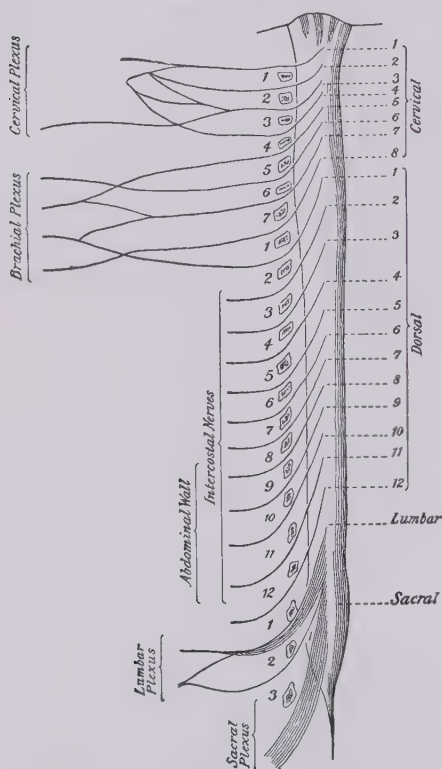

Fig. 75.—Diagram showing the groupings and plexuses of the spinal nerves (redrawn after Baker).

nerve to which they give origin. Thus, the eighth dorsal nerve arises from the eighth dorsal segment.

The most important regions are the cervical and lumbar enlargements. The former (fourth cervical to first dorsal) gives origin to the nerve-roots that form the brachial plexus, and in the latter (first lumbar to the fifth sacral) originate the nerves that supply the muscles of the legs. The spinal cord ends at the base of the first lumbar vertebra, hence the segments do not correspond in location to the vertebra whose name it bears. The intraspinal course of the nerve-roots before they emerge between the vertebra being longer, the lower their origin from the cord. This causes the roots from the lumbar and sacral regions to pass down through the spinal canal to the respective vertebra between

which they emerge as a bundle known as the *cauda equina*. To determine the relation of the segments to the spinous processes of the vertebræ, in the cervical region add one to the number of vertebra, and this will give the segment opposite. In the upper dorsal region add two, and in the lower dorsal (sixth to eleventh) add three. The lower three lumbar segments are opposite the lower part of the eleventh spinous process and the space below it. The sacral segments are under the twelfth dorsal spinous process and the space below it (Fig. 75).

The following table (Starr, modified by Mills and Dana from the experimental and clinical studies of Thorburn and others) shows the localization of function (not organs) in the different segments of the cord:

LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD

<i>Segment.</i>	<i>Muscles.</i>	<i>Reflex and Centers.</i>	<i>Sensation.</i>
First cervical.	Rectus laterales. Rectus capitis. Anticus and posticus. Sternohyoid. Sternothyroid.		
Second and third cervical.	Sternomastoid. Trapezius. Scaleni and neck. Omohyoid. Diaphragm.	<i>Hypochondrium (?)</i> . Sudden inspiration produced by sudden pressure beneath the lower border of the ribs.	Back of head to vertex and neck. (Occipitalis major, occipitalis minor, auricularis magnus, superficialis colli, and supraclavicular.)
Fourth cervical.	Diaphragm. Deltoid. Biceps. Coracobrachialis. Supinator longus. Rhomboid. Supra- and infraspinatus.	<i>Pupillary</i> (fourth cervical to second dorsal). Dilatation of the pupil produced by irritation of the neck.	Neck. Shoulder, anterior surface. Outer arm. (Supraclavicular, circumflex, external musculocutaneous, cutaneous.)
Fifth cervical.	Deltoid. Biceps. Coracobrachialis. Brachialis anticus. Supinator longus. Supinator brevis. Deep muscles of shoulder-blade. Rhomboid. Teres minor. Pectoralis (clavicular part). Serratus magnus.	<i>Scapular</i> (fifth cervical to first dorsal). Irritation of skin over the scapula produces contraction of the scapular muscles. <i>Supinator longus</i> . Tapping the tendon of the supinator longus produces flexion of forearm. <i>Biceps</i> (fifth cervical).	Back of shoulder and arm. Outer side of arm and forearm to the wrist. (Supraclavicular, circumflex, external cutaneous, internal cutaneous, posterior spinal branches.)
Sixth cervical.	Deltoid. Biceps. Brachialis anticus. Subscapular. Pectoralis (clavicular part). Serratus magnus. Triceps. Pronators. Rhomboid. Latissimus dorsi.	<i>Triceps</i> (fifth to sixth cervical). Tapping elbow tendon produces extension of forearm. <i>Posterior wrist</i> (sixth to eighth cervical). Tapping tendons causes extension of the hand.	Outer side and front of forearm. Back of hand, radial distribution. (Chiefly external cutaneous, internal cutaneous, radial.)
Seventh cervical.	Triceps (long head). Extensors of wrist and fingers. Pronators of wrist. Flexors of wrist. Subscapular. Pectoralis (costal part). Serratus magnus. Latissimus dorsi. Teres major.	<i>Anterior wrist</i> (seventh to eighth cervical). Tapping anterior tendons causes flexion of wrist. <i>Palmar</i> (seventh cervical to first dorsal). Stroking the palm causes closure of the fingers.	Radial distribution in the hand. Median distribution in the palm, thumb, index, and one-half of the middle finger. (External cutaneous, internal cutaneous, radial, median, posterior spinal branches.)
Eighth cervical.	Triceps (long head). Flexors of wrist and fingers. Intrinsic hand muscles.	Ulnar area of hand, back, and palm, inner border of forearm. (Internal cutaneous ulnar.)
First dorsal.	Extensors of thumb. Intrinsic hand muscles. Thenar and hypothenar muscles.	Chiefly inner side of forearm and arm to near the axilla. (Chiefly internal cutaneous and nerve of Wrisberg or lesser internal cutaneous.)
Second dorsal.	Inner side of arm near to and in the axilla. (Intercostohumeral.)

LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD			
<i>Segment.</i>	<i>Muscles.</i>	<i>Reflex and Centers.</i>	<i>Sensation.</i>
Second to twelfth dorsal.	Muscles of back and abdomen. Erectores spinæ.	<i>Epigastric</i> (fourth to seventh dorsal). Tickling m a m m a r y region causes retraction of the epigastrium. <i>Abdominal</i> (seventh to eleventh dorsal). Stroking side of abdomen causes retraction of belly. <i>Vasomotor centers.</i> Second dorsal to second lumbar.	Skin of the chest and abdomen, in bands running around and downward, corresponding to spinal nerves. Upper gluteal region. (Intercostals and dorsal posterior nerves.) Eleventh and twelfth dorsal testicle.
First lumbar.	None.	<i>Cremasteric</i> (first to third lumbar). Stroking inner thigh causes retraction of scrotum.	Skin over groin and front of scrotum. (Ilio-hypogastric, ilio-inginal.) Testicle.
Second lumbar.	Vastus internus.	<i>Patellar.</i> Striking patellar tendon causes extension of the leg.	Outer side and upper front of thigh. Lumbar region. (Genitocrural, external cutaneous.)
Third lumbar.	Sartorius; adductors of thigh.		Front and outer side of thigh. Inner side of leg and foot.
Fourth lumbar.	Flexors of thigh. Extensors of knee. Abductors of thigh.	<i>Gluteal</i> (fourth to fifth lumbar). Stroking buttock causes dimpling in fold of buttock.	Inner side of thigh, leg, and foot. (Internal cutaneous, long saphenous, obturator.)
Fifth lumbar.	Outward rotators. Flexors of knee. Flexors of ankle. Peronei. Extensors of toes.	<i>Achilles tendon.</i> Over-extension causes rapid flexion of ankle, called <i>ankle-clonus</i> .	Back of thigh and outer side of leg and ankle; sole; dorsum of foot. (External popliteal, external saphenous, musculocutaneous, plantar.)
First and second sacral.	Calf muscles. Glutei. Peronei. Extensors of ankle. Small muscles of foot.	<i>Plantar</i> (fifth lumbar to second sacral). Tickling sole of foot causes flexion of toes and retraction of leg.	Back of buttock and thigh, side of leg and ankle; sole; dorsum of foot.
Third, fourth, and fifth sacral.	Perineal. Muscles of bladder, rectum, and external genitals.	Genital center. Vesical center. Anal center.	Circumanal region, anus, rectum, penis, urethra, vagina, perineum. Skin of posterior surface of scrotum. (Small sciatic, pudic, inferior hemorrhoidal, inferior pudendal.)

To the foregoing table, which illustrates spinal localization, should be added another, showing what functions reside in the pons and medulla, as follows:

<i>Nuclei.</i>	
III.	{ Sphincter iris. Ciliary muscles. Levator palpebræ superioris. Rectus internus (in convergence). Rectus superior. Rectus inferior.
IV.	{ Obliquus inferior. Obliquus superior. (Upper facial group.)
V.	{ (Associated movement of levator palpebræ.) Muscles of lower jaw.
VI.	{ Rectus externus. Rectus inter. of opposite side in lateral movements.
XII.	{ (Lower facial group.) Muscles of tongue.
VII.	—Facial muscles.
IX.	{ Muscles of pharynx.
X.	{ Muscles of esophagus.
XI.	{ Muscles of larynx. (Motor cortical area, see p. 995.)

The skin areas innervated by the different segments are shown in Fig. 76. A true segmental type of anesthesia only occurs when the posterior spinal roots are involved. If the roots are irritated there may be a zone or area of

hyperesthesia or shooting pains in the course of the nerves arising from these roots—root pain (pp. 1013, 1056, 1077, 1128).

Certain groups of symptoms indicate lesions in certain regions. Thus, a lesion in the cervical segments will cause more or less paralysis of the arms, according to its location, and if transverse, motor paralysis of the central neuron type and sensory paralysis below the seat of the lesion. This is due to the fact that motor impulses will be unable to pass by way of the motor tracts through the diseased area, and sensory impulses will be unable to pass by way of the sensory tracts from the periphery to the brain. The paralyzed muscles supplied by the involved segments will show the characteristics of the peripheral neuron type (p. 991). If in the dorsal segments, there will be motor

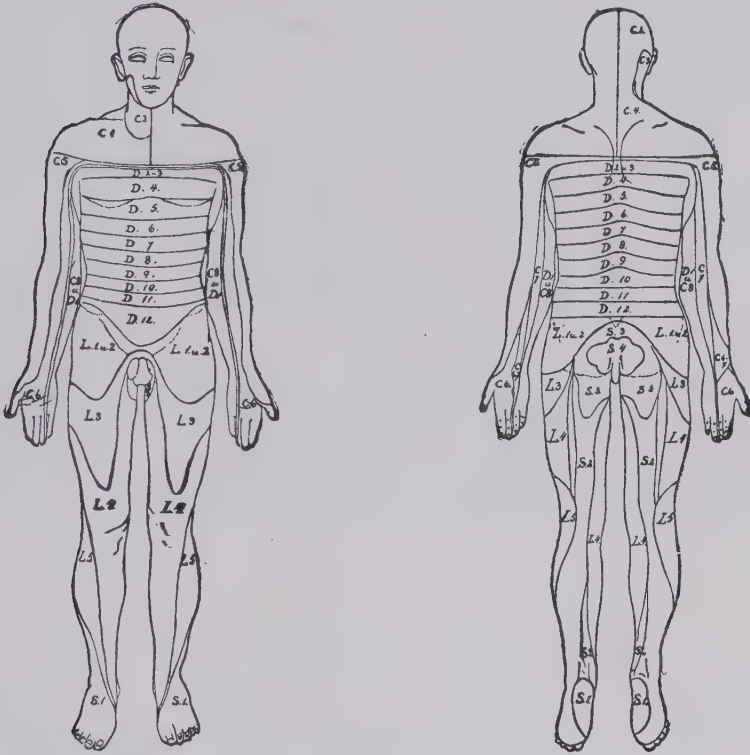

Fig. 76.—Showing the regions innervated by the different spinal roots or the corresponding segments of the cord. It should be remembered that the limits are not in reality so sharply defined, but extend into one another (Kocher).

paralysis of the central neuron type and loss of sensation below the seat of the lesion. In the lumbar segments the muscles supplied by those affected will show the peripheral type of paralysis, below it will be of the central neuron variety. The area of anesthesia will depend for its upper limit upon the segments involved (Fig. 76).

Sensory loss extending to the umbilicus means a lesion involving as its upper limit the *ninth dorsal* segment; if one inch below this, the *tenth*. When this segment is involved, if the patient attempts to raise the shoulders from the bed, the umbilicus will be pulled upward. This is due to the fact that the upper part of the rectus muscle is not paralyzed, while the lower is. The nipples correspond to the *fourth dorsal* segment.

If the *fifth cervical* is involved alone, the biceps, brachialis anticus, deltoid, and supinator longus are paralyzed, the other muscles of the arm and shoulder escaping. The biceps-jerk will be lost and the triceps-jerk present. When the *sixth cervical* is thus involved, the fifth escaping, these muscles are not involved and the arms will be in the position of abduction from the body, the forearms flexed on the arms and in the supine position. The biceps-jerk will be present and the triceps lost. Certain parts of the cord are known as the *epiconus* and *conus*. Symptoms indicating lesions in these locations and in the *cauda equina* are given on p. 1080.

Owing to the arrangement of the various tracts of the spinal cord a lesion involving its lateral half causes a peculiar combination of symptoms, frequently termed *Brown-Séquard's paralysis*.

It is met with particularly as a result of injuries (knife-thrusts and the like), though it may also be due to tumor or caries of the cord, to syphilis, or to any process causing compression of one-half of the cord. Such lesions intercept the motor impulses of the same side; the fibers having crossed in the medulla, the sensory fibers, conducting pain and temperature impressions, cross in the cord soon after entering, and hence these forms of sensation will be absent on the side opposite to the lesion; tactile sensation may also be abolished, but in some cases is not (*vide* Fig. 77). A lesion in the cervical cord above the arm nuclei causes motor paralysis of both arm and leg of the same side (spinal hemiplegia) and sensory paralysis on the opposite side. If in the dorsal or lumbar cord, the leg on the corresponding side is paralyzed, while that of the other is anesthetic. Lesions are seldom strictly confined to one side of the cord; but overlap a trifle, so that there is apt to be some loss of power on the anesthetic side; this, however, may be due to the recrossing of a few motor-fibers at a lower level. The side of the lesion may be hyperesthetic. Muscular sense is diminished or lost on the same side. Above the hyperesthetic region a zone of anesthesia commonly exists, and above this, again, an area of hyperesthesia. The reflexes are increased on the side of the lesion (inhibition being removed), and the temperature of that side is usually higher. On the anesthetic side the motor power, reflexes, muscle sense, and temperature are all normal.

GENERAL SYMPTOMATOLOGY

Information on this subject will also be found in the sections on Cerebral and Spinal Localization and on pp. 995, 1005.

Nervous diseases are usually spoken of as being either *functional* or *organic*; but, as our methods of research become more refined and our technic more perfect, the breach between these two groups is being gradually but steadily lessened.

Organic nervous diseases may be produced by two types of lesions:

1. *Irritative*, causing an increase of function, continuous or intermittent.
2. *Destructive*, resulting in paralysis of motion or sensation, or both.

Irritative lesions are prone to become destructive in course of time.

When a complete pathway is involved a system disease is said to be produced. Thus the disease known as amyotrophic lateral sclerosis (p. 1083), in which the lesion is a degeneration confined to the motor tracts, is one of this type. When two or more paths or neuron complexes are simultaneously involved combined system disease results.

Brain lesions may be (a) focal or (b) diffuse. Cord lesions are either (a) transverse, (b) focal, or (c) insular (a series of foci).

Cord lesions result in ascending or descending degeneration, the destructive process traveling, as a rule, in the direction in which impulses are normally transmitted. In the fillet degeneration may extend up or down.

The theory has been advanced that the vulnerability of the tracts of the spinal axis is in direct proportion to the degree of their functional activity; hence the reflex (sensory and pyramidal) tracts are more likely to degenerate under nutritional disturbances or toxic processes than other parts.

The following may be accepted as a general rule: the motor nervous system is the last to develop, the first to lose, and the last to regain, its function; while the sensory nervous system is the first to develop, the last to lose, and the first to regain, its function. In making a diagnosis it is, therefore, of the utmost importance to try to determine the locality and extent of the morbid process, and to ascertain whether the lesion is a focal or systemic one. The symptomatology of system diseases is pretty constant, and, except in their very incipency, they are usually not difficult of diagnosis. The symptoms of focal diseases, on the other hand, vary, of necessity, according to the location of the focus. They are often difficult and at times impossible to diagnose.

Irritative motor lesions produce, according to the degree of irritation, either fibrillary muscular twitchings or mild or severe convulsions, tonic or clonic in character (p. 996).

Destructive motor lesions, according to their extent, produce mere muscular weakness, paresis, or actual paralysis of a single muscle, groups of muscles, or of the entire musculature of one or more limbs.

Irritative sensory lesions give rise to pain, paresthesia, hyperesthesia, or hyperalgesia.

Pain is a very important symptom. Sharp and shooting pains may indicate irritation of the posterior nerve-roots (root-pain) or a symptomatic neuralgia (p. 1015). The feeling of a tight band about the body (girdle-pain) also denotes irritation of posterior nerve-roots. General hyperesthesia and pain occur in spinal meningeal irritation. Pain in the back aggravated by jarring is characteristic of vertebral disease. Burning pain is often due to neuritis. Backache may be due to neurasthenia, hysteria, or myelitis.

A very important form of pain is *headache*. This may be due to a number of different causes not connected with the nervous system, and may be located in different parts of the head, which often have a relation to the cause. It differs from neuralgia in not being confined to the distribution of particular nerves, although the seat of the pain is in the branches of the fifth nerve in the meninges. The important causes are:

1. *Reflex Irritation*.—Ocular (eye-strain or inflammation or commencing glaucoma); disease of the nasal cavity and accessory sinuses; middle-ear disease; diseased teeth; disease of the pelvic, thoracic, or abdominal viscera.

2. *Toxemia*.—These comprise infections, as the prodromes of infectious diseases, malaria, and syphilis before secondary symptoms appear; metabolic disturbances and diminished elimination, as uremia, diabetes, gout, hepatic disease, constipation, and exophthalmic goiter; action of drugs and poisons, as alcohol, tobacco, tea, coffee, lead, nitrites, quinin, carbon monoxid, opium.

Circulatory Disturbances.—Passive hyperemia due to disease of the right side of the heart, pressure on veins, emphysema; active hyperemia, as in the beginning of acute meningitis; anemia due to loss of blood, idiopathic anemias, or disease of the heart or arteries which prevents sufficient blood from reaching the brain, as arteriosclerosis.

Neuroses, as hysteria, neurasthenia.

Organic Disease of the Brain and its Membranes.—Tumor, abscess, meningitis due to syphilis or other cause, encephalitis.

Caries of the Cranial Bones.—Indurative or muscular, due to so-called rheumatic nodules in the muscles of the scalp and neck.

Migraine (p. 1138).

The diagnosis of the cause depends upon careful study of the case. Headache due to cerebral syphilis is usually much worse at night. If due to circulatory disturbance it is often throbbing and made worse by either raising or lowering the head, according to whether hyperemia or anemia is the cause. Pain due to eye-strain is brought on by using the eyes. It is either supra-orbital or occipital. When due to disease of the frontal sinus the pain is throbbing, usually appears after the patient has arisen, and passes off toward evening. It is aggravated by coughing or lowering the head. In indurative headache the muscles are tender and often nodules will be felt in them. It frequently comes on after exposure to cold winds or washing the hair.

The treatment of headache depends largely upon the cause. Relief may be obtained by using the various coal-tar analgesics, as phenacetin, acetanilid, etc. Caffein is often of service in those due to neurasthenia or mental exhaustion from any cause. Local applications, as menthol rubbed over the forehead, inhalation of carbonate of ammonia (smelling-salts), or heat applied to the head, may be of service.

Indurative headaches should be treated by some form of salicylic acid, vibratory massage, and the high-frequency current over the muscles of the neck and scalp.

Destructive sensory lesions cause a more or less complete absence of sensation, as analgesia, anesthesia, or loss of temperature sense.

By the term "analgesia" is meant loss of the sense of pain, by "anesthesia" is meant loss of the sense of touch. The prefix "hyp" preceding these words means diminished but not complete loss of sensibility. It is

important to remember that pressure may be felt when tactile sense is lost. Therefore in testing for the presence or absence of tactile sensibility, as little pressure as possible must be made. The peripheral nerves contain three sets of fibers (Head, Rivers, and Sherren; *Brain*, 1905) as follows:

1. Those which subserve deep sensibility and conduct the impulses produced by *pressure and movement of limbs*. The fibers of this system run mainly with the *motor nerves* and are not destroyed by division of the sensory nerves of the skin. These fibers also are located in the tendons. If pressure is severe enough pain may be caused.

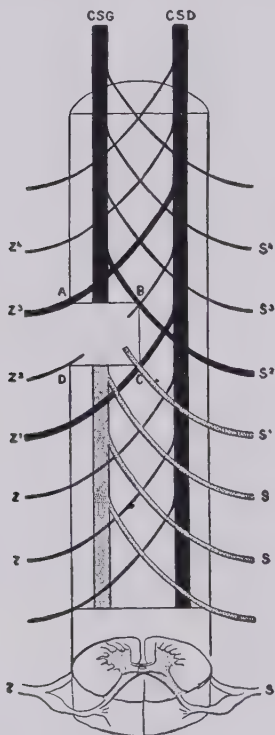

Fig. 77.—Scheme representing cord lesion and effects in Brown-Séquard paralysis (after Brissaud): CSG, Left sensitive tract; CSD, right sensitive tract; A, B, C, D, lesion involving the left half of the cord; S₁, S₂, S₃, sensory roots from right side of body; Z₁, Z₂, Z₃, sensory roots from left side of body; Z₁, Z₂, and S₁ are irritated only at the points A, B, C, and their peripheral area is hyperesthetic; Z₃ is divided and its skin area is anesthetic on the same side as the lesion. Corresponding to S₁ and all the roots below arising from the right side of the body, there is anesthesia.

2. Those which subserve *protopathic sensibility*, *i. e.*, painful stimuli and extremes of heat and cold, but inability to localize the spot stimulated.

3. Those which subserve *epicritic sensibility*, *i. e.*, the power of cutaneous localization, of the discrimination of two points, and of the finer degrees of temperature, as cool and warm. Protopathic sensibility returns first after a sensory nerve has been injured.

If the tracts conveying sensations from the muscles and tendons are not functioning, loss of *muscle sense* results, *i. e.*, inability to recognize the direction of active and passive movements and the position of the extremities. One of these may be lost without the other.

The use of the electric current gives important information in distinguishing between motor paralysis due to a central neuron lesion and a peripheral (p. 991). In that due to lesions of the former the muscles respond to both the faradic and constant currents, the contraction being characterized by a sharp, quick jerk of the muscle, which in the case of the constant current occurs first when the cathode or negative pole is placed over the muscle being tested or treated. If of the latter, there is either a diminution or loss of faradic contractility, and at first an increase in the contraction caused by the constant current, which may become diminished later. The contraction instead of being quick is *slow* and *tetanic* in character, and in some cases the weakest current that will cause contraction is when the anode or positive pole is placed over the muscle. This, known as the serial change, is not always present. If it is, it may be indicated by the following formulæ:

Normal: $KClC > AnClC$.

Abnormal: $AnClC > KClC$ or $AnClC = KClC$.

Lesions of this neuron, if very mild, may not cause any change in the electric reactions, except possibly some lessening of faradic contractility.

Neuralgia, *headache*, *vertigo*, and *nystagmus* are symptomatic conditions of importance (*vide*).

I. DISEASES OF THE PERIPHERAL NERVES

NEURALGIA

Definition.—Neuralgia (*nerve-pain*) is a term used to denote painful sensations that have the following characteristics: 1st. In their distribution they follow the course of the nerve-trunks or their branches. 2d. They show a tendency to shift from place to place. 3d. There are painful points (*points douloureux*) along the course of the nerve-trunks. 4th. Intermision and remission of the pain. 5th. There are no constant objective signs and no constant morbid changes in the nerves. True neuralgia is, therefore, a functional condition, and a symptom produced by a number of different causes.

Any nerve in the body may be affected. Quite often one can find no definite cause of the neuralgia. A number of cases classified as such are due either to a mild perineuritis or to disease of the root ganglion, as in herpes zoster. In many of these it may be difficult to make a differential diagnosis if the process is not severe enough to interfere with the function of the nerve, and such cases may be classified with the neuralgias.

Etiology.—Anemia from any cause; toxemia, which may be of exogenous origin, as from lead, arsenic, mercury, copper, alcohol, tobacco, tea, coffee, any of the infectious diseases, or endogenous, as diabetes and nephritis; the

deprivation of either morphin or cocain in a habitué; reflex, as the referred pains of visceral disease, thus a sciatica may be due to prostatic disease, neuralgic pain in the distribution of the sixth dorsal nerve may be due to heart disease, and so on¹; heredity, neuropathic, gouty, and scrofulous individuals being especially liable; exposure to cold and wet; chronic vascular disease, especially arteriosclerosis. The early stages of involvement of nerve trunks from pressure of tumors, especially neuromata, aneurysm, fractures, exostoses, displacements of bones, etc.; irritation, as from decayed teeth (p. 1017), etc.; general impairment of health, as in neurasthenia.

General Symptomatology.—The neuralgic attack may be of sudden or slow onset, with or without prodromata. When the latter exist they consist of a sense of uneasiness, perverted sensations, chilliness, and stinging or slight burning pains. The pain is usually of a paroxysmal, darting, boring character, radiating into the distribution of the affected nerves. In the intervals there may be either dull pain or freedom from it. In the case of the reflex neuralgias the area supplied by the affected nerve-roots is the seat of the pain. It is apt to be increased by movements of the affected parts, drafts, or excitement. Tenderness may be found over certain points, especially where the nerve emerges from a bony canal (points of Valleix); these are not always present. The affected part is usually hyperesthetic; occasionally, however, it is anesthetic, and may continue so for some time after an attack.

Reflex muscular contraction may be present in proportion to the intensity of sensory irritation. Vasomotor symptoms manifest themselves in the flushing or blanching of the affected part and in increased secretions, as sweating.

Trophic disturbances may result in temporary or permanent changes. To the former belong the herpetic and urticarial eruptions, while the latter groups include change of color in, loss of, or overgrowth of the hair, various changes in the skin (as pigmentation and morphea, and even ulceration, though in the latter instance there is probably a more profound pathologic change than that which we regard as the cause of neuralgia). Unless the attacks are severe or prolonged, however, the general system seldom suffers.

Diagnosis.—Neuralgia must be distinguished from *neuritis*, a mild attack of which, as has been said, it may resemble very closely. So much so, in fact, that in some cases the distinction cannot be made. Whenever the function of the nerve is interfered with, as shown by motor weakness, constant diminution of sensibility, absent or diminished reflexes, tenderness along the nerve-trunk, and wasting of the muscles, neuritis is present. Headache is distinguished by the fact that the pain is more or less diffuse, and is not paroxysmal and shooting in type. It must be remembered that pain of a neuralgic type may occur in diseases of the cranial or spinal bones, tumor of the cord or its membranes, tabes dorsalis, multiple sclerosis, syringomyelia, meningomyelitis, basal meningitis, cervical pachymeningitis, tumor of the cerebellopontile angle, of the gasserian ganglion, and inflammation of the sensory root ganglia, either cranial or spinal. The diagnostic points will be detailed under their respective headings.

Prognosis.—This depends upon the cause, whether removable or not; some forms, especially those of the fifth and sciatic nerves, are very intractable (p. 1017). There is always the danger in chronic cases of a drug habit being formed.

Certain types, as tic douloureux and sciatica (p. 1020), require special mention.

¹ These relations have been studied and classified by Henry Head, *Brain*, 1893, p. 1; 1894, p. 23; 1896, p. 153.

Treatment.—The first requisite in the treatment of neuralgia is to ascertain whether it is due to local or general causes. That of the former class may be caused by a cicatrix, neuroma, aneurysm, neoplasm, or by caries or traumatism; and the treatment must necessarily be directed toward the removal of the cause when possible. When the fault is a general one, the neuralgia may occur either as the immediate result of the systemic disease or, remotely, as the result of the altered blood state (anemia). This is particularly well illustrated by an attack of malaria, in which it is obvious that success can only be obtained by attention to the underlying cause. It is sometimes necessary to use an analgesic, of which morphin is certainly the best. Its therapeutic value is most decided when the drug is given hypodermically, and, if injected directly over the track of the painful nerve (*e. g.*, supraorbital branch of the fifth), it not only affords immediate relief, but also obviates recurrences of the painful paroxysms in many instances. It is, however, scarcely necessary to urge the exercise of caution, for the morphin-habit is readily formed in these cases. The following may also be used: antipyrin, phenacetin, codein, veratrum viride, aconite, also counterirritants and vesicants, including the galvanic current, which is applied by placing the anode over the tender spots if they exist, otherwise over the seat of the pain. A rapidly interrupted faradic current applied over this area and the high-frequency current may also prove valuable. The general tone of the system must be attended to, bad habits prohibited, the state of the bowels regulated, and the eyes examined and corrected for errors of refraction. Rest is a valuable adjunct to any form of treatment. In severe neuralgia of either the brachial or lumbosacral plexus division of the posterior roots has been practised with varied success.¹ (See also p. 1018.)

TIC DOULOUREUX

This is a neuralgia involving one or more of the branches of the fifth nerve. It varies greatly in character and intensity in different cases, and in its severest forms is one of the most terrible of all the diseases of the nervous system.

The *pathology* is doubtful. In those cases that have been subjected to surgical operation, excised portions of the nerves sometimes were normal and sometimes contained a moderate number of degenerated fibers. In other cases in which the gasserian ganglion has been removed and examined, considerable sclerosis of the blood-vessels has been detected, alterations in the axis-cylinders of the nerves, and occasionally moderate changes in the ganglion cells. It is not known exactly how these lesions produce the symptoms, but it is probable that vascular alterations are exceedingly important.

The *etiology* is various. Neuropathic heredity appears to play an important part. It is more frequently a disease of late than of early life. Peripheral irritation is frequently found, and when removed often results in complete cure. Among the structures disease of which is a frequent cause of tic douloureux are the nose and the cavities entering into it, and the mouth. Lesions of the former structures comprise chronic irritations, spurs, occlusion of the nasal openings, and suppuration. In the latter, abscesses at the roots of the teeth, irritated pulp, and occasionally, either non-eruption or malpositions of the teeth, are among the exciting factors. It is possible that eye-strain may also be an exciting cause.

The *symptoms* may be variable in extent, duration, and intensity. In the mild form there is only an occasional paroxysm, limited to one of the branches of the nerve, such as the type that occurs in acute coryza. In the more severe

¹ *New York Med. Jour.*, August 3, 1907, p. 192, and *Jour. Nerv. and Ment. Dis.*, September, 1907, p. 589.

form there may be repeated paroxysms, the intervals varying from a few minutes to several days, involving the whole side of the face, and causing, for the time being, complete prostration on the part of the patient. The pain is often radiating, or of a rending or boring character, and sometimes so severe as to cause nausea. It is often accompanied by certain vasomotor or secretory phenomena, such as flushing, perspiration, or excessive tear production, and even in some cases more or less persistent edema of the skin. In some instances there may be more or less twitching of the facial muscles. The duration of the attacks varies greatly. The paroxysms may succeed each other frequently for long periods of time, or until the patient becomes insane or commits suicide; in other cases, after a few paroxysms, the attack passes off and may not return for months. In some instances the pain is persistent, and although in these cases it is rarely severe, the discomfort of the patient is sometimes greater. The painful points are: for the first branch, the supra-orbital foramen; for the second, the infra-orbital foramen; for the third, the mental foramen. Often the surrounding portions of the skin, particularly those where the periosteum is near the surface, are tender. If the disease continues for some time there may be trophic changes, such as the formation of ulcers, drying of the skin, and the appearance of gray hairs.

The *diagnosis* may have to be made from tumor involving the gasserian ganglion or one in the cerebellopontile angle. The former can be distinguished by the existence of anesthesia in the fifth nerve distribution, the pain is usually constant instead of paroxysmal, and there is paralysis of the muscles of mastication. The diagnostic points of the latter are given on p. 1110. Bulbar tabes (p. 1129) may also cause pain in the course of the fifth nerve. Neuralgic pain in front of the auricle and within the meatus may be due to disease of the geniculate ganglion or intumescentia gangliformis (p. 1039). A skiagram will show the existence of non-erupted teeth.

The *prognosis* depends largely upon the cause. In the so-called idiopathic cases it is exceedingly unfavorable.

The *treatment* consists first in the removal of the cause, if it can be found. The eyes, nose, and mouth should be carefully examined, and any source of irritation thoroughly removed. For the treatment of the paroxysms, if they are mild, the coal-tar analgesics may be employed. If severe, the only drug that is at all effective is morphin, which is preferably given hypodermically. Of course, in nearly all instances, if the disease is chronic, the patient becomes addicted to the use of this drug. Occasionally, the external application of a mixture of the ointments of opium and belladonna has proved of service. Strychnin, in full doses, combined with complete rest and liquid diet, aconitin, nitroglycerin in old people in full doses, have sometimes rendered the attacks milder and less frequent. They should be given hypodermically. Salicylates may also prove useful. The general health of the patient should be improved if possible, and the disease treated expectantly for some time. The galvanic current, the anode being placed over the painful areas and given without interruption, may sometimes prove useful. Formerly, section of the painful nerve branch was employed, and even resection of a portion of the nerve, but the results were either so trifling or so transient that in recent years the tendency has been to resort more frequently to the excision of the gasserian ganglion. This is a serious operation, and the mortality is considerable; nevertheless, it is often wiser to employ it early rather than to delay until the patient is exhausted by long suffering. Spiller has suggested the section of the sensory root of the ganglion, and this operation gives the same results as excision of the ganglion. A satisfactory method of treatment, especially in old people or those whose general nutrition is poor, if medical methods fail, is the injection of alcohol into

the region of the foramina rotundum or ovale, according to the branch affected.¹ By this plan relief for several years at least may be obtained. The ophthalmic division cannot be injected safely, the supraorbital branch may be. Attempts with some success have also been made to inject the gasserian ganglion.² When the pain is confined to the supra-orbital nerve large doses of quinin may be of service.

NEURALGIA OF THE NECK AND TRUNK

The cervical branches of the dorsal and lumbar nerves are involved in this group.

1. *Cervico-occipital neuralgia*, occurring in the occipital and posterior parietal region, is apt to be quite severe, but when not due to spondylitis (the result of caries) or neoplasms the prognosis is fair. It is sometimes the result of direct pressure, as in carrying heavy loads on the neck and shoulders. The painful spot is found between the mastoid process and upper cervical vertebræ. Falling of the hair may also occur. This is much more apt to take place, however, when the occipitalis minor is involved, as it is said that the latter is generally a syphilitic neuralgia.

2. *Intercostal Neuralgia*.—The middle intercostal nerves are most liable to be affected, and generally on the left side. The posterior dorsal branches are seldom involved. When specially severe and persistent, intercostal neuralgia may be a symptom of disease of the cord or its membranes, aneurysm of the aorta, neoplasms, or disease of the vertebræ or ribs. Traumatism and cold also give rise to it. This form of neuralgia is most common in women, the painful spots being at the extremity and at the middle of the ribs. The pain is of a sharp, lancinating character and radiates along the nerve. It is intensified by all movements of the chest; hence the affected side is more or less fixed. Herpes may develop, but in such cases it is probable that an inflammation of the root ganglion exists (p. 1070).

3. *Mastodynia* is really a variety of intercostal neuralgia, and occurs almost solely among women. It is very painful and gives rise to the development of tender "lumps" in the breast, simulating malignant disease. The paroxysms are often accompanied by vomiting.

4. *Lumbo-abdominal neuralgia* is not a common form. The pain is chiefly in the lumbar region, though the hypogastrium, genitals, and buttocks may also be involved.

NEURALGIA OF THE EXTREMITIES

Cervicobrachial neuralgia occurs in the distribution of the four lower cervical nerves. When the condition is bilateral we should look for disease of the cord or its membranes, especially tabes, for new growths in either the spinal canal or bones of the arm, or for disease of the vertebræ. When unilateral, any of the causes already enumerated may be operative; also angina pectoris, referred pain as from gall-stones, cervical rib and a primary or radicular neuritis. The radial and ulnar nerves are more frequently affected than the median. The pain is most apt to be distributed along the whole course of the nerve, but painful points are found in the following situations: in the axilla; over the brachial plexus; on the shoulder, where the cutaneous branches of the circumflex nerve emerge through the deltoid muscle; about the middle of the outer surface of the upper arm; over the ulnar nerve; in the sulcus between the olecranon and epitrochlea; also near the wrist and at the bend of the elbow over the musculospiral nerve. x-Ray examination of the cervical region should be made.

¹ *Jour. Amer. Med. Assoc.*, January 20, 1912, p. 155.

² *Ibid.*, May 3, 1913, p. 1354; November 4, 1916, p. 1357.

Femoral or crural neuralgia is a somewhat rare type that attacks the anterior surface of the thigh, the knee-joint, and the inner surface of the leg and foot.

Obturator neuralgia is distributed along the inner side of the thigh down to and including, the knee-joint. This form is common in women subject to ovarian diseases, and may be mistaken for the pain of hip-joint disease.

Sciatica is such a common condition that a more extended description is necessary. The term is applied to pain in the course of the sciatic nerve, whether due to a pure neuralgia or a neuritis. It is probable that the majority of the cases are due to a perineuritis in which the presence of the exudation is not sufficient to cause marked interference with the nerve functions. It may be caused by any of the causes of neuralgia (p. 1015), but most cases are due to exposure, especially marked and sudden changes in temperature. Traumatism and prolonged pressure is also a frequent cause of the neuritic form. That due to pressure most frequently occurs after childbirth or during pregnancy. It occurs most commonly in men during middle life. Some cases are due to chronic constipation. The painful points are in the gluteal region and the popliteal space or malleolar region, though tenderness may be elicited along the whole course of the nerve. The pain is sharp and shooting, or more often of a tearing variety. It may be localized to the region either of the sciatic notch or calf. The anterior crural nerve may also be involved. It is increased by putting the nerve on the stretch, which can be done by forcibly flexing the thigh on the body (Laseque's sign), and by motion after a period of rest. Rarely both nerves are involved, especially if due to toxemia. Pain may also be felt in the lumbar region. Fine or coarse tremors or spasms may be present. Herpes occasionally develops along the course of the nerve. In cases due to neuritis of any severity the Achilles jerk is absent, wasting and weakness of the muscles occur, and sensation in the foot and leg may be diminished or absent.

In making the *diagnosis* it must be borne in mind that tabetic pains and diabetic neuritis may simulate *sciatica*. The pain of hip-joint disease and either inflammation or relaxation of the sacro-iliac synchondrosis may also simulate it. An enlarged transverse process of the fifth lumbar vertebra has caused similar pain, and Dr. J. Chalmers DaCosta has informed the writer that he has seen 2 cases apparently due to chronic appendicitis, as the pain disappeared after removal of the appendix. A careful examination, both clinical and by the *x-ray*, will reveal the true condition. The same may be said of tumor involving the cord and its membranes (p. 1077). Lesions of the cauda equina also cause sciatic pain which is usually bilateral, and, in addition, there will be atrophy and paralysis and involvement of the sphincters (p. 1080). Intrapelvic growths should also be borne in mind. The pain of *intermittent claudication* occurs only after exercise, is not limited to the course of the nerves, and the posterior tibial and dorsalis pedis arteries will not be palpable. In making a *prognosis* it must be borne in mind that it is often rebellious to treatment, but most cases ultimately recover. Relapses are apt to occur.

The most useful plan of treatment is absolute rest in bed, with the limb kept perfectly still by means of sand-bags or a long splint, with the application of heat along the course of the nerve, and the galvanic current, the anode over the sciatic notch and the other at the foot, applied daily for ten minutes without interruption. High-frequency, applied by the method of diathermy, and the static-wave current are useful in many cases. Full doses of the salicylates should be given internally. Local applications of one of the salicylic acid preparations, as a 25 per cent. ointment of mesotan, may also be of service. In old people with arteriosclerosis full doses of nitroglycerin and potassium iodid may give relief. In severe chronic cases electricity, as mentioned above, and counterirritation, preferably by means of a succession of small fly-blisters along

the course of the nerve, is of great value. When all else fails, stretching the nerve after exposing it often cures, but sometimes aggravates, the symptoms. The bowels should always be kept free. Deep injections of cocain, eucaïn, theïn, ether, or chloroform are sometimes used, and even distilled water may give relief when injected into the nerve. The use of guaiacol ($\pi\pi j$ to ij —0.066–0.1332) in association with chloroform ($\pi\pi x$ —0.666) by this method has yielded very encouraging results in my hands.¹ Excellent results have been reported from deep perineural injections of salt solution.²

Neuralgia of the Genitalia and Rectum.—These varieties are not met with frequently. The former is sometimes a symptom of stone, prostatic disease, or stricture, and in women ovarian and uterine neuralgias are generally hysteric manifestations. Coccygodynia, unless of traumatic origin, is almost solely found in women. The pain in the region of the coccyx is excruciating at times, and may even call for operation.

Visceral Neuralgia.—As implied by the name, these forms are neuralgias resident in the various viscera. They most frequently attack the stomach or bowel, and are recognized as colic. Other viscera may also be involved (liver, kidney). Such pains may be simulated by tabetic crises (p. 1128).

NEURITIS

Definition.—An inflammation of a nerve or of its fibrous envelope.

It may be confined to a single nerve, termed *local neuritis*, or a number of nerves may be affected, when it is termed *multiple* or *polyneuritis*.

Pathology.—The inflammation may be chiefly confined to the sheath of the nerve (perineural) or may, in addition, involve the deeper portions of the sheath (endoneurium), in which an accumulation of lymphoid elements will be found between the nerve-bundles. This form is known as *interstitial neuritis*, and is the condition usually found in the localized form. The nerve will be found to be swollen and red in color, but the nerve-fibers do not appear involved. Eventually, however, changes resembling those found in wallerian degeneration may occur, the myelin becoming fragmented, the nuclei in the sheath of Schwann increasing in number, the nuclei of the internodal cells becoming swollen, and the nerve-fibers undergoing granular degeneration. In *parenchymatous neuritis*, the condition found in multiple neuritis, the nerve-fibers are primarily and principally affected. Changes like those met with in wallerian degeneration described above are met with, but the sheath shows little evidence of inflammation.

Etiology.—(a) *Local neuritis* may be due to—(1) Exposure or cold (the so-called *rheumatic neuritis*). (2) Extension of inflammation from neighboring parts. (3) Traumatism—wounds, compression, excessive stretching resulting from fractures or dislocation, electric shock. (4) Microbic and autogenetic poisons. (5) Arteriosclerosis. (6) Stoop shoulders, which cause compression of the axillary structures between the humerus and ribs, causing either brachial or ulnar neuritis.³

(b) *Multiple neuritis* may be due to—(1) Poisons of extrinsic origin—carbon monoxid, alcohol, carbon bisulphid, lead, arsenic, mercury, ether. (2) Posions resulting from the infectious fevers (typhoid, diphtheria, variola, typhus, leprosy, beriberi, measles, syphilis, tuberculosis, septicemia, gon-

³ Goldthwait, *Jour. Amer. Med. Assoc.*, September 11, 1909, p. 852.

orrhea, malaria, influenza). (3) Poisons produced within the body, as from gout, rheumatism, diabetes, and pregnancy. (4) Cachexias, anemia, carcinoma, arteriosclerosis). (5) Cases arise in which no definite cause can be ascertained; these are the so-called *idiopathic* or spontaneous cases.

Symptoms.—(a) **Focal Neuritis.**—In localized neuritis the symptoms vary according to the function of the nerve involved. In the case of a sensory nerve there is pain, usually of a boring or shooting character, along its course and distribution. There is also tenderness on pressure over the nerve. The skin in extreme cases may be hyperalgesic (though tactile sensation is often lowered), reddened, edematous, and sweating. In the more chronic cases trophic symptoms eventually arise, as glossiness of the skin and an impaired growth of the nails. When a motor nerve bears the brunt of the attack there is more or less impairment of motion, even amounting to paralysis; and ultimately wasting of the muscles, which may show reactions of degeneration (p. 1015), occurs. When both motor and sensory nerves are simultaneously involved the symptoms will necessarily partake of a mixed character. Many cases of a mild type occur in which the symptoms consist of pain, tenderness on pressure over the affected nerves, some impairment of motion, slight atrophy, and a diminished contractility to the faradic current. The constitutional symptoms are, as a rule, of little moment. The symptoms of neuritis affecting special nerves are detailed on pp. 1027 to 1054.

(b) **Multiple neuritis** is an involvement of the peripheral nerves in various parts of the body, affected simultaneously or in quick succession, and due to endogenous or exogenous poisons.

Among cases due to poisons of extrinsic origin is *alcoholic neuritis*. This is the most common type of multiple neuritis. It results from spirit-drinking in moderate amounts and continued over a long time. The onset is generally slow, being preceded by gastric catarrh, insomnia, and particularly numbness and tingling of the extremities. A rapid, weak heart and a tendency to sweating on exertion may also be present. Weakness, especially of the extensor muscles of the wrists and dorsal flexors of the feet; pain and muscular tenderness, the latter being most prominent in the muscles of the calf, where it is usually an early symptom, are soon noticed. As a rule, the legs are first affected, and in mild cases the arms may escape. As a rule, however, all of the nerves supplying the extremities ultimately become more or less affected, and, in extreme cases, cranial nerves may also suffer. The reflexes are lost (rarely the knee-jerks may be increased in the early stages), muscular atrophy becomes marked, and pain and tenderness very severe. Rarely loss of control of the bladder and rectum take place. Fever is seldom noticed. More or less impairment of pain, tactile, and muscle sense may also be present. The early loss of power in the extensor muscles soon causes double wrist- and foot-drop, and the gait, owing to the effort to make the toes clear the ground, is of a peculiar high-stepping variety, known as "steppage gait."

The cutaneous reflexes are preserved unless the anesthesia is marked. In less severe cases a certain amount of inco-ordination may be present. When this is the case, the absence of the knee-jerk, the loss of muscular sense, occurrence of ataxia, and the pains in the extremities simulate locomotor ataxia, and the term *pseudotabes* has been applied to the condition. Vasomotor and trophic symptoms appear, and in some cases the special senses are involved (impairment of vision, amblyopia, limitation of the color-field). The mental symptoms are important. They may be so slight as to consist merely of loss of memory, irritability, perhaps an hallucination or illusion (particularly after nightfall, and especially if the patient has had insomnia), or they may be very severe, consisting of marked mental impairment, hallu-

cinations, delusions, disorientation, etc., a symptom group known as Korsakow's psychosis. The duration of an attack varies from a few weeks to a year or more.

Arsenic neuritis differs from the above in that the mental symptoms are generally absent. The onset may be much more abrupt and the course is usually shorter.

Carbon bisulphid neuritis occurs chiefly in workers in rubber factories and imitation silks. There are noted intense frontal headache, giddiness, marked excitability, muscular cramps, and possibly convulsions. *Saturnine neuritis* is confined to motor nerves, and especially to those of the upper extremities, the posterior interosseous branch of the musculospirals being especially liable to be involved, causing double wrist-drop. Any or all nerves may, however, become affected. Peculiar features are the usual absence of pain and tenderness, and the escape of the supinator longus and extensor ossis metacarpi pollicis muscles. Lesions of the anterior cornua are more likely to occur in saturnine multiple neuritis than in any of the other varieties. Delirium (lead encephalopathy), optic neuritis, and convulsions may occur, but are not common symptoms. Multiple neuritis is a frequent sequel of diphtheria; it is also rarely attended with pain and tenderness, and has been fully described on p. 154.

Cases due to other forms of infectious disease may be local or multiple, and generally present symptoms similar to those of neuritis due to any other cause. *Recurring Multiple Neuritis*.—A few cases have been reported in which attacks of more or less wide-spread paralysis, due to neuritis, have recurred. *Senile neuritis* occurs in old age, and is probably a degeneration due to arteriosclerosis. The symptoms develop gradually and consist of weakness and numbness of the limbs, especially the lower; absent knee-jerks, sometimes slight atrophy and diminished response to the faradic current. Cranial nerves may also be affected.

Multiple neuritis has followed the employment of the Pasteur treatment for rabies.

Spontaneous or the so-called *idiopathic neuritis* does not differ from the general type of the disease, except that no cause can be discovered to account for it.

Beriberi.—This is a form of multiple neuritis, occurring endemically, chiefly in the islands of the Pacific Ocean and in Asia. It is especially prevalent in Japan and the Philippines. Sporadic cases are met with in increasing frequency in Europe and America, brought on ships from the Orient. There is some dispute concerning its etiology, but the prevailing view is that it is due to the use of food in which the so-called vitamins are absent. This is notably so when the diet is one of "polished" rice. It is especially apt to occur where many are crowded into a limited space, as jails, barracks, ships, etc. Moisture and heat favor its development.

The essential feature of the pathology is the changes in the nerves; these are inflammatory and degenerative. Degeneration in the muscles also occurs, and not infrequently serous effusion. A variety of clinical types have been recognized. Of these, the most important are the wasting and the wet forms. The onset may be rapid or more gradual. In the first type there is loss of power in the limbs, wasting of the muscles, and more or less emaciation. Subjectively, there are pain and paresthesiæ in the limbs, tenderness in the muscles and over the nerve trunks. The patients also complain of weakness, dyspnea, and palpitation. The wet form is characterized by the earlier or later occurrence of general anasarca, with effusion into the serous cavities. The swelling may be enormous and obscure the muscular wasting. Sometimes the dyspnea

and palpitation of the heart predominate. The prognosis is usually favorable, but the course is prolonged and recurrence is not unusual. In the cardiac form death may occur in a few days.

Diagnosis.—This does not present any difficulty, as a rule. In the early stages, *acute anterior poliomyelitis* and *acute ascending paralysis* may be mistaken. In the former constitutional symptoms usually precede by several days the development of the paralysis, which, when it occurs, is usually more or less general, to be followed by a rapid improvement in most of the affected limbs. The paralysis in multiple neuritis develops progressively. If pain and tenderness occur in poliomyelitis, they consist of a general hyperesthesia, and are not confined to the affected nerve-trunk, as in neuritis.

In *ascending paralysis* there are no sensory symptoms, there is neither muscular atrophy nor electric change, and the order in which the paralyzes supervene differs from that of peripheral neuritis.

Cases of pseudotabes are sometimes confounded with *locomotor ataxia*. The main points of differentiation are included in the following table:

PSEUDOTABES	LOCOMOTOR ATAXIA
The course is shorter, and often results in recovery.	The course is progressive from bad to worse, and chronic in nature.
Pain is never of the fulgurant type.	Fulgurant pains often are present. Pain-crises are almost diagnostic.
There is tenderness over the nerve-trunks. Sensory disturbances are more marked (tingling and numbness).	There is no tenderness over the nerves. Sensory disturbances are less marked.
Argyll Robertson pupil is absent.	Argyll Robertson pupil is present.
There is a "foot-drop," with the typical "steppage gait."	No "foot-drop." The toes are raised, and the foot is brought down flatly, with the heel first.
Paralysis is often present.	There is no actual loss of power.

The distinguishing symptoms from progressive neural atrophy are given on p. 1026.

Prognosis.—Peripheral neuritis may terminate in one of the following ways: 1. In complete recovery. 2. With damaged peripheral nerves. 3. With injury to the central nervous system, especially of the cells in the anterior horns. 4. In death from failure of the organic centers, especially that of respiration. The prognosis is generally good, though in the acute variety (from any cause) it should be guarded, and occasionally is grave. Exposure and chill, alcohol, diphtheria, and beriberi give rise to the most serious types, and often cause death by failure of the heart or respiration or by coagula in the vessels. Mild cases may entirely recover in a few weeks, while severe ones often require a year or two.

Treatment.—First ascertain the cause and, if possible, remove it. It may be unwise in alcoholic cases to stop the alcohol suddenly, but each case must be judged on its merits. Rest is very important, and all sources of worry should be stopped. Locally, anodynes may be employed and the part wrapped in cotton wool. Ointments of either ichthyol and belladonna, or some of the salicylic acid preparations for external use, as mesotan, are often of service. The pain can often be relieved for several hours by the application of the galvanic current, applied without interruption down the limb. In acute cases, especially in the earlier stages, the salicylates are valuable. The general health should be toned up by strychnin and tonics, and by nourishing but easily digestible foods. Further medication will depend upon the etiology, quinin being demanded in malaria, iodids and other measures to eliminate the lead in

lead cases. As soon as the acute cases have subsided, massage and passive movements should be begun, galvanism applied to the muscles, and warm water or sulphur baths administered. Care should be taken to prevent deformity due to the unopposed action of antagonistic muscles, as when foot- or wrist-drop is present.

PROGRESSIVE NEURAL MUSCULAR ATROPHY

(*Hoffmann*)

(*Progressive Neurotic Muscular Atrophy; Charcot-Marie-Tooth-Type of Progressive Muscular Atrophy; Peroneal Type, Gowers*)

Definition.—A degenerative process, apparently commencing in the nerves, and characterized by muscular degeneration, with subsequent contractions, sensory disturbances, and a loss of the reflexes.

Pathology.—Sclerosis of the posterior columns of the cord, slight degeneration of the pyramidal tracts, alteration of the columns of Clarke, atrophy of the cells in the anterior horns of the cord, degeneration of the peripheral nerve-fibers and of the intramuscular branches, atrophy of the muscle-fibers, and chronic spinal meningitis have been found by different observers in cases of this disease.

Etiology.—Heredity seems to play an important part in the causation of the disease, which may either occur in successive generations of a family or affect several members of the same generation. Sporadic cases occasionally occur for which it is impossible to trace any ancestral influence, though, as the disease has been known to skip a generation, it is not impossible that such cases are still hereditary. Males are much more frequently affected than females, and the disease almost invariably commences between the ages of ten and twenty years.

Symptoms.—As the name implies, muscular wasting usually begins in the muscles of the feet or hands, either the peronei, the common extensors of the toes, or the small muscles of the foot itself, or else in the muscles of the thenar and hypothenar eminences and the interossei. Usually the atrophy is symmetric. In the feet it leads to an early development of club-foot, which is most pronounced when the extremity is at rest. Very early the atrophy of the small muscles causes the toes to assume the claw position, and the atrophy of the peroneals causes foot-drop, so that in walking the foot is dragged along the ground. In the later stages the foot becomes permanently fixed in a position of equino-varus or valgus. The hands have the characteristic appearance given by a flattening of the ball of the thumb and middle finger. The interosseal grooves also become deeper and the fingers gradually assume the claw-like position (*main en griffe*). The disease extends slowly upward, involving the muscles of the calf and forearm; the muscles of the thighs, upper arms, and trunk usually escape. The affected muscles usually show distinct fibrillary twitchings. When electrically examined, the muscles either show a marked diminution in reaction to the galvanic and faradic currents, or distinct reaction of degeneration can be elicited. Similar electric changes are also found in the nerves. Mechanical excitability of the muscles is considerably diminished, these changes being found also in the muscles that are apparently healthy. The tendon reflexes are usually absent, although in the early stages, when the muscles of the thigh are still unaltered, the knee-jerk may be merely diminished. Sensation is sometimes unaltered, but ordinarily there is some diminution of sensibility in the peripheral parts of the limbs. Often there are paresthesiæ

and, occasionally, pains of considerable intensity. The general condition of the patient, however, remains excellent. The vegetative organs are unaffected, and nutrition is, therefore, intact.

The **diagnosis** can be made from other forms of progressive muscular atrophy (particularly the type "Aran-Duchenne," p. 1082) by the sensory disturbances, the fact that the atrophy first appears in the small muscles of the feet, and the early age at which the symptoms appear; from the *muscular dystrophies* by the presence of fibrillary tremors, sensory symptoms, and changes in the electric reactions and the escape of the proximal muscles; from multiple neuritis by the absence of tenderness over the nerve-trunks; from acute poliomyelitis by the mode of development.

Friedreich's ataxia (p. 1085) may cause a somewhat similar deformity of the feet, but nystagmus and speech disturbance are present in it and not in progressive neural atrophy.

The **prognosis** is good as regards life, but unfavorable as regards cure or even improvement. The course of the disease is extremely slow.

The **treatment** employed in the other forms of amyotrophy may be tried, but so far nothing has succeeded in staying the course of the disease.

NEUROMATA

Neuromata, or tumors of nerves, have been described as (a) true and (b) false.

(a) *True neuroma* or ganglioneuroma is one which contains nerve-cells and is very rare. Tumors containing nerve-fibers have also been so classed, but according to Adams should not be.

(b) *False neuromata* contain no nerve elements. The growth is situated on the nerve-trunk itself, and consists of either fibrous, myxomatous, gliomatous, or sarcomatous tissue.

False neuromata may occur singly or be multiple. In the latter we have the condition known as *plexiform neuroma*, in which any or all of the various nerve cords may be occupied by great numbers of tumors. The roots within the spinal canal may also be involved. In connection with these the sensory nerve-endings in the skin may be involved, causing small painful subcutaneous nodules termed *tubercula dolorosa*.

In *generalized neurofibromatosis* or *von Recklinghausen's disease*, tumors which resemble those of plexiform neuroma are present on the different nerve-trunks. They frequently involve cranial nerves and the roots within the spinal canal. In addition, soft fibrous nodules, often pedunculated and of varying size, are scattered over the body. They develop from the sheaths of the cutaneous nerves. In addition, there are spots of brownish pigmentation of the skin and sometimes congenital nevi. Various symptoms referable to the nervous system may be present according to the location of the growths and parts pressed upon. Pain may or may not be present, and there may be more or less dementia. The disease may be hereditary.

Amputation or *stump neuromata* are bulbous swellings on the ends of nerves which have been divided by operation or injury. They consist of nerve-fibers growing from the central end of the nerve toward the periphery, and are painful.

Etiology.—Neuromata also may be due to traumatism. When multiple, however, they are usually hereditary, occurring in families of a neurotic or strumous diathesis. They are most commonly found in men.

Symptoms.—There may be none. When present their character necessarily depends on the nature of the nerve involved and whether the lesion is an irritative or destructive one. More or less pain, numbness or tingling, paresthesia, and palsy are among the most common. The tumors can usually be felt by palpation.

Treatment.—Apart from anodynes, operative measures alone are of value, except when the tumors are the result of syphilis, as occasionally happens; in such cases specific treatment must be employed.

It must not be forgotten, however, that stump neuromata may occur in those hereditarily predisposed, in which case, as Bowlby has pointed out, their removal will almost surely be followed by a return.

DISEASES OF THE CRANIAL NERVES

OLFACTORY NERVE

The following morbid conditions have been described in connection with the sense of smell:

(a) *Hyperosmia* or *Olfactory Hyperesthesia*.—The sense of smell is abnormally acute, so that objects, and even persons, can be recognized by this means. It occurs in hysteria and insanity.

(b) *Parosmia* (perverted sense of smell) may occur for one or for many odors, and is often associated with an obtunding of the normal sense.

(c) *Subjective sensations* of smell are due to the same causes as the above. An olfactory aura may precede an attack of epilepsy. Olfactory hallucinations occur occasionally in the insane, and in irritative lesions of the uncinate gyrus (Fig. 68).

(d) *Anosmia* or *olfactory anesthesia* (loss of the sense of smell) may be caused by—(1) Injury to the peripheral filament by local disease of the nasal mucous membrane. (2) Injury to the nerve-trunk or bulb, by blows on the head, basal fractures of the skull, bone disease, and meningitis. Anosmia may occur during locomotor ataxia. Pungent and powerful odors have been said to cause loss of the sense of smell, due to excessive stimulation. There may be a congenital absence of the olfactory nerves. (3) Centric lesions, as tumors in the region of the uncinate gyrus (Fig. 68). Unilateral anosmia has been described as part of a hemianesthesia, due to a lesion in the posterior part of the internal capsule and in hysteria.

In testing the sense of smell it is advisable to use aromatic oils, as they only stimulate the olfactory nerve, while ammonia and such strong substances also stimulate the fifth nerve. It is obviously necessary to make a rhinoscopic examination.

Treatment is generally unsatisfactory, though the cause must be removed when possible. When the disturbance is due to some general condition, as hysteria, it may, of course, be disregarded, as it will improve with the disease.

DISEASES OF THE RETINA, OPTIC NERVE, AND TRACT

The Retina.—Hemorrhage into the retina may be venous or arterial, single or multiple, monocular or binocular. It may be part of a general vascular change; occasionally it occurs during parturition, but more often at the menopause; it may be an indication of renal trouble or of some primary or symptomatic anemia, as in leukocythemia, pernicious anemia, or malaria. Hemor-

rhage is prone to occur also in depraved nutritional conditions, in purpura, and in scurvy.

More or less complete loss of vision develops in these cases, either suddenly or gradually; an ophthalmoscopic examination is necessary to make the diagnosis. If the hemorrhage is superficial, the eye-ground is red and swollen; if deeper, the blood escapes between the fibers of the retina, spreads them out, and assumes a flame-shaped appearance.

Retinitis.—Three forms of this condition are commonly described—(1) Albuminuric, (2) syphilitic, and (3) pigmentary.

(1) *Albuminuric retinitis* is probably not a distinct affection, but part of a general fibrovascular change associated with nephritis. The failure of vision may precede the advent of albuminuria, but more often the two conditions are coincident. It occurs in chronic nephritis, especially in the interstitial variety.

The retinal changes, according to Gowers, are either *hemorrhagic* or *degenerative*. In the former the arterial blood occupying the interstices between the fibers assumes a striated or feathery aspect, while in the degenerative form white patches of fatty degeneration or deposits of cholesterin are dotted over the fundus; they may also be grouped about the macula lutea, or around the disk. Occasionally the latter appears swollen, owing to the effusion of serum into the fiber layer.

(2) *Syphilitic retinitis* generally occurs in the later stages of acquired syphilis, and particularly in neglected cases. Failure of vision directs attention to the eye-ground, which is found to have either scattered or uniformly distributed whitish or slightly opalescent filmy patches upon it. The vitreous may be turbid also. Retinitis is far less common than choroiditis or chorioretinitis.

(3) *Pigmentary retinitis* is essentially a chronic process, usually attacking young adults, and, as a rule, more than one member of a family. It may also occur in inherited syphilis and in low grades of vitality. The affected parts receive a deposit of pigment which specially follows the course of the main arteries. At the same time a circumferential annulus of pigment forms. This gradually encroaches more and more upon the disk, until finally atrophy ensues.

Among retinal affections occur also—

(a) **Toxic Amblyopia.**—This is due, as a rule, to tobacco or alcohol, but may be due to lead, quinin, salicylic acid, uremia, diabetes, and the infectious diseases. Failure of vision is gradual and progressive, though it rarely reaches absolute blindness. The center of the field is chiefly affected, and a central scotoma for red and green exists. It is believed to be due to a retrobulbar neuritis. The term *amblyopia* is applied to dimness of vision due to functional causes. If complete blindness is so caused it is termed *amaurosis*. They may be due to hysteria, neurasthenia, anemia, and reflex irritation.

(b) **Hemeralopia**, or *day-blindness*, may either be functional or a symptom of some retinal affection—*e. g.*, hyperesthesia or albinism, or the result of central cataract. Objects can either not be seen at all or only indistinctly during the day or in a strong artificial light; but at night vision is excellent.

(c) **Nyctalopia**, or *night-blindness*. In this condition vision may be normal during the day or in a strong artificial light, but after nightfall or in a darkened room objects can be seen only with difficulty or not at all. It is usually associated with syphilitic retinitis.

Optic Nerve.—The important pathologic conditions of the optic nerve, especially with reference to diseases of the nervous system, are: (1) *Neuritis* and (2) *atrophy*. (1) Neuritis is met with in two forms: first, where the lesion is not visible at the intra-ocular end of the nerve (orbital optic neuritis or

retrobulbar neuritis, see Toxic Amblyopia), and, second, where the lesions are visible at the intra-ocular nerve-ending. The latter is the more important, and is also known as papillitis. Optic neuritis may be caused by the acute infectious diseases, syphilis, lead, alcohol, uremia, anemia, menstrual disorders, exposure to cold, rheumatism, injuries, disease of the orbital region, and intranasal and accessory sinus lesions. Rarely it is congenital, and mild forms may be caused by refractive errors. When the nerve head projects markedly into the interior of the eye, it is known as "choked disk," or from the condition present, papilledema. This is not a true neuritis, but is due to mechanical causes. The early injection with stasis of the retinal vessels, edema, and elevation of the nerve-head, and final cellular infiltration, with new tissue formation leading to atrophy, are due to distention of the sheath of Schwalbe by obstructed cerebrospinal fluid.¹ Neuritis at times may be associated. Kidney disease may cause a similar condition. Intracranial lesions are the most frequent causes. Of these, brain tumor ranks first. Others are meningitis, cerebral abscess, cerebral and meningeal hemorrhage, thrombosis of the cavernous sinus, chronic hydrocephalus, serous meningitis, and aneurysm of the internal carotid. Vision may not be lost for some time. If the process is not arrested, consecutive atrophy occurs.

(2) *Optic Atrophy*.—This may be *primary*, when it is usually associated with disease of the spinal cord and brain, as tabes dorsalis, parietic dementia, and multiple sclerosis, *secondary*, when it results from pressure more or less directly applied to the optic chiasm or tracts, and *consecutive*, when it follows a previous neuritis or "choked disk." There is also an hereditary form known as Leber's disease, and that which occurs in amaurotic family idiocy (p. 1172).

In any case there is contraction of the field of vision and colors are not perceived in the normal order, *i. e.*, blue, red, green, but are reversed in various ways (dyschromatopsia). This also occurs in functional disorders, as hysteria. There is more or less dimness of sight. In the hereditary form the disk is less white than in the other, and the vessels are almost normal in appearance.

The Optic Tract.—The lesions of the optic tract may cause either blindness, dimness of vision, or *hemianopsia*. By the latter is meant blindness of one-half the visual field. As the light rays cross, the blind field is opposite to the blind half of the retina. Thus, if the nasal half of the retina is not functioning, the temporal field will be blind. It is always due to a lesion at or posterior to the chiasm. When the latter is the case, blindness in the temporal field of one side and nasal field of the other is caused. This is termed *homonymous lateral hemianopsia*. The blind fields are in the side opposite the lesion (Fig. 78). Lesions of the chiasm usually affect the decussating fibers, causing blindness of the nasal halves of the retina, and, in consequence, temporal hemianopsia. This condition occurs in basal tumors, especially of the hypophysis, and has also been observed in acromegaly, in tuberculous basal meningitis, and in hydrocephalus. When homonymous hemianopsia exists, to determine if the lesion is located in or anterior to the corpora quadrigemina, a very valuable sign, that, however, cannot always be elicited, is the failure of the pupil to contract when light is thrown upon the blind half of the retina. This is termed *Wernicke's hemianopic pupillary inaction* sign and is explained by the fact that the pupillary reflex center is situated in the anterior corpus quadrigeminus, lateral geniculate body, and pulvinar, which are termed the primary optic centers. If the lesions affect the optic thalamus or the internal capsule, hemiplegia and hemianesthesia are also often present or may form the most

¹ Bordley and Cushing, *Jour. Amer. Med. Assoc.*, 1909, lii., p. 353.

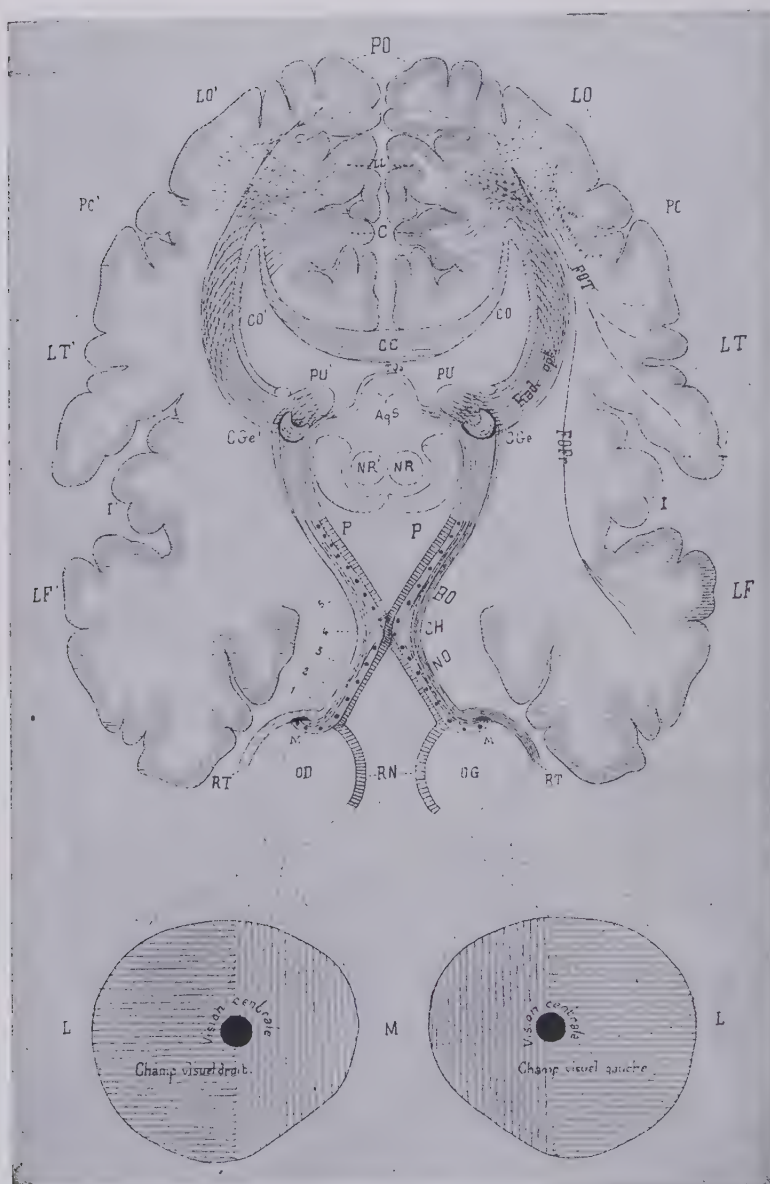

Fig. 78.—Diagram of the visual apparatus (after Vialat): *LO, LO'*, occipital lobes; *C*, cuneus; *Rad. opt.*, optic radiation; *TQa*, anterior corpus quadrigenus; *P U, P U'*, pulvinar; *CGe*, external geniculate ganglion; *BO*, optic tract; *CH*, optic chiasm; *NO*, optic nerve; *OD*, right eye; *OG*, left eye; *RN*, nasal half of retina (supplied by the opposite hemisphere); *RT*, temporal half of the retina (supplied by the homolateral hemisphere); *M*, macula lutea. A total transverse lesion at 1, 2, or 3 would cause total blindness of the right eye. A lesion at 4, destroying the central part of the chiasm, would cause blindness of the nasal halves of the retinae, and therefore bitemporal hemianopsia. A lesion at 5 would cause blindness of the right halves of the retinae, and therefore left homonymous hemianopsia. The pupillary reflex would be lost in the affected half of the eye in all these cases. A lesion in the optic radiation would cause symptoms similar to those of the corresponding optic tract, excepting that the pupillary reflex would be preserved. Lesions of the cortex cause various disturbances of vision according to the part affected.

important symptoms. Lesions posterior to the anterior corpora quadrigemina produce hemianopsia without disturbance of the pupillary reflex. These lesions are divided into two groups, the cortical and the subcortical, and they may be of two varieties, either irritative or paralytic. The irritative lesions give rise to hallucinations of sight, which may vary from the scotomata of migraine to most complex visions and may indicate tumor in the cuneus (Fig. 68). Occasionally curious symptoms are produced, the visual field being sometimes irregular, while at others only certain elements of sight are affected, cases having been reported in which the hemianopsia only involved the recognition of colors, not of form. In all these cases the pupillary reflexes are not affected. Bilateral lesions do not always lead to total blindness; sometimes the macula lutea escapes and the patient is able to see only by direct fixation. Cortical lesions are those involving the occipital lobe. The center of visual perception appears to be in the cuneus and calcarine fissure; if this is destroyed on both sides, blindness occurs. If on one side, lateral homonymous hemianopsia (Fig. 78). The center for the recognition of the object seen is apparently upon the convex surface of the occipital lobe, probably in the second and third convolutions, but it may extend also into the temporal lobe. When this is destroyed the patient can see either objects, words, letters, or symbols, as the case may be, with which he was once familiar, but fails to recognize them; this is called *mind-blindness* or visual agnosia (see p. 1004). Hemianopsia is very frequently merely a temporary symptom, and as such it may occur in uremia, apoplexy, migraine, and certain intoxications, especially that of lead. It may also occur in brain tumor, and disappear if the pressure is relieved, as by trephining. It is a permanent symptom only when the visual tract has been involved by some destructive lesion. If the patient is perfectly conscious and intelligent, it is not difficult to recognize it; nevertheless, its presence can often be detected in young children and in those who are only partially conscious or unable to speak. This can be accomplished by taking a bright object, placing it behind the head, and then bringing it forward slowly, first on one side and then on the other. It will then be noted that the patient perceives it on the hemianopsic side only when it has been brought to the middle line, while when moved on the other side the eyes will turn toward it when it is still a considerable distance from this point. Another method is to bring a blunt object (a wisp of cotton) very nearly in contact with the cornea, first on the one and then on the other side of the median line. The palpebral reflex will occur upon the normal side while the object is still some distance away; on the blind side only when it has come in contact with the conjunctiva.

DISEASES OF THE MOTOR NERVES OF THE EYEBALL (THIRD, FOURTH, AND SIXTH)

The extrinsic ocular muscles are supplied by these three nerves, while the intrinsic are supplied by the third and the sympathetic.

I. The **motor oculi**, or **third nerve**, is purely motor, and supplies all the muscles of the eye except the superior oblique and external rectus, and controls in part also the ciliary muscle and the sphincter of the iris. Its apparent origin is from the inner side of the crus cerebri just anterior to the pons. It can be traced through the crus, however, to its deep origin in a nucleus beneath the corpora quadrigemina, situated in the floor of the aqueduct of Sylvius. Above the crus it pierces the dura, passes between the two clinoid processes of the sphenoid bone, along the outer wall of the cavernous sinus, where it receives some filaments from the cavernous plexus of the sympathetic; it then divides into two branches that enter the orbit through the sphenoid fissure. The superior and smaller division supplies the superior rectus and

levator palpebræ superioris, while the inferior and larger branch subdivides into three portions, one going to the internal rectus, another to the inferior rectus, and the third to the inferior oblique.

Lesions of the third nerve result in (1) spasm or (2) paralysis.

Spasm rarely if ever occurs in all the muscles simultaneously. Any muscle may be affected, but the internal rectus and levator palpebræ are specially liable. It is met with in meningitis, hypermetropia, and hysteria.

Nystagmus is a simultaneous and associated movement of both eyes in various directions and is a symptom which is apparently although not in all cases, actually caused by clonic spasm of these muscles. There are two types, viz., *oscillating nystagmus*, in which the movements in each direction are equally rapid, and *rhythmic nystagmus*, in which there is a slow movement in one direction and a quick movement in the opposite. The former is due to either acquired or congenital visual defects, as when there are either corneal or lens opacities or impaired function of the optic nerve occurring early in life. It is also seen in miners and is sometimes present in apparently normal individuals. A *pseudonystagmus* occurs in weakness of the ocular muscles (p. 1034).

The rhythmic type occurs spontaneously if there is irritation of either the labyrinth or vestibulo-ocular tract (p. 1041).

It may be either lateral or horizontal, rotary or up and down. The direction is said to be that of the quick movement, thus, if this is to the right, it would be right horizontal nystagmus. The slow movement is due to the vestibular disturbance, and the quick to the recoil back to the normal position. If the nystagmus is not apparent by ordinary observation, it may be increased by turning the eyes in different directions. This is greater when the eyes are turned in the direction of the quick movement. In normal persons it may be caused by stimulating the vestibular apparatus by the Bárány tests, viz., turning, caloric, and electric (p. 1041), and this fact may be of service in localizing certain brain lesions (p. 1111).

Irritation of the center or nerve may cause contraction of the pupil (*myosis*), as occurs in locomotor ataxia. The same result is brought about by paralysis of the cervical sympathetic.

Paralysis.—The nerve may be involved in any part of its course by either inflammatory deposits, tumors or neuritis, or the nucleus may be diseased. (See Ophthalmoplegia, p. 1035.)

Relapsing and recurring palsy are two varieties. The first occurs chiefly in syphilitic subjects. One nerve becomes affected and partially recovers; the other one then becomes paralyzed, and partially recovers, relapses, and so on. The internal muscles may be involved.

Recurring or periodic palsy, the *migraine ophthalmique* of Charcot, is a rare form (p. 1138). It occurs in both sexes, but women are especially susceptible. It may begin in infancy and recur at intervals for years, the attacks being periodic, lasting a few days to six or eight weeks, and ending in complete recovery. They may be precipitated by some emotional disturbance, by menstruation, or by exhaustion. Their exact nature is not understood, but they resemble migraine in that there is severe headache or pain, usually over one eye, and in their association with vomiting.

Generally paralysis of the extra-ocular muscles is partial, and the symptoms will vary according to the muscles affected. When they are all involved there are ptosis, divergent strabismus, diplopia, and dilated pupil, with loss of the light reflex and accommodation.

Intra-ocular Paralysis.—(a) **Cyclopegia**, or ciliary muscle paralysis, gives rise to a loss of the power of accommodation, so that "far-sight" is good, while "near-sight" is blurred and indistinct. This can be corrected by a convex

glass. Bilateral cycloplegia is often due to a nuclear lesion. It occurs most frequently as a symptom of neuritis following diphtheria.

(b) **Iridoplegia.**—The pupil may be dilated (*mydriasis*) from palsy of the sphincter or spasm of the dilator, or it may be contracted (*myosis*) from the antithesis of the above.

The iris has three actions—two reflex and one associated: First, a reflex contraction of the sphincter on exposure of the eye to the light; second, a reflex dilatation of the radiating fibers on stimulation of some cutaneous nerve; and, third, a contraction on accommodation, usually, but not necessarily, associated with convergence (Gowers).

First, light-reflex iridoplegia. The iris reflex is lost in locomotor ataxia, in general paresis, and occasionally in disease of the peripheral portion of the third nerve, and sometimes also in syphilis. Accommodation and convergence are, however, usually preserved (*Argyll Robertson pupil*). When these also are lost the condition is termed *ophthalmoplegia interna* (see p. 1035).

In testing this reflex care must be taken to avoid the contraction of accommodation. The patient should look at a remote part of the room; then a light is brought suddenly in front of and 3 or 4 feet distant from the eye. One eye should be examined at a time, the other being covered, but not closed.

Second, skin-reflex iridoplegia. Normally, painful stimulation of the skin of the neck causes reflex dilatation of the pupil (pupillary skin-reflex), the afferent impulse being carried along the sympathetic. In locomotor ataxia myosis often exists. In such cases Erb showed that the skin-reflex was lost (*spinal myosis*).

Third, accommodation iridoplegia, in which the power of accommodation is lost. The pupil does not become smaller when looking at near objects. Westphal and Piltz have recently discovered independently that in certain pathologic conditions the pupil contracts strongly upon closure or attempted closure against resistance of the eyelids. This reflex occurs most constantly in general paresis. Its exact significance is not known.

II. The **fourth nerve**, or **patheticus**, the smallest cranial nerve, supplies the superior oblique muscle. Its superficial origin is to the outer side of the crus cerebri, just in front of the pons. The fibers can be traced backward to the valve of Vieussens, in the substance of which it decussates with its fellow. Its deep origin is in a nucleus in the floor of the aqueduct of Sylvius, immediately behind and in close connection with the third-nerve nucleus. After piercing the dura mater the nerve runs along the outer wall of the cavernous sinus and enters the orbit through the sphenoid fissure. Since the superior oblique muscle directs the eyeball downward and rotates it, paralysis causes defective downward and inward movements, and consequent diplopia with inclination of the head forward and to the sound side. When occurring alone it is probably due to a nuclear lesion.

III. The **sixth nerve**, or **abducens**, has its deep origin in the floor of the fourth ventricle in close proximity to the seventh-nerve nucleus. Its superficial origin is from the lower part of the pons, in the groove between it and the medulla. Emerging, it pierces the dura, runs along the cavernous sinus, and enters the orbit through the sphenoid fissure to supply the external rectus. Owing to its long course, this nerve is specially liable to injury, usually from pressure due to tumors or from syphilitic or other forms of meningitis. Paralysis of the muscle causes convergent strabismus and consequent diplopia, owing to an inability to rotate the eye outward. If the nucleus is involved there will be loss of associated lateral movement of the eyes to the side of the lesion (that of the sixth-nerve palsy). This is due to the fact that when it is desired to make such a movement the impulse is sent from the

cortex of the opposite side to the sixth-nerve nucleus and hence through the posterior longitudinal bundle to that part of the third-nerve nucleus of the other side that controls the internal rectus (p. 1010). Conjugate deviation, the eyes being directed away from the side of the lesion, may also be observed.

In such cases when the eye with the paralyzed external rectus is covered, the opposite internal rectus will act, though less readily than normally. Independent contraction of the internal rectus is controlled alone by the third-nerve nucleus. Conjugate deviation also occurs in supranuclear lesions, as in apoplexy (p. 1094); if irritative, the deviation is away from the side of the lesion; if paralytic, toward it.

General Symptomatology of Paralysis of the Eye-muscles.

—Loss of power in the ocular muscles is indicated by five kinds of symptoms (Gowers): (1) *Limitation of Movement*.—The amount of limitation in the movement of the eyeball is in direct ratio to the degree of palsy. In complete palsy the globe is ultimately fixed, owing to contraction of the unopposed muscle. In partial paralysis, as the limit of movement is approached the motion is often jerky (*paralytic or pseudonystagmus*—p. 1032).

(2) *Strabismus*.—Owing to defective movement the axes of the eyes do not correspond. "The deviation of the axis of the paralyzed eye from parallelism with that of the sound eye is termed the 'primary deviation.'"

(3) *Secondary Deviation*.—"If the sound eye is prevented from seeing the object, and the patient looks at this (is made to 'fix' it) only with the affected eye, the sound eye is moved still farther in that direction, and hence the deviation of the visual axes is increased. This is called the 'secondary deviation,' and depends on the fact that two muscles normally acting in unison are equally stimulated (innervated) for any given movement. When one is weak, the amount of nerve force employed to move the sound eye acts equally on the impaired eye, and hence the overaction. In paralytic strabismus fixation with the sound eye shows the primary deviation, while fixation with the affected eye reveals secondary deviation. In ordinary strabismus due to spasm this does not hold good; it matters not which eye is used, deviation remains the same."

(4) *Erroneous Projection*.—We judge of our relation to surrounding objects by the position of the eyeball as indicated to us by the degree of stimulation necessarily brought to bear on the ocular muscles. When one of these muscles is weak, the additional stimulation (innervation) necessary to move it in fixing an object impresses us with the idea that it is really farther away than is actually the case, and in attempting to touch it the finger goes beyond. This erroneous projection, or interference of visual sense impressions, causes a disturbance of equilibrium and gives rise to vertigo, which has been named "ocular vertigo."

(5) *Double Vision*.—This is not due alone to a difference in the axis of vision, causing images on non-corresponding portions of the retina, but also to the erroneous projection. "If the patient looks with both eyes, the field of the unaffected eye, being normally projected, does not correspond with the field of the affected eye; the images formed in the two eyes are mentally referred to different positions; objects are seen double" (Gowers). The "true image" is that one formed in the sound eye, while the retina of the affected eye receives the "false image." The symptom is known as *diplopia*.

Homonymous or simple diplopia is that in which the false image appears on the "same side of the other as the eye by which it is seen." This is due to paralysis of an abductor muscle—*convergent strabismus*. *Crossed diplopia* occurs in divergent strabismus, the result of paralysis of an adductor. The false image appears to be on the other side of the real object—*i. e.*, toward the sound eye.

Gowers' mnemonic is, "When the visual lines (prolonged ocular axes) cross, the diplopia is not crossed."

Ophthalmoplegia, a paralytic condition of the eye muscles, may be partial or complete. Either the internal or the external muscles may be involved, constituting *ophthalmoplegia interna* or *externa*, and, when both are affected, total ophthalmoplegia. The lesion may be due to disease either of the nerve trunks or nuclei. The former may be due to some infectious disease, as diphtheria; excessive use of alcohol, arteriosclerosis; traumatism, causing either fracture at the base of the skull or hemorrhage into the region of the nerves; pressure of an aneurysm of a cerebral blood-vessel, basal meningitis, especially if syphilitic, and tumor. The latter may also be due to infectious diseases and excessive use of alcohol. Chronic lead-poisoning may also cause it, and it may be an early manifestation of either tabes, paresis, disseminated sclerosis, or cerebral syphilis. Tumors, inflammation within the orbit, or fractures involving it, and thrombosis of the cavernous sinus may also be causes of a more or less complete ophthalmoplegia. If acute, the condition may be due to a hemorrhage in the region of the nuclei, or an embolus or thrombosis in a branch of the basilar artery, or an inflammation of the nuclei, due either to infection or intoxication, as mentioned above (polio-encephalitis superior of Wernicke). Symptoms of bulbar palsy may coexist in chronic nuclear degenerations.

The **symptoms** vary necessarily according to the muscles involved. The eyes fail to follow objects and the face acquires a peculiar expression ("Hutchinson face").

The **treatment** consists in the removal of the cause when possible. When known to be due to syphilis, either salvarsan or neosalvarsan should be administered, and repeated at intervals of a week or two until at least six injections have been given or the Wassermann reaction in the cerebrospinal fluid is negative. Mercury and the iodids must be given in the intervals and for some time after the last injection. It is well to use the latter in any case in which the etiology is doubtful. In inflammatory cases counterirritation is employed by blisters placed on the temples, behind the ears or at the occiput, or by leeches. Internally, the salicylates, mercury, iodids, and general tonics are useful. Rarely a case will recover spontaneously. Electricity is probably of little value. The diplopia, unless it can be obviated by a suitable lens, should be met by means of an opaque glass placed over one eye.

DISEASES OF THE FIFTH NERVE

The trigeminus nerve has an extensive origin from the floor of the fourth ventricle. It supplies with sensation the whole region innervated by all the other cranial nerves except the first and second. It resembles a spinal nerve in that it has two roots, a motor and sensory, and on the latter a ganglion (*gasserian*). From the latter arise three sensory branches—viz., the ophthalmic, superior maxillary, and inferior maxillary. A motor root joins the last named, the largest branch of the fifth nerve.

Morbid conditions of the fifth nerve cause sensory, motor, or gustatory symptoms. The lesion may be: (1) Pontine hemorrhage, softening, sclerosis, or tumor. (2) Disease or injury at the base of the brain—*e. g.*, meningitis, gumma or other tumor, caries of bone. (3) Disease or injury of the branches, as neuritis, pressure due to aneurysm of the internal carotid or to a tumor in the cerebellopontile angle or sphenomaxillary region, orbital cellulitis, and punctured wounds of the mouth and nose. (4) Rarely fracture of the skull. (5) Diseases of the gasserian ganglion.

Symptoms.—Sensory Portion.—In the irritative stage the chief feature is pain; this may be shooting, boring, or burning in character. Tender-

ness along the course of the nerve and hyperesthesia may also exist. Later, anesthesia develops in the distribution of some or all of the branches in the skin of the face and in the mucous membrane of the nose, mouth, lips, tongue, and, in some cases, of the hard and soft palate also, but pressure sense is not interfered with. The occurrence of such anesthesia, associated with pain, indicates an organic lesion, usually of the ganglion, as distinguished from a functional neuralgia (p. 1018). Such symptoms may be due to bulbar tabes.

The secretions are often increased, though at first they are lessened; hence the anosmia, due to dryness of the nasal mucosa. Loss of sense of taste may also occur. Other trophic changes are: inflammation and ulceration of the gums, looseness of the teeth, and inflammation of the eye. Corneal opacities, ulceration, sometimes perforation, and finally complete destruction of the eye—neuroparalytic ophthalmia—are noted. This is especially apt to occur when the gasserian ganglion is involved. Painful and intractable herpes may develop. Hemifacial atrophy may result from disease of the fifth nerve (Mendel).

Motor Portion.—*Paralysis.*—Partial or complete inhibition of the movement of the muscles in the region supplied—*i. e.*, those of the jaw, the masseter, temporal, pterygoid, mylohyoid, and the posterior belly of the digastric. The degree of palsy can be ascertained by placing a finger on each masseter or temporal muscle while the patient alternately opens and forcibly closes the mouth. In external pterygoid paralysis movement toward the sound side is impossible, and on depression of the lower jaw it deviates toward the affected side. Ultimately wasting of the muscles takes place.

Spasm (the so-called “masticatory spasm” of Romberg) may be tonic or clonic. In tonic spasm—trismus or lockjaw—the jaw is firmly set and the muscles are hard, rigid, and sometimes painful. This occurs in tetanus, in certain cases of tetany and hysteria, in caries of the teeth, occasionally after exposure, and in irritative centric or peripheral lesions. Clonic spasm is more or less continuous or intermittent. The former consists of short, quick, vertical, or (rarely) lateral movements (*e. g.*, gnashing of the teeth), usually associated with some other condition, as paralysis agitans, general convulsions, and the like, or it may exist alone, especially in women late in life. The intermittent form is rare and occasionally occurs in chorea. Contractions are single, forcible, and are separated by some little time. The tongue and cheeks may be bitten in the attack. (See Tic, p. 1144.)

Gustatory Portion.—*Symptoms* referable to this portion are not always present in disease of the fifth nerve. Many neurologists do not believe that gustatory sensations are transmitted by it, the glossopharyngeal (p. 1043) being believed by them to be the nerve of taste. If the fifth does take part in this function, it does it for the anterior two-thirds of the tongue. There may be a loss of taste without sensory disturbance, or *vice versâ*, or both may exist contemporaneously. Lesions of the nerve-root or middle-ear disease may cause it, but pontine lesions, as a rule, do not. It occurs in paralysis of the seventh nerve if the lesion is in the facial canal, due to involvement of the chorda tympani. A perverted sense of taste—*parageusia*—may be present in hysteria and insanity. Increased sensitiveness—*hypergeusia*—and subjective sensations of taste may result from irritative lesions, and the latter may precede an attack of epilepsy (as an aura).

The **diagnosis** is not difficult as a rule. Anesthesia in the area supplied by the nerve, with pain, is in favor of organic disease, the nature of which must be determined by the accompanying symptoms. Spasm may be simulated in cases of rheumatism or rheumatoid arthritis involving the temporomaxillary articulation.

Treatment.—The underlying cause should be attacked when possible. Salvarsan, mercury, and the iodids should be administered in specific cases and the salicylates in those due to exposure. Analgesics, and even opiates, may be necessary. Sometimes vigorous counterirritation is of value. Attention must be paid to the condition of the general system.

DISEASES OF THE SEVENTH OR FACIAL NERVE

The nucleus of this nerve in the floor of the fourth ventricle is in relation with those of the sixth, eighth, and twelfth nerves. Like the spinal nerves, it has an upper and a lower neuron or motor segment, the former extending from the cortical center in the lower Rolandic region to the nucleus, while the latter runs from the nucleus to the periphery. Lesions may involve any part of the tract, producing either spasm or paralysis.

Spasm.—This may be either general or partial, affecting only the orbicularis palpebrarum (*blepharospasm*). It is sometimes called *tic facialis* or mimic spasm (p. 1144).

Etiology.—The commonest causes are peripheral irritations, and particularly those that involve the trigeminus, as carious teeth, conjunctivitis, or some nasal irritation. Less frequently irritation in some other part of the body, as intestinal parasites or uterine disease, may be the exciting cause. Finally, there may be lesions in any part of the motor tract supplying the face, either in the cortex (meningeal tumor, exostoses, or focal softening), when it becomes one of the manifestations of the jacksonian convulsion; in the facial nucleus in the lower part of the pons; along the course of the facial nerve (aneurysm or atheroma of the vertebral artery, tumor in the cerebellopontile angle); and as a sequel of peripheral paralysis of the nerve (Bell's palsy). Morbid changes in the nerve itself or in the muscles have not been observed.

The **symptoms** of the disease include, first, the *spasm*: this is usually a sudden clonic convulsion of the muscles of one side of the face, with closure of the eyelids and retraction of the angle of the mouth. Rarely there are associated movements of the palate and eyeballs. The spasms may be single or they may occur in groups frequently repeated, or recur constantly at more or less irregular intervals. Less frequently the contraction may be tonic in character, lasting several seconds or even minutes. These forms are frequently associated with clonic spasms. Ordinarily the spasm is painless. Sometimes there is also *tinnitus aurium*. Occasionally edema of the face, especially in the orbital region, occurs. The immediate exciting cause of an attack may be fatigue or excitement, or it may occur as an associated movement, as in a case that I observed, in which spasm always accompanied the beginning of speaking.

The **diagnosis** must be made from *tic* (p. 1145). It may be occasionally confounded with *chorea*, especially when the latter is chiefly localized in the face, or with *athetosis* due to infantile brain lesions. In the former the movements are not so quick nor confined exclusively to the anatomic distribution of a certain nerve; in the latter hemiplegia will usually coexist (p. 1101). In fact, *athetosis* is a spasm. Recognition of the cause is often very difficult, and a careful examination of the whole body should be made for any possible source of irritation.

The **prognosis** is extremely unfavorable for cure, since only in cases of recent occurrence, and with a distinct source of peripheral irritation, is permanent recovery likely.

The **treatment** consists in the removal of any source of irritation and the application of electricity, particularly the mild galvanic currents, with the

anode over the nerve. Patrick¹ has injected alcohol into the region of the nerve at the stylomastoid foramen with success. The use of antispasmodics, as conium, gelsemium, morphin, and the bromids, may give temporary, but rarely permanent, relief.

Paralysis.—Depending on the seat of the lesion, we have—(a) supranuclear, (b) nuclear, and (c) infranuclear palsy. The following table presents the general differences between upper and lower neuron palsy:

SUPRANUCLEAR PARALYSIS	NUCLEAR AND INFRANUCLEAR PARALYSIS
The upper part of the face is not affected, the muscles of the angle of the mouth being chiefly concerned.	All parts of the face involved, including the orbicularis and frontalis. Nuclear palsies are sometimes incomplete.
Voluntary movements are more impaired than the emotional.	Voluntary and emotional movements equally affected.
All reflex movements are normal.	All reflex movements are lost.
Electric reaction is normal, or only slightly impaired to both galvanic and faradic currents.	Reactions of degeneration are present.

(a) *Supranuclear paralysis* is generally associated with hemiplegia, the palsy of face and limbs being on the same side—i. e., opposite the lesion, which may consist of a hemorrhage, tumor, abscess, softening. It may be the result of injury, and may be situated in the cortex, corona radiata, or the internal capsule. When the cortical face center is alone involved, the limbs escape (*monoplegia facialis*). This form is rare.

(b) *Nuclear paralysis* is due to hemorrhage, tumor, or softening at the site of the nucleus in the pons, in which case paralysis of the arm and leg of the opposite side frequently coexists. It may also result from an attack of diphtheria, and very rarely occurs in cases of anteropoliomyelitis (polioencephalitis). It most commonly occurs in connection with the involvement of the motor nuclei of the ninth and tenth nerves and the nucleus of the twelfth in the disease known as glossolabiolaryngeal paralysis or chronic bulbar palsy. As already noted, the symptoms are similar to those of infranuclear paralysis, but the affection is usually bilateral (*supra*).

(c) *Infranuclear paralysis* is caused by pressure on the nerve at the base of the brain by tumors, meningitis, aneurysm, or hemorrhage. In the facial canal the nerve may be damaged by bone disease or some form of otitis. This is the seat, too, of the so-called "rheumatic neuritis," the result of exposure or infection (Bell's palsy).

Fracture of the base of the skull or injury to the nerve as it emerges from the stylomastoid foramen may result in facial palsy. *Diplegia facialis* is rare, but may be caused by a single lesion in the pons, where the facial paths cross, or by two lesions, one on either side. The causes enumerated above, when bilateral, beget double facial paralysis.

Lesions in the lower part of the pons may result in crossed hemiplegia, the fibers being involved in their course between the nucleus and the point of emergence of the nerve, the side of the pons. The face will be paralyzed on the same side as the lesion, since this latter is below the decussation of the facial tracts, and involves the outgoing nerve, together with opposite hemiplegia (Fig. 70). In alternate or crossed hemiplegia the facial palsy is of the infranuclear type, while in ordinary hemiplegia the supranuclear type is met with. Certain symptoms of nerve irritation may precede the actual palsy or may be concomitant, such as slight pain and tenderness, some swelling in front of the ear, muscular twitching, and occasionally vertigo.

¹ *Jour. Nerv. and Ment. Dis.*, January, 1909.

Symptoms.—The affected side is immobile and expressionless, and the normal lines are diminished or abolished. This is seen most markedly in those above middle life. The eye cannot be closed, owing to weakness of the orbicularis palpebrarum, and, as the tears are not directed into their proper channel, the eye waters. Voluntary and emotional movements are lost. Whistling and smoking are performed with difficulty, if at all; if the cheeks are puffed out, air escapes upon the paralyzed side; food collects between the teeth and cheek, owing to paralysis of the buccinator; in drinking the patient inclines the head to the sound side to prevent escape of the liquid from the corner of the mouth. The dilator naris is paralyzed; hence sniffing is interfered with, and the sense of smell is diminished on that side.

When the tongue is protruded it seems to be drawn toward the palsied side. This is not the case, however, the effect being due to contraction of the unopposed muscles on the sound side of the face. All reflex movements are lost. The palate is not affected and sensation is not impaired. When the nerve is involved between the *intumescentia gangliiformis* and the origin of the chorda tympani—i. e., within the facial canal—taste is lost in the anterior part of the tongue, and there is some diminution in the secretion of saliva. When other parts of the nerve are diseased, taste is not interfered with. Hearing may be increased, owing to paralysis of the stapedius, with consequent unopposed action of the tensor tympani. When due to middle-ear disease and in disease of the base of the brain, involving both facial and auditory nerves, hearing is lessened. In the latter, however, bone conduction will be either diminished or lost. Some degree of wasting takes place in the affected muscles, and both quantitative and qualitative electric changes quickly follow the palsy. If the *intumescentia gangliiformis* is involved, we may have herpes of the auricle and neuralgic pains in the ear in addition to paralysis. This may also occur without paralysis.

The duration of an attack varies from a few days to several months or a year, and in rare cases it is permanent. The onset is usually acute, and the acme of the attack may be reached in from a few hours to a couple of days.

Diagnosis.—From the table previously given it will be easy to differentiate supranuclear from infranuclear palsy. When contractures have taken place, owing to the furrows thus produced the affected side may be taken for the sound side, but on getting the patient to whistle the true state of affairs will manifest itself.

Prognosis.—In the rheumatic cases and those due to middle-ear disease recovery usually occurs in from six weeks to three months. Permanent contractures and deformity sometimes associated with clonic spasm may result.

Treatment.—Search for the cause. If ear disease is present, make provision for free drainage; if syphilis, give salvarsan, with iodid of potash, and mercury. In cases due to cold, the so-called rheumatic palsies, counterirritation is especially called for, and cantharidal collodion, fly-blisters, or the actual cautery behind the ear or over the occiput are very useful. The bowels should be freely opened, and diaphoretics or hot baths, alkaline diuretics, and salicylates administered; in the inflammatory stage small doses of mercury are of value, and later mercuric iodid or general tonics. After the acute symptoms have subsided (in about ten days), galvanism should be employed to stimulate the nerves and to help in maintaining the tone of the muscles. When contractures threaten in the late cases the use of electricity should be dispensed with. When the paralysis has become permanent, benefit can sometimes be rendered by transplanting parts of either the hypoglossal or spinal accessory motor nerves into the trunk of the facial peripheral to the lesion.

DISEASES OF THE AUDITORY NERVE

The eighth nerve has its deep origin in the medulla. It consists of two parts: the cochlear, which has to do with hearing, and the vestibular, which has to do with maintaining of our relation to space, or, in other words, our equilibrium. The auditory fibers decussate in the region of the nuclei, passing in the posterior extremity of the internal capsule to the opposite hemisphere. The cortical center is in the temporosphenoidal lobe (first and second convolutions, Fig. 67). It is also connected with the medial geniculate body and posterior corpora quadrigemina; the vestibular branch, in addition, is connected with the cerebellum. Destruction of the cortical center of the left side results in *word-deafness* (p. 1002). Rarely the auditory tract may be involved between the cortex and the nucleus. The nerve may be implicated at the base of the brain by tumors of the cerebellopontile angle, aneurysms, hemorrhage, meningitis, and traumatism. Erb has described a primary nerve degeneration in *tabes dorsalis*. Disease may attack the labyrinth, either primarily or secondarily to middle-ear disease, which, if confined to the cochlear division, causes deafness, and, if to the vestibular branch in the semicircular canals, vertigo (*infra*). If both branches are involved, deafness and vertigo coexist. Drugs—quinin, apiol, salicylates—may cause deafness similar to the labyrinthine variety. In anemia and in other conditions in which the general health is below par, also in hysteria, hearing may be affected. The lesions give rise either to an increased or diminished sense of hearing.

(a) *Hyperacusis*, in which certain or all sounds are intensified. Paralysis of the stapedius muscle causes low notes to be heard with great intensity. Auditory hyperesthesia may also occur in hysteria or during the course of cerebral or general disease.

(b) *Dysacusis*—difficult hearing—may be due to middle-ear disease, or it may exist as a “nervous deafness,” the result of labyrinthine or nerve disease. These may be differentiated by means of the tuning-fork. Normally, air-conduction is better than bone-conduction, and if in a deaf person a tuning-fork can be heard vibrating longer when held against the skull vault or temporal bone than in front of the ear, there is some impairment of conduction in the meatus or middle ear. When the patient is deaf, and yet the normal relation is maintained between air- and bone-conduction, the labyrinth or the nerve is at fault.

(c) *Tinnitus aurium*—irritation of the auditory nerve—a condition in which subjective sounds occur, such as whirring, buzzing, ticking, or ringing in character. In certain subjects they are worse at night than during the day, and at times they are paroxysmal; as a rule, in any case they are intensified when the general system is below par.

Tinnitus may be caused by anemic or depraved nutritional states, high blood-pressure, intracranial aneurysm, pressure on the cervical sympathetic by enlarged glands, tumors, or aneurysm, impacted cerumen, otitis media, labyrinthine disturbance, blows upon the head, excessive auditory stimulation, loud noises, or it may occur during an attack of migraine or as an epileptic aura. In a neurasthenic individual the subjective noise, no matter what the cause, will be accentuated. The more complex and elaborate the sound, the greater the probability of its being of central origin.

Treatment.—Careful search must be made for the cause of any of these morbid conditions just described, and, when practicable, they should be removed. The system should be brought into as good a condition as possible. In hyperesthesia bromids occasionally avail. In dysacusis little can be done when the cause is labyrinthine. The same is true when the nerve or its centers are involved. For tinnitus, counterirritation and electricity may be tried

externally, and iodids internally, but with little hope of relief; in addition, sedatives, as the bromids, are generally called for, and even morphin may be necessary in paroxysmal attacks. Occasionally a single large dose of pilocarpin (gr. $\frac{1}{10}$) may give relief for some time. Operation has been resorted to (p. 1043).

(d) *Vertigo or dizziness*, is due to disease or disturbance of either the internal ear or its intracranial pathways. According to Jones and Fisher¹ these are as follows: The fibers from the horizontal semicircular canals pass through the eighth nerve, enter the brain stem at the junction of the medulla and pons, and run to Deiter's nucleus. There they divide into two pathways, one of which passes through the posterior longitudinal bundle in the pons to the nuclei of the eye muscles. It is concerned in the production of nystagmus and is known as the vestibulo-ocular tract (p. 1032). The other, known as the vestibulocerebellocerebral tract, is responsible for vertigo. Its course is from Deiter's nucleus, through the inferior cerebellar peduncle, to the cerebellum (three vestibular cerebellar nuclei). From here it passes upward through the superior cerebellar peduncle, crus, and thence to the cerebral cortex of both sides, but principally the opposite. The cortical center is believed by Mills to be in the posterior portion of the second temporal convolution. This center is connected with other parts of the cortex, especially the frontal lobe.

From the vertical semicircular canal the fibers, after passing through the eighth nerve, ascend in the pons to a point above its middle, where, at an undetermined cell nest, they divide into two pathways, one of which becomes part of the vestibulo-ocular tract and the other (vestibulocerebellocerebral tract) passes through the middle cerebellar peduncles to the cerebellar nuclei above mentioned of the same side. From here their course is similar to those from the horizontal canal.

Disturbances of this apparatus may be due to a number of causes, either functional or organic..

1. *Visual defects*, as loss of muscle balance or eye-strain.
2. *Disease of either the middle or internal ear* (p. 1042).
3. *Organic disease of the brain*, especially if any part of the tracts above mentioned is involved.
4. *Toxemia*, as alcohol, tobacco, quinin, salicylic acid, auto-intoxication from constipation, etc.
5. *Derangement of the cerebral circulation*, as in anemia, cardiac weakness, and arteriosclerosis.
6. *Neuroses*, as neurasthenia and hysteria.
7. *Obstruction of the nasal passages and sinuses*.
8. *Acute vertigo* may be due to swinging, sea-sickness, rapid rotation of the body, looking down from great heights, blows on the head, and passing an electric current through it.
9. A *hereditary form* has been described.

Vertigo may be *subjective*, in which the patient feels as if he were whirling about, and *objective*, in which objects seem to move about the patient.

It is frequently accompanied by nystagmus (p. 1032), mental confusion, pallor, and nausea and vomiting.

To determine if the vertigo depends upon organic disease and also its location the turning, caloric, and pointing tests of Bárány are used. These depend upon the facts that in a normal person either whirling the patient about or syringing the external ear with water of certain temperatures causes nystagmus and vertigo. If the lesion is a distinctive one of the internal ear or eighth nerve both of these phenomena together with hearing are lessened or absent. If the vestibulo-ocular tract is interfered with nystagmus will be absent, but vertigo

¹ *Pennsylvania Med. Jour.*, December, 1916, pp. 174-178.

will be present. If nystagmus is present and vertigo absent the lesion is in the vestibulocerebellocerebral tract. Vertigo in these tests is indicated by the presence or absence of past pointing. This depends on the fact that normally with the eyes closed one can locate a point in space which he has previously touched or seen the location of. If vertigo is present the patient cannot locate this point, as he loses his relation to it, and he points to one side or the other of it, and is said to "past point."

The researches especially of Jones and Fisher of the University of Pennsylvania have enabled them by these tests to make very helpful deductions in determining, in a given case of vertigo, the cause and location of the lesion, to detail which there is not space here. Certain of them are mentioned under Tumors of the Pons and Cerebellum.

A form of aural vertigo known as Ménière's disease demands special mention.

MÉNIÈRE'S DISEASE

Definition.—An aural or labyrinthine vertigo—originally described by Ménière in 1861; the cardinal symptoms are vertigo, deafness, noises in the ear, and sometimes vomiting.

Pathology.—There may be an inflammation or atrophy of the nerve-endings. There are also changes in the labyrinthine membrane from any cause or from hemorrhage.

Etiology.—Ménière's disease is most common after thirty, and is rarely met with before that age. It is twice as common in men as in women. The precise lesion is labyrinthine, and is the result of exposure, gout, syphilis, senile change, congestion, and, more rarely, hemorrhage. Any cerebral disturbance or gastric or other irritation is apt to induce an attack.

Symptoms.—Vertigo is present, and varies from an extremely slight transient attack, and one that is entirely subjective, to one of almost explosive violence. The patient may have a sensation of having been struck, and then of falling heavily to the ground. The slight form may be continuous with more or less frequent severe attacks, or a complete intermission of days, weeks, or months may transpire. The attacks may arise without apparent cause, or as a result of a blow or even a sudden movement, and occur during both working and sleeping hours. The giddiness, when severe, causes nausea and vomiting, and, if prolonged, bile is vomited as in ordinary bilious attacks. When the attack is very acute momentary unconsciousness supervenes. Nystagmus and diplopia may occur during an attack. Tinnitus and deafness usually exist together, the former may be either mild or very severe. It is usually constant, and possibly worse during an attack; it may be entirely absent between the attacks. The latter (nervous deafness) is constant and of varying severity in different individuals.

Diagnosis.—The occurrence of vertigo and tinnitus in a person with more or less nervous deafness, with or without gastric symptoms, establishes the diagnosis. The tinnitus and the character of the deafness usually suffice to distinguish this from other forms of vertigo. Vertigo and deafness may also be caused by middle-ear disease, but in such a case examination (p. 1040) will show that the deafness is not of nerve origin. Similar symptoms may also be caused either by a growth or patch of meningitis situated in the cerebellopontine angle. In such a case other symptoms of brain tumor or meningitis will be present, and the seventh nerve is also usually affected. In epilepsy with auditory auræ the period of unconsciousness is generally much longer, and on regaining consciousness the patient is dull and drowsy for some time. It is possible also, as a rule, to elicit a history of convulsions.

Prognosis.—In some cases the condition grows progressively worse until deafness supervenes, when it ceases. Often, however, arrest or improvement, or even complete recovery, may be secured. In heart disease the shock may prove fatal, and in the very acute but, fortunately, rare cases the prognosis is always bad.

Treatment.—Counterirritation over the mastoid process and the internal use of bromids to lessen the morbid sensibility will prove valuable. The emunctories must be gotten in good condition, and any underlying disease, as arteriosclerosis, syphilis, or gout, must be treated. Charcot suggested the use of drugs that produce tinnitus—quinin, for instance. The cases were worse at the time, but some of them seemed to improve subsequently. Gowers employs sodium salicylate in 5-gr. (0.324) doses, thrice daily, believing that more good arises when such drugs are given in moderation. Small doses of pilocarpin sometimes do good. Nitroglycerin and the nitrites are sometimes of value in cases associated with arteriosclerosis. Division of the auditory nerve has cured some cases.¹

DISEASES OF THE GLOSSOPHARYNGEAL NERVE

The ninth cranial nerve has its origin in the posterior part of the floor of the fourth ventricle, in close relation with the pneumogastric nerve. Our knowledge as to its function is not exact, both because it is seldom if ever involved alone, and also, on account of its many connections (with the trigeminus, the facial, the pneumogastric, and the sympathetic nerves), it is difficult to say whether the terminal fibers involved represent the functions of its roots or of one of its connections (Gowers).

Its fibers are distributed to the tonsils, the back of the tongue, the soft palate, the pharynx, the Eustachian tubes, the tympanic cavity. It supplies both motor and sensory fibers, it is also the nerve of taste, certainly for the posterior portion of the tongue, and possibly, by means of connections with the fifth nerve, for the anterior as well. This nerve is involved in the nuclear degenerations that are spoken of as bulbar palsies. It may also be affected by meningitis or new growths.

DISEASES OF THE PNEUMOGASTRIC NERVE

As already stated, the origin of the tenth cranial nerve is in intimate relation with that of the ninth. It is also continuous below with that of the eleventh, and all three are associated with the center for the hypoglossal nerve. The nerve proper arises from the side of the medulla, and runs on either side of the neck in the sheath of the carotid artery, lying behind that vessel. It enters the thorax in front of the subclavian artery on the right side, and between the subclavian and the carotid on the left; then it courses beside the esophagus, and is distributed to the pharynx, larynx, lungs, heart, esophagus, and stomach, and sends fibers to the intestines and spleen.

The esophageal fibers are both motor and sensory, gastric fibers being chiefly sensory. The vagus is in part the motor nerve of the intestines. It also contains both accelerator and inhibitory fibers for the respiratory center, is the cardiac inhibitory nerve and a vasodilator, and is said to contain trophic fibers for the heart and lungs.

Etiology.—The nerve may be involved at its nucleus either by hemorrhage or softening. The nuclei of the ninth, eleventh, and twelfth nerves, and frequently the seventh are simultaneously attacked, either wholly or in

¹ Ballance, *The Lancet*, 1908, vol. ii.

part, giving rise to a group of symptoms known as *bulbar palsy*. The tenth nerve at its superficial origin may be compressed by neoplasms, aneurysms, and the products of *meningitis*; in its course down the neck it may suffer pressure, or may either be tied in ligating the carotid artery or cut in the removal of a tumor or enlarged glands. Very rarely it may be injured by incised or punctured wounds, or be the seat of neuritis due to exposure or to some toxemia. The morbid conditions of the pneumogastric are best studied by considering the branches of distribution separately.

(a) **Pharyngeal Branches.**—The muscles and mucous membrane of the pharynx are supplied by branches of the pneumogastric and glossopharyngeal nerves, constituting the pharyngeal plexus. The pharynx may be the seat of spasm of paralysis: this is purely a "functional" condition, and usually occurs in hysteric (*globus hystericus*) or in nervous individuals.

Paralysis of the pharynx causes difficulty in swallowing, so that food remains in the mouth instead of being passed into the esophagus. Particles often enter the larynx and give rise to paroxysms of coughing, and at times cause choking. When the soft palate is also paralyzed, the food is regurgitated into the nose. The lesion is generally nuclear. The root of the nerve may be involved as it leaves the side of the medulla by meningitis or by pressure from a neoplasm or an aneurysm. It may also be caused by a toxic neuritis, as in diphtheria.

(b) **Laryngeal Branches.**—The superior laryngeal nerve furnishes sensory fibers to the mucous membrane of the larynx above the vocal cords, and supplies also the cricothyroid and epiglottidean muscles. The inferior or recurrent laryngeal nerve, which takes its origin in the superior thoracic region, winds around the arch of the aorta on the left side and around the subclavian artery on the right, reaching the larynx by running up between the trachea and esophagus. It is the sensory nerve of the larynx below the vocal cords, also of the entire trachea, and supplies all the muscles of the larynx except those named above. It has been shown that the motor fibers of the larynx come from the glossopharyngeal nucleus, the pneumogastric fibers being sensory.

Spasm of the larynx is due to overaction of the glottis-closers (the adductors), though some cases described in this category are probably instances of abductor paralysis. The condition is rather rare in adults, but quite common in children (*laryngismus stridulus*), and particularly in rachitic subjects. An attack may also be induced in those predisposed by any form of nerve irritation or catarrhal condition of the respiratory tract. It may be part of a general neurosis; it is sometimes seen in *tabes dorsalis* (*laryngeal crisis*); and Liveing reports that he has seen it take the place of an attack of migraine. *Spastic aphonia* consists of a spasm induced whenever an attempt to speak is made. Laryngeal spasms occur most frequently at night. Dyspnea is the most striking symptom, and is so intense in some cases that suffocation seems imminent. The patient may be cyanotic. Soon the retained carbonic acid gas causes relaxation, but, as the cords open slowly, the inspiration is accompanied by a crowing sound, and the expiratory sound is harsher than normal.

Paralysis of the larynx may be the result of a nuclear degeneration (glossopharyngeal), as in chronic bulbar paralysis; this form may occur in disseminated sclerosis, *tabes dorsalis*, general paralysis of the insane, and in certain toxemias. The paralysis is generally bilateral; rarely it is unilateral.

A cerebral lesion in the laryngeal cortical center may cause pseudobulbar paralysis. Since the two centers are compensatory, the lesion must be bilateral. This may also be caused by capsular lesions (p. 997).

The nerve may be involved at its root or in any part of the trunk, and such lesions are usually unilateral. The recurrent laryngeal nerve, especially the left, is more apt to be diseased than the superior, on account of its position. Thus, the arch of the aorta is more frequently the seat of an aneurysm than the subclavian; enlarged thoracic glands, neoplasms, and an enlarged thyroid can also damage these nerves. The peripheral filaments may be attacked as part of a multiple neuritis.

In certain cases the muscles become weakened without being paralyzed, this possibly being due to a local neuritis, or to a congestion and inflammation of the mucous membrane from overuse (*clergymen's sore throat*), or as the result of exposure.

The following are the chief forms of paralysis:

(1) *Complete Paralysis*.—By this is generally understood paralysis of all except the cricothyroid and epiglottidean muscles, though occasionally these may also be involved. Since the cords are paralyzed, phonation is impossible. As a rule, there is no interference with respiration, though the pressure of the in-going air may bring the cords nearer together, and thus produce a certain amount of inspiratory harshness.

As the cords cannot be closed, coughing is impossible, as the air escapes through the glottis, and no expulsive force can be given to it. When the paralysis is unilateral these symptoms will of necessity be modified, and some degree of phonation may be possible. The most common cause of this condition is an involvement of the recurrent laryngeal nerve; the lesion may, however, be nuclear or in the course of the nerve-trunk.

(2) *Paralysis of the Abductors*.—The only special abductor muscles are the posterior crico-arytenoids. When they are involved the glottis fails to open in inspiration, and the unopposed adductors bring the vocal cords together. They are still more closely approximated during inspiration by the column of air, and hence the prolonged, stridulous inspiratory sound. Phonation and expiration are practically unchanged. It is quite likely that many cases supposed to be instances of hysteric spasm of the glottis are really cases of abductor paralysis.

In unilateral paralysis the normal movements of the unaffected vocal cord prevent any marked degree of dyspnea and stridor: phonation is usually hoarse and of low pitch. In cases of long duration the symptoms become more marked as the unopposed adductors undergo secondary contracture and still further narrow the glottis.

This condition may be due either to central disease or to some local change. The abductor muscles may be degenerated, while all the other laryngeal muscles are healthy, or one or both recurrent nerves may be affected. These nerves innervate both the abductors and adductors, and it is not clearly understood why the abductors alone should suffer when the parent nerve-trunk is involved. At any time it might be a very grave condition, for should any swelling of the cords supervene nothing but a prompt laryngotomy could prevent suffocation.

(3) *Adductor Paralysis*.—The cords move normally during respiration, and hence there is no stridor; as they cannot be approximated, however, phonation is impossible. This condition is met with in hysteria, producing hysteric aphonia, in public speakers who overtax their voices, and also in laryngitis.

The table on page 1046, from Gowers' text-book on *Diseases of the Nervous System*, enables one to get a comprehensive idea of the subject.

SYMPTOMS	SIGNS	LESIONS
No voice; no cough; stridor only on deep inspiration.	Both cords moderately abducted and motionless.	Total bilateral palsy.
Voice low-pitched and hoarse; no cough; stridor absent or slight on deep breathing.	One cord moderately abducted and motionless, the other moving freely, and even beyond the middle line in phonation.	Total unilateral palsy.
Voice little changed; cough normal; inspiration difficult and long, with loud stridor.	Both cords near together, and, during inspiration, not separated, but even drawn nearer together.	Total abductor palsy.
Symptoms inconclusive; little affection of voice or cough.	One cord near the middle line, not moving during inspiration; the other normal.	Unilateral abductor palsy.
No voice; perfect cough; no stridor or dyspnea.	Cords normal in position, and moving normally in respiration, but not brought together on an attempt at phonation.	Adductor palsy.

Sensory disturbances of the larynx are rare, and especially hyperesthesia. Anesthesia may be due to hysteria, or to bulbar paralysis, or to disease of the superior laryngeal nerve. It is dangerous, as food may enter the windpipe.

(c) **Cardiac Branches.**—These with branches from the sympathetic form the cardiac plexus. The vagus contains both accelerator and inhibitory fibers, but the latter predominate; therefore irritation of the nerve, either centric or peripheral, will slow the heart's action. Czermak was able to slow the action of his heart by pressing a small tumor in his neck against the vagus nerve. When the function of the nerve is lowered, inhibition is removed and the heart's action becomes rapid. This may be brought about by a toxemic neuritis, by pressure, accidental ligature, or by incised or punctured wounds. Various emotions and nervous states may bring about the same result.

(d) **Pulmonary Branches.**—Both accelerator and inhibitory fibers exist, but in this case the accelerator influence predominates, so that irritation results in increased respiratory movements or even in bronchial spasm, since the bronchial muscles are also supplied by this nerve. It is this nerve that is supposed to be concerned in the production of asthmatic paroxysms. Therefore, when the nerve function is lowered the respirations become much slower. The nerve is supposed to contain trophic fibers for the lungs.

(e) **Esophageal**, (f) **Gastric**, and (g) **Intestinal Branches.**—The esophageal branches are rarely damaged, and irritation (spasm) occurs more frequently than paralysis. The pneumogastric gives the sensory, and in part the motor, nerve supply to the stomach, and irritation gives rise to increased contractions with some pain.

The sensation of hunger is supposed to be associated with the vagus nerve, and vomiting may result from direct or reflex irritation. Paralysis causes some diminution of the gastric contractions. Normally, the vagi accelerate intestinal peristalsis.

Treatment.—It is almost always impossible to remove the cause of the above conditions. Syphilitic lesions are probably the most amenable, and in the various laryngeal palsies electricity may be employed, though it is of somewhat doubtful utility, and in abductor palsy may possibly exert a harmful influence by stimulating the adductors. Strychnin and general tonics should be administered. Massage of the larynx may be tried, and in spasmodic conditions attention should be directed to the general physical state. All

sources of nerve irritation should be removed if possible, and bromids, or even chloral, should be given.

Vagotony.¹—This term has been applied to a neurosis in which there is hypertonicity or irritation of the nerves comprising the autonomic nervous system (p. 993), but principally of the vagus nerve and evidence of increased innervation of the organs controlled by it. Symptoms referable to the gastro-intestinal tract are most prominent and consist of a state of hypertonus in the musculature of the stomach and intestines causing principally spastic constipation, a tender palpable colon, a tightly contracted external sphincter, abdominal pain and tenderness which may be mistaken for either that of appendicitis, cholecystic, duodenal, or gastric lesions, depending whether the transverse colon or cecal region is affected. Pain may also be experienced in the region of the descending colon. It is usually more marked either just before or after defecation, and may be excited by cold drinks or rapid eating. Attacks of mucous diarrhea may occur at intervals. Hyperacidity of the stomach and pylorospasm, bronchial asthma, bradycardia and cardiac arrhythmia, increased perspiration and urination, facial flushing, cold extremities, contracted pupils, eosinophilia, hypersensitiveness to pilocarpin, and dermatographia are also symptoms that may occur. A confirmatory test, not always present, is dilatation of the pupils on forced inspiration and contraction on expiration; also the pulse may be likewise quickened or slowed. Smith² has called attention to the resemblance of the symptoms of anaphylaxis to those of vagotony, and states that it manifests itself chiefly through vagus irritation. The relation, therefore, of the symptoms of vagotony to certain articles of diet is important. Other causes may be ductless gland disturbances, principally hyperthyroidism and chronic bacterial infection, principally tuberculosis.

The sympathetic division of the vegetative nervous system may similarly be affected and produce symptoms the reverse of those mentioned as characteristic of vagotony. This complex has been termed *sympathicotony*. In addition to the symptoms the following tests may be used to differentiate the two, viz.: pilocarpin causes sweating and salivation in the former and none in the latter; dyspnea caused by vagotony is relieved by atropin, that caused by sympathicotony is not; in vagotonia there is increased carbohydrate tolerance, in sympathicotony it is diminished. Epinephrin given to one with sympathicotony causes tachycardia, increased blood-pressure, and exophthalmos.

For *vagotony* belladonna in some form in full doses is of great value. Constipation should be treated with either phenolphthalein, agar-agar, liquid vaselin, or olive oil. Enemata of olive oil may be useful. The diet should be carefully regulated.

DISEASES OF THE SPINAL ACCESSORY NERVE

This nerve consists of two parts—an external or spinal, and an internal or accessory, portion. The latter has already been described in connection with the pneumogastric nerve. It forms the motor portion of that nerve, and is distributed to the laryngeal and pharyngeal muscles. The spinal element arises from the multipolar ganglion cells in the anterior gray horns of the cervical cord, ascends and enters the cranium through the foramen magnum, and leaves it, after joining with the accessory part, through the jugular foramen. It supplies the sternomastoid muscle and in part the trapezius.

Injury or disease of the nerve may result in spasm or paralysis. Only the spinal part is considered in this section.

¹ Spitzig, *Jour. Amer. Med. Assoc.*, January 31, 1914, 364; Wolfsohn, *Ibid.*, May 16, 1914, p. 1335; Held and Gross, *Ibid.*, January 22, 1916, p. 233.

² *Jour. of Nerv. and Ment. Dis.*, January, 1917, p. 26.

TORTICOLLIS

(Wry-neck)

This may be a congenital or an acquired condition.

Congenital torticollis, or "fixed wry-neck," is the result of an atrophy and shortening of the sternomastoid muscle, brought about by some intra-uterine condition or, possibly, by an injury at birth. The right muscle is most commonly affected. The head turns slightly toward the sound side; the eye may deviate, and curvature of the cervical spine may develop.

Facial asymmetry is a usual concomitant of this condition. The face on the same side as the lesion develops less rapidly than the other side, and in time secondary contracture of the unopposed muscles takes place. The torticollis can be cured by tenotomy, but the facial asymmetry persists. Fixation is necessary for a while when contracture exists.

Spasmodic wry-neck may be tonic or clonic. These forms may coexist, alternate, or occur independently in different individuals. The condition is met with almost exclusively in adults, and occurs most frequently in middle-aged men.

Pathology.—Usually no macroscopic or microscopic evidence of any lesion has been discovered, and the condition is probably dependent upon an overactivity of the neurons in the various centers that control the muscles of the affected part. Some cases belong to the Tics (p. 1144).

Etiology.—The influence of sex and age has been mentioned; a neurotic heredity may also predispose. Torticollis may follow habit-spasm, or some injury to the head or neck, or exposure to cold, the latter constituting the "rheumatic" type. It may be due to an irritative lesion either in the spinal cord above the fifth cervical segment, or to tumor, hemorrhage, meningitis, or bone disease in the upper part of the vertebral canal. Most cases are apparently functional, and may be due to reflex irritation, as eye-strain, or occur without apparent cause.

Symptoms.—The occiput is drawn toward the shoulder of the affected side, the chin is elevated, and the face rotated more or less toward the sound side. The sternomastoid may alone be affected, but the upper fibers of the trapezius are usually also involved. In addition, the superior obliquus and complexus of the same side and the splenius capitis and inferior obliquus of the opposite may be involved. Affection of the deep muscles causes greater retraction of the head than when the sternomastoid and trapezius alone are the seat of spasm. Spinal curvature may ensue, the convexity being toward the sound side. This only takes place in cases that have existed for some time. Clonic spasm is infinitely more distressing and more apt to be permanent.

Some pain and muscular twitching may precede the onset of the attack, though, as a rule, muscular contractions are the first indication. These are mild at first, and rarely abruptly, more commonly slowly, they increase in severity. As the case progresses other muscles, and even those of the arm, become involved. Cases have been described in which certain muscles or groups of muscles in the hand or arm have been primarily affected, the condition gradually spreading from them. The spasm usually ceases during sleep. An attack may cause pain, but, as a rule, it induces merely a feeling of fatigue in the muscles; it is worse if the patient is excited or emotional. Bilateral spasm may occur, the muscles of both sides being equally affected (*retro-colic spasm*). Gowers speaks of a case in which the backward displacement of the head was so great that the face was horizontal and looked directly upward.

Diagnosis.—As a rule this is not difficult. When spasm is induced by enlarged and painful glands beneath the sternomastoid the age of the patient will be of value in determining the true condition. This usually occurs in children; true wry-neck, on the other hand, very rarely commences before the thirtieth year. Hysteric spasm may also simulate spasmodic torticollis, but it generally occurs in young women, and usually other evidences of hysteria are also present. The *rheumatic type* and the rigidity induced by *caries of the spine* must be differentiated from one another and from spasmodic wry-neck. If the rigidity comes on suddenly, following exposure to cold or wet, and the pain is not increased at night or by depressing the head upon the spine, and is relieved by hot applications, the condition is probably rheumatic. When the rigidity and pain are of slow onset, without history of exposure, and the pain is both worse at night and is increased by depressing the head upon the spine, but is relieved by elevating the head, the condition is very probably one of *caries of the spine*. If there is doubt, a skiagram will reveal the true condition. In irritative lesions within the spinal canal, either intra-, or extramedullary, the spasm is usually bilateral and tonic, and other symptoms of involvement of the cord are likely to be found.

Prognosis.—Very rarely the torticollis may diminish or even cease after an existence of months or years. Usually, however, it is persistent, either being stationary or slowly increasing in severity and widening in range. The prognosis must always be guarded, and in severe cases grave as to recovery, though the disease does not shorten life.

Treatment.—Generally very little can be expected from medication. Bromids, morphin, chloral, hyoscyamus, or cannabis indica may be tried, as may the various forms of counterirritation. Atropin, in increasing doses, administered hypodermically into the muscles, has been effectual in some cases. Massage of the affected muscles and rest in bed may also at times be of service. Galvanism should be tried, the negative pole being placed over the occipital region and the positive over the affected muscles. Nerve-stretching and tenotomy of the affected muscles is of very little value. The only surgical procedure that has proved of any distinct value is neurectomy of the spinal accessory and posterior branches of the upper four cervical nerves, with excision of a part of the nerves to prevent reunion. This necessarily causes paralysis and atrophy of the muscles supplied; but, since it often abolishes the spasm, the slight loss of power and the interference with the movement of the head are comparatively infinitesimal. The results, however, are not positive, even so far as the spasm is concerned.

PARALYSIS OF THE SPINAL ACCESSORY NERVE

The accessory portion has been previously considered in describing the laryngeal branches of the pneumogastric.

In the spinal portion the nuclei may be involved in degenerative lesions of the motor region of the spinal gray matter. The nerve-trunk may be damaged by pressure from exudative products (meningitis), tumors, or caries, with resulting paralysis and wasting of the sternomastoid and, in part, of the trapezius. This latter muscle is also supplied by the cervical nerves. The patient has difficulty in rotating the head to the side opposite that on which the paralysis exists, and the affected muscle does not stand out in movements of the head. Unless secondary contraction of the unopposed muscle sets in, no deviation occurs when the head is at rest. The only portion of the trapezius that is involved in paralysis of the external part of the eleventh nerve stretches from the occipital bone to the acromion. The normal contour of the neck is lost in such cases, and the ability to raise the arm is interfered with because the trape-

zius cannot fix the scapula, the fulcrum of the deltoid. Bilateral paralysis may occur as in progressive muscular atrophy; if both sternomastoids are involved, the head falls backward; if both trapezii, it falls forward.

The **treatment** is that of the underlying cause. If the lesion is nuclear, practically nothing can be done. If the condition is due to pressure, in some cases relief may be obtained. Electricity and massage should be employed during the recovery of the nerve.

DISEASES OF THE HYPOGLOSSAL NERVE

The nucleus of the twelfth cranial nerve is in the most posterior portion of the floor of the fourth ventricle. It is said by some observers that the nuclei of the fibers for the palate and vocal cords that run in the spinal accessory nerve may be in the lower part of the twelfth-nerve nucleus.

The cortical center for this nerve is in the lower part of the ascending frontal convolution, in the neighborhood of the cortical facial center. This propinquity probably explains the simultaneous involvement of the facial and lingual muscles in some cases. The hypoglossal is the motor nerve for the tongue and for most of the muscles attached to the hyoid bone. Spasm or paralysis may follow disease of the nerve.

Spasm may be either unilateral or bilateral. It is probably met with most commonly in hysteria, or as a part of some general convulsive condition, as epilepsy or chorea. It may also be associated with facial spasm, as mentioned above. Irritation of the fifth nerve (dental caries, ulceration of the gums) seems to be responsible for some cases. "Paroxysmal clonic spasm" is a form in which the tongue is rapidly thrust in and out (p. 1144). Various sensations in the affected region may precede the attack. A rare form—*aphthongia*—is induced when an attempt to speak is made. The prognosis in this condition is good, and a general tonic treatment is indicated.

Paralysis may result from supranuclear, nuclear, or intranuclear lesions.

Supranuclear.—The lesion may be anywhere between the cortex (lower part of the ascending frontal gyrus) and the medulla, and causes paralysis on the opposite side. In this condition the affected muscles do not atrophy nor do they show any electric change. If unilateral, the tongue when protruded deviates to the side of the lesion.

Nuclear.—The lesion is usually degenerative. It may either be of sudden onset (vascular), less rapid, but still acute (inflammatory), or it may be chronic, as in bulbar palsy or tabes dorsalis. The nuclei are so close together that the condition is almost invariably bilateral.

Infranuclear.—The fibers may be injured by the pressure of neoplasms or by the products of meningitis or of syphilis. Disease of the bone may also involve the nerve in its passage through the foramen. More rarely, some traumatism or disease of the upper cervical vertebræ may simultaneously injure the eleventh and twelfth nerves.

Symptoms.—Paralysis and atrophy of one or both sides of the tongue and fibrillary twitchings may be noted, and if the condition be unilateral, the tongue when protruded deviates toward the affected side. Articulation, mastication, and swallowing are but very slightly interfered with. In the bilateral form, however, these are very much impaired; the tongue cannot be protruded and lies motionless on the floor of the mouth. The atrophy is muscular. This throws the mucous membrane into deep folds. Sensation and taste are unaltered.

Diagnosis.—If the lesion is supranuclear, there is usually hemiplegia on the same side as the lingual paralysis, without atrophy of the tongue muscles. When nuclear it is, as has been said, generally bilateral and forms part

of a bulbar paralysis. There is also wasting of the lingual muscles. When the fibers are involved in the medulla there is paralysis of the tongue on one side, of the limbs on the other, and the tongue deviates from the paralyzed side of the body. Outside the medulla the condition is, as a rule, unilateral, and the spinal accessory fibers are frequently involved. In the nuclear and intranuclear varieties there is wasting of the muscles.

The **prognosis** is usually unfavorable, and the **treatment** consists of a course of general tonics and of mercury and the iodids, with counterirritation.

DISEASES OF THE SPINAL NERVES

DISEASES OF THE CERVICAL PLEXUS

The branches arising from the posterior divisions of the upper four cervical nerves may be the seat of pain (cervico-occipital neuralgia) (p. 1019).

Phrenic Nerve.—This nerve is usually involved as a result of some lesion of the ganglion cells in the anterior gray horns at the level of the third or fourth cervical segments. The trunk may be damaged by pressure, as by aneurysm or neoplasms, or by traumatism, or it may be the seat of neuritis. More or less immobility of the diaphragm follows, amounting in some cases to complete paralysis. This is not readily seen with the patient at rest, and in women it is specially hard to observe, as their breathing is chiefly of the costal type. The abdomen moves in during inspiration, and out during expiration, forming the reverse of the normal movements. Exertion readily causes dyspnea, and pulmonary diseases are apt to be exaggerated as the products of secretion accumulate. If the lesion is bilateral, death occurs in a very short time after distressing dyspnea. Neuritis of one phrenic nerve has been observed, and leads to high position of the diaphragm on the affected side, with collapse of the corresponding lung. The x-ray may assist in the diagnosis.

Irritation of this nerve causes the symptom known as *hiccup*, which may be due to various gastro-intestinal disturbances, neuroses, and in some cases seems to be idiopathic. It is often very rebellious to treatment. A stubborn functional form occurs in hysteria (see also p. 1157).

The treatment of chronic hiccup consists in the administration of nerve sedatives, as valerian, hyoscin hydrobromate, bromids, etc.; rest, electricity in the form either of the constant or faradic current, either placing one electrode (the anode if the former is used) on the neck back of the sternomastoid muscle and the other on the body in the region of the diaphragm, or placing them on each side of the body in this region. Injections of apomorphin (gr. $\frac{1}{2}$) have been recommended. In extreme cases morphin must be used.

DISEASES OF THE BRACHIAL PLEXUS

This may either be involved *in toto*, or any of its branches may be affected separately, or the nerve-roots that unite to form the brachial plexus. Isolated disease of any of the roots may be produced by injury, caries of the vertebræ, or meningeal disease. The symptoms will be almost exactly the same as those produced by disease of the corresponding segment of the cord, but are more likely to be unilateral, and to be either purely motor or sensory, unless the lesion is extensive.

The posterior thoracic supplies the serratus magnus muscle. It may be injured directly by pressure, as in the carrying of heavy loads on the shoulder or

by a fall or other traumatism. Rarely, it follows exposure to cold. Its involvement may be a part of an anterior poliomyelitis or of a progressive muscular atrophy or dystrophy. When the muscle is paralyzed the posterior edge of the scapula stands out prominently, and particularly when the arm is moved forward. Neuralgic pains in the neck generally precede the neuritis. The course of the disease is always slow. During the early stage counterirritation, the iodids and mercury internally, and later electric stimulation to keep up the tone of the muscles, constitute the treatment.

Combined Paralysis.—Two or more nerves, or even the entire plexus, may be involved at one time by new growths in the cervical region, pressure by a cervical rib, neuritis, stretching or rupture of the nerves by wounds, fractures, or dislocations, particularly by subcoracoid dislocation and stoop shoulders, which cause compression of the axillary structures between the humerus and the ribs.¹ Duchenne has described a form of palsy produced in infants during birth, due to laceration of and hemorrhage about the nerve-fibers by severe traction on either the head when the shoulders are obstructed or on the shoulders in breech presentations. The roots involved are usually the fifth and sixth, frequently just at their junction. The muscles involved are the deltoid, biceps, brachialis anticus, supinator longus, infra- and supraspinati. Other roots and muscles may also be affected. This condition is known as "obstetric paralysis." Brachial neuritis may follow some injury to one of the nerve branches (ascending neuritis) or it may be primary. The latter variety is rare and usually occurs after middle life, especially in cases with a gouty history. The roots only are affected in many cases (radicular neuritis). Paroxysmal or continuous pain, increased by any movement of the arm and tenderness on pressure over the affected nerves, especially over and to the inner side of the coracoid process of the scapula, is the chief symptom. If on the left side, it stimulates angina pectoris. Motor loss is not, as a rule, marked. Aortic aneurysm, cervical rib, vertebral disease, spinal tumor, cervical pachymeningitis, and cervical tuberculosis must be excluded.

Individual Nerves of the Arm.—These may be damaged by pressure due to a tumor, an aneurysm, or to callus. *Sleep-palsy* and *crutch-palsy* are both pressure palsies. The nerves may also be contused or torn in fractures or dislocations, and palsy may follow a fall or blow upon the shoulder; I have seen it occur in a heavy man after a fall upon the hand. Primary or secondary neuritis may develop, and, very rarely, neuromata appear.

The *suprascapular* nerve supplies the supra- and infraspinati muscles. Paralysis causes imperfect outward rotation of the humerus and rotation of the scapula, with elevation and inversion of the lower angle. Various movements of the arm are thereby interfered with, and the limb tires very readily. More work is thrown on the deltoid, and in time it hypertrophies, causing it to stand out more prominently against the infraspinatus. The skin over the scapula is usually anesthetic.

The *circumflex* nerve supplies the deltoid and teres minor and the skin over the deltoid and the shoulder-joint. Paralysis results in inability to raise the arm and in wasting of the muscles, with or without anesthesia. Adhesions may form in the joint (p. 1186).

The *musculospiral* nerve is more often paralyzed than any other nerve of the arm, its position rendering it particularly liable to pressure. It supplies the triceps and supinator longus muscles, and is the extensor nerve of the arm. It also supplies the skin on the radial side of the forearm, dorsal surface of the thumb and hand, corresponding to the index and middle fingers. A lesion high up results in paralysis of the extensors of the elbow, wrist and hand, and of the

¹ Goldthwait, *Jour. Amer. Med. Assoc.*, September 11, 1909, p. 852.

supinators. Probably the point most commonly attacked is about the middle of the humerus. In such cases the triceps escapes. The characteristic symptoms, however, are wrist-drop and finger-drop, consisting of an inability to extend the hand on the forearm, also the first phalanges of the fingers and thumb. In pressure palsies, usually due to sleeping with the head upon the arm, particularly after the excessive use of alcohol, the power of supination is usually lost also. Sensory symptoms vary and are seldom pronounced. There may be slight impairment or tingling or burning sensations.

This condition can usually be differentiated from lead-palsy by the rapidity of onset—by the fact that pressure palsies are almost invariably unilateral, and that the supinators are involved. Lead-palsy has a slow onset and is bilateral, generally without supinator involvement. Loss of sensation precedes the pressure palsy. The history too will generally throw some light on the case. I have seen a case of right-sided unilateral wrist-drop in a man who worked in lead with his right hand only. Bilateral wrist-drop may occur in any form of toxic neuritis, but the involvement of other nerves, the manner of attack, and the history of the case will serve to simplify the diagnosis.

Recovery follows in almost all cases of musculospiral nerve involvement, though in cases in which qualitative nerve changes have taken place it is necessarily delayed.

The *treatment* is that of neuritis.

The *median nerve* supplies the pronators, digital flexors, except the ulnar half of the deep flexor, the radial flexor of the wrist, the abductor and flexor muscles of the thumb, and the two radial lumbricales. It furnishes sensation to the radial side of the palm and front of the thumb, and to the front and back of the first and second and half of the third fingers. This nerve may be the seat of an injury or of neuritis, but is seldom involved alone. A form described by Hunt¹ is due to pressure upon the nerve at the base of the thenar eminence, the principal symptoms being atrophy and paralysis of the muscles forming it. Localization in this group distinguishes it from a beginning progressive muscular atrophy (p. 1082). The most striking symptoms of median nerve palsy are wasting of the thenar eminence and an inability to oppose the thumb to the tips of the fingers. Loss of pronation of the forearm. Ulnar flexion of the wrist alone remains. Flexion of the second phalanges upon the first is interfered with. Sensation may or may not be lost.

The *ulnar nerve* supplies the ulnar flexor of the wrist, the ulnar half of the deep flexor of the fingers, the muscles of the little finger, the adductor and inner head of the shorter flexor of the thumb, the interossei, and some of the lumbricales. It supplies with sensation the front of one and a half and the back of two and a half fingers on the ulnar side. Paralysis causes radial deviation of the hand in flexion of the wrist, loss of adduction of the thumb, and inability to move the little finger. The hypothenar prominence disappears.

The first phalanges cannot be flexed, and the second and third cannot be extended. This is exaggerated in old cases, though still it is not so marked as the "claw hand" of progressive muscular atrophy, since the first two lumbricales escape, being supplied by the median nerve. Sensory symptoms vary. If the deep palmar branch alone is affected, as it may be by pressure, as it passes between the tendinous origins of the abductor minimi digiti and flexor brevis minimi digiti, the sensory symptoms are absent.² Care must be taken not to mistake this condition for the beginning of a progressive spinal muscular atrophy (p. 1082).

¹ *Jour. Ner. and Ment. Dis.*, January, 1910, p. 56.

² Hunt, "Occupation Neuritis of Deep Palmar Branch of Ulnar Nerve," *Jour. Nerv. and Ment. Dis.*, November, 1908, p. 673.

The *diagnosis* is usually easy. It is well to remember that, since this nerve is the lowest in its point of origin of any considered in this group, ascending cord diseases will involve it before any of the other brachial nerves. It may also be damaged by disease limited to the lowest part of the cervical enlargement of the cord.

DISEASES OF THE LUMBAR AND SACRAL PLEXUSES

The **lumbar plexus or its branches** may be involved by abdominal growths, enlarged glands, psoas abscess, disease of the vertebræ, neuritis, and rarely by wounds or dislocation of the hip or during parturition.

The Obturator Nerve.—When the power of adduction of the thigh is lost and the affected leg cannot be crossed over the other, outward rotation is somewhat impaired.

Anterior crural nerve paralysis causes loss of power and wasting of the extensors of the knee, loss of knee-jerk, and anesthesia of most of the thigh and the inner side of the leg and foot.

The *superior gluteal nerve* supplies the gluteus minimus and medius muscles. When it is involved adduction and circumduction of the thigh are lost.

The **sacral plexus and its branches** may be damaged by pelvic neoplasms or inflammation, neuritis (generally secondary to sciatic nerve involvement), pressure during labor, wounds, dislocations, aneurysms, and diseases of the bone.

The *small sciatic nerve* supplies the gluteus maximus muscle. It is seldom involved alone. Lesions cause difficulty in rising from the sitting posture and anesthesia of the back of the thigh and of the upper part of the leg posteriorly.

The *great sciatic nerve* supplies the flexors of the leg and the muscles below the knee, and also sensation to the outer half of the leg, the sole, and part of the dorsum of the foot. Paralysis causes more or less interference with the act of walking, anesthesia in the part supplied, and wasting of the muscles. More or less weakness of them may sometimes be discovered in sciatica. (See Sciatica, p. 1020.)

The *external popliteal or peroneal nerve* supplies the tibialis anticus, the peronei, the long extensor of the toes, and the extensor brevis digitorum; it also supplies sensation to the outer half of the front of the leg and to the dorsum of the foot. Paralysis causes foot-drop and toe-drop, rendering it necessary to lift the leg high in walking, so that the foot will clear the ground; this constitutes the *stepping gait* referred to in the section on Neuritis. If sensory impairment is present it will be found in the outer half of the front of the leg and the dorsum of the foot.

The *internal popliteal nerve* supplies the popliteus, tibialis posticus, the calf muscles, the long flexors of the toes, and the muscles of the sole. When paralyzed, flexion of the foot and toes is impossible, and sensation is lost over the back of the leg in its lower part and over the sole. In old cases talipes calcaneus results. The plantar nerves are rarely, if ever, involved alone. Disease of the plexuses outside the canal must be distinguished from lesions inside involving the cauda equina (p. 1080), most commonly these are either a fracture dislocation of one or more lumbar vertebræ below the first; hemorrhage, or tumor. If the first, the diagnosis is easy, as the fractured vertebræ can be easily recognized by inspection, and in doubtful cases, the skiagram. A history of traumatism is important in both fracture and hemorrhage, and the symptoms are usually bilateral, but not always strictly symmetric; the pain is severe. Tumor should be indicated by a slow but progressive development of atrophic paralysis, absence of reflexes, sensory paralysis, intense sacral pain of a radiating character, and often tenderness in the same region. There is also usually sphincter paralysis.

Solution of continuity in an *intercostal nerve*, as in a fracture of a rib, rarely gives rise to any symptom except a small area of anesthesia at the sternal end of the corresponding interspace.

Neuralgic affections of these nerves are described on p. 1019.

II. INFLAMMATION OF THE MENINGES

Meningitis is very rarely a primary condition. Both the dura and pia may be involved. In the former case the inflammation is usually due to some morbid condition of the vertebræ, while in the latter it is secondary to some infection, as in pyemia, sepsis, pneumonia, typhoid, or the acute exanthemata. It may be part of a tuberculous condition (*vide* Tuberculosis, p. 238) or of epidemic cerebrospinal meningitis (p. 87). Injuries also lead to inflammation of the meninges of the cord.

INFLAMMATION OF THE DURA MATER

CEREBRAL PACHYMENINGITIS

Inflammation.—This may be met with on the outer or inner surface (*pachymeningitis externa* or *interna*). Of the external variety the chief causes are (a) traumatism, (b) disease of the bone, (c) syphilis, and (d) middle-ear disease. That due to traumatism is often seen, and in the mildest form is of little moment. When severe and accompanied by fracture with or without displacement, infection of the membranes may either take place at once or later from diseased bone. That form due to caries or any other form of osteitis is always dangerous, owing to the possibility of infection of the diploë. The brain sinuses will then become affected, and infected emboli may pass into the circulation, with the development of pyemia. In the syphilitic variety the inner table of the skull is thickened and roughened, and more or less pus and granular material is found between it and the dura (see also Syphilis of the Nervous System). Sinuses may communicate with the exterior.

The **symptoms** are indefinite in mild cases, and may consist only of *headache*. In the severe forms there are *headache*, *malaise*, *chills*, *fever*, *drowsiness*, and later *stupor*, and rarely *convulsions*, *paralysis*, or other symptoms of compression. The ophthalmoscope may reveal more or less evidence of *choked disk*. Rigors are suggestive of the onset of pyemia.

The **treatment** varies with the cause. Antiphlogistic measures and counter-irritation are of value, and in the severe grades operative interference may be necessary. The internal variety either occurs as a simple inflammation or may be so acute as to cause extravasation of blood. This may organize, and, together with the products of inflammation, cause a pseudomembrane. Rarely is pus found.

Internal hemorrhagic pachymeningitis, or hematoma of the dura mater, is characterized by the formation of a fibrous exudate upon the inner surface of the dura, into which capillaries extend that subsequently rupture. It is found most commonly among alcoholics, the insane, and epileptics. It occurs rarely in childhood.

The **symptoms** are variable. The entire course may be without symptoms, or they may be marked by the existence of other conditions. More frequently there are *headache* and *convulsions*, followed later by *paralyses*, coma, and

death. The location of the lesion causes considerable modification of the symptomatology. In the milder form recovery frequently occurs, or the case may become chronic. If the onset is sudden, the symptoms may resemble those of hemorrhage.

The **diagnosis** is always difficult. In children muscular contractions and convulsions are frequently met with; in adults the slow onset may be the only difference between this condition and an attack of epilepsy. Of course, there is a greater periodicity in the latter; but a repetition of the attacks occurs in hematoma, and, as already stated, the repeated hemorrhages are believed by some to be the cause of the lamination of the false membrane.

The **prognosis** is extremely unfavorable in children, but is much less so in adults.

The **treatment** calls for the use of leeches behind the ears and over the temples, the ice-cap, and counterirritation. Free movement of the bowels should be promptly secured, and later the iodids or mercurials should be administered.

SPINAL PACHYMEINGITIS

Definition.—Inflammation of the dura mater. The dura may be involved on its outer or inner surface (*pachymeningitis externa* or *interna*), or the loose connective tissue between the dura and bony canal may be the seat of a peripachymeningitis.

Pachymeningitis externa is always secondary, and usually results from disease of the vertebræ, due to syphilis, tuberculosis (Pott's disease), or malignant disease, or from pressure due to tumors or to traumatism. It may be either acute or chronic. Of the latter type, cases due to Pott's disease are most common. The membrane is involved to a greater or less extent. The internal surface may escape entirely, or it may be slightly roughened and adherent to the arachnoid; externally, however, the dura is usually thickened, rough, and covered with a cheesy material.

Pachymeningitis interna was first described by Charcot in 1871, and named *pachymeningitis cervicalis hypertrophica*. It is of obscure origin, but traumatism, alcoholism, and syphilis have been given as causes. The dura is generally much thickened, and gives the impression of being made up of a number of concentric layers. Hemorrhages may occur within the dura or within the newly formed tissue. The pia is only involved to a slight degree, as a rule, but becomes adherent to the dura. Areas of degeneration may occur in the cord, as may also dilatation of its central canal. As implied by the name, this variety of pachymeningitis is found chiefly in the cervical region, and the clinical symptoms result from involvement of the nerve-roots and compression of the cord. It is a chronic process, and has been divided into three periods, as follows: (a) *The painful period*, lasting, as a rule, two or three months, in which severe neuralgic pains exist, their location being determined by the roots involved. They are mostly in the occiput and upper extremities. Early there may be hyperesthesia, numbness, tingling, and, rarely, a herpetic eruption. (b) *The Paralytic Period*.—As a result of compression of the motor roots an atrophic paralysis of the upper extremities develops. A peculiar selective tendency is manifested, the distribution of the median and ulnar nerves being principally involved. This results in a modified "claw-hand" deformity and in an overextension of the wrists, with flexion of the fingers. Anesthesia may be noted. (c) *Spastic Paraplegia*.—This results when the compression has produced degeneration of the cord. Generally, there are paresis of the lower extremities and increased reflexes, but no muscular wasting, since the trophic centers are intact. Occasionally, however, anesthesia and

paralysis of the legs and bladder develop, bed-sores following, and finally death from exhaustion.

The *prognosis* is unfavorable, practically all cases terminate in death, but the duration is variable.

The *diagnosis* must be made from amyotrophic lateral sclerosis, vertebral caries, syringomyelia, and from pressure by tumors. Amyotrophic lateral sclerosis does not give rise to sensory disturbances; bulbar symptoms are often present, the lower extremities may atrophy, and the bladder functions are preserved. In vertebral caries tenderness on jarring will be present, and a skiagram will probably show evidence of bone disease. Syringomyelia induces characteristic symptoms of loss of temperature and pain sense with the preservation of tactile sense (dissociation of sensation), although this may rarely be present in pachymeningitis, but severe neuralgic or radiating pains are rare in syringomyelia. From tumor the diagnosis may be difficult, the symptoms in this, however, usually develop more gradually and at first are unilateral.

Treatment is not of much avail. Potassium iodid and mercury are the chief measures. In cases otherwise hopeless an exploratory operation is sometimes justifiable.

LEPTOMENINGITIS

Definition.—Inflammation of the pia mater. This may be either acute or chronic.

CEREBRAL LEPTOMENINGITIS

Cerebral leptomeningitis is an inflammatory condition of the pia arachnoid; it occurs in various forms, that may be classified either according to the distribution of the process, into meningitis of the convexity, of the base, or cerebrospinal meningitis, or according to the cause.

Etiology.—As it is infectious, this is always micro-organismal. It is customary to distinguish between the forms produced by the pyogenic micro-organisms and by the tubercle bacilli. Among the former the most important are the pneumococcus, the meningococcus, the staphylococcus, and the bacillus of influenza, but a great variety of other bacteria have been found, such as the colon bacillus, the typhoid bacillus, and others in rare or isolated instances. The method of access to the meninges varies, either along the blood or lymph-channels from some focus of infection, as the lungs, the nasal cavities, or in the course of an infectious process that gives rise to bacteremia, as pyemia; or by direct extension, as in middle-ear disease, or disease of the sinuses of the face. Meningitis, particularly the tuberculous variety, may follow injuries to the head. It may be due to syphilis. Purulent meningitis may occur at any age. Tuberculous meningitis is more common in childhood and is described on p. 238.

Pathology.—In the extent and degree of the inflammation great variations exist. It may be either (1) limited to the convexity, with or without involvement of the sides; (2) limited to the base; or (3) general, involving both convexity and base. In the early stages and in the mild forms there may be no more than an injection of the part. Later, inflammatory products are met with, usually following the course of the meningeal vessels, but sometimes covering considerable areas. This form of leptomeningitis, unlike the tuberculous variety, is prone to attack the convexity of the brain.

Symptoms.—These are very varied, and naturally depend on the *seat* and *extent* of the inflammation. Those cases in which symptoms pointing to involvement of the base occur need not be discussed here, since they are

considered in detail under the tuberculous variety. In any case *headache*, localized or general, is usually present. In children too young to talk its presence is often indicated by crying or putting the hand to the head. *Delirium*, *insomnia*, and *coma* are also met with in different cases. There is more or less *fever*. *Constipation*, a *coated tongue*, *vomiting*, a *rapid pulse*, are usual, and the *tâche cerebrale* may be elicited. Spasmodic movements may occur, or even general *convulsions*. Of course, in cases of inflammation of the base, the cranial nerves become affected, and we have *ptosis* or *strabismus*, *facial spasm* or *palsy*, and, if the fifth nerve is involved, *sensory* and *trophic* changes. The head is usually retracted until it seems to bore into the pillow; the muscles of the back of the neck are tense; the spine is often rigid; the abdomen retracted, and the limbs flexed. The tendon reflexes are exaggerated and cutaneous irritability greatly increased. *Kernig's sign* consists in the inability of the patient to straighten the leg when the thigh is flexed to a position of 90 degrees to the axis of the body. It is nearly always present in acute non-tuberculous meningitis, but often absent in the tuberculous form; occasionally it may be found in focal encephalitis, either acute or chronic, and even in acute infectious disease—typhoid fever. It is, therefore, valuable as a suggestive sign of meningitis, but can no longer be considered pathognomonic. Brudzinski's sign may be present (p. 92). If a suppurative ependymitis is present, a condition similar to acquired hydrocephalus occurs, except the fluid within the ventricles is purulent. This has been termed pyocephalus. Its occurrence is indicated by a return of symptoms after recovery has apparently commenced. The spinal fluid will be clear. A type frequently found in young children, and thought by many to be a form of sporadic cerebrospinal meningitis (p. 87), consists of an inflammation confined to the meninges of the posterior part of the base of the brain from the optic commissure to the medulla. From its location hydrocephalus frequently develops; blindness, due to pressure on the optic chiasm, also is common. The intense retraction of the head is a characteristic symptom. It is known as *posterior basic meningitis*.

Diagnosis.—Where no etiologic hint can be obtained the diagnosis is generally in doubt for two or three days. There may be nothing more than a reflex irritation (dental or gastro-intestinal), or possibly one of the infectious fevers. The symptoms should be studied in their entirety; one or two supposedly pathognomonic signs should not be allowed to cloud our vision. In some cases it may be necessary to distinguish meningitis from the so-called *serous meningitis* (p. 1059). Meningitic symptoms, associated with marked delirium, may occur in the course of acute articular rheumatism. In this condition the cerebrospinal fluid will be clear (p. 1061). The condition is known as cerebral rheumatism. It must also be borne in mind that meningeal symptoms are simulated by the infectious diseases; this is especially so in children. The condition is known as meningism or meningismus. The spinal fluid will be negative (p. 1061). The glycyL-tryptophan reaction¹ has been advocated as a test for all forms of meningitis. Major and Nobel found it positive in all of a series of 17 cases, mostly tubercular. It is obtained by placing 1 c.c. of the suspected cerebrospinal fluid in a test-tube with an equal quantity of glycyL-tryptophan, then 1 c.c. of toluol is added. The mixture is placed in an incubator for three hours, after which a few drops of dilute acetic acid are added. An oversaturated solution of calcium chlorid is then added drop by drop, and a red color is produced if free tryptophan is present, *i. e.*, in meningitis. The test should be made with various dilutions with sterile normal salt solution from 1 : 200. Having made the diagnosis of meningitis, it becomes important to **differentiate** the *tuberculous* from the *non-tuberculous*

¹ *Archives Intern. Med.*, September, 1914, p. 383.

variety. The family history is of importance. In *tuberculous meningitis* the focal symptoms usually appear early, and are due to involvement of the cranial nerves at the base of the brain, chiefly those controlling the eye. The eye-grounds often show a slight perineuritis without choked disks, and perhaps one or more miliary tubercles. There is sometimes a mild form of confusional delirium, often preceding the appearance of focal symptoms. The leukocytes are slightly, if at all, increased. There is rarely rigidity of the neck. In other forms of meningitis this appears early; the optic nerve shows intense inflammation and there is usually pronounced leukocytosis. Examination of the fluid withdrawn by lumbar puncture (p. 1061) is important. A differential count of the leukocytes in the spinal fluid should always be made (Cytodiagnosis, see p. 1061).

Prognosis.—This is always grave. A percentage of cases of epidemic cerebrospinal meningitis, varying with the severity of the epidemic, may recover. In all other forms any termination, except in death, is exceedingly exceptional. Remissions frequently occur in the symptoms, and the course may be very prolonged.

Treatment.—We have no specific, and all that can be done is to meet the symptomatic indications. Absolute quiet in a darkened room, an ice-cap to the head, and the internal use of full doses of hexamethylenamin (urotropin) and repeated lumbar puncture may be of service. The bowels must be kept free by salines and fever reduced, if necessary, by cool sponging. Opium may have to be given for pain. The introducing into the spinal cord of serums other than the meningococci, according to the cause of the meningitis, may be tried. Anti-influenzal serum is often efficacious. If pyocephalus occurs the serum must be introduced into the ventricles.¹ If of syphilitic origin, either mercury should be used by inunction or injection or salvarsan (606) employed. In certain cases—*e. g.*, those secondary to middle-ear disease—either opening the skull above and below the tentorium and draining,² or the operation of Haynes,³ which consists in draining the cisterna magna in the posterior fossa, may seem justifiable, although the results have not been particularly encouraging. When in doubt the physician should not delay action until too late, but should call in a surgeon while there is still hope for some benefit.

The treatment of the epidemic and tubercular forms is detailed on pages 87 and 238.

SEROUS MENINGITIS

(*Meningitis Serosa; Wet Brain*)

A condition, first described by Quincke, which in the acute form may arise spontaneously or follow various infective processes. Chronic alcoholism is a frequent cause. The symptoms resemble those of acute cerebral meningitis, and lumbar puncture may be necessary to establish the diagnosis, in serous meningitis, the fluid being clear, not containing organisms, and escaping under great pressure. The more chronic type closely simulates tumor of the brain, especially a subtentorial growth, as paralysis of cranial nerves, choked disk, convulsions, and ataxia may all be symptoms of this condition.

The *symptoms* are apt to fluctuate, and if they develop acutely after an infection of some sort it would be in favor of serous meningitis. In some cases

¹ *Progressive Medicine*, March, 1917, p. 37.

² Day, *Annals of Otolaryngology, Rhinology, and Laryngology*, June, 1911.

³ *Trans. Amer. Laryngol., Rhinol., and Otol. Soc.*, 1912, and *Prog. Med.*, March, 1913, p. 43.

an inflammation of the ependyma exists, and internal hydrocephalus (p. 1113) may follow.

The *prognosis* is doubtful, but recovery takes place in a fair proportion of cases. In the alcoholic type the greater the rigidity and retraction of the head, the worse the outlook.

Quincke advises mercurial inunctions in all cases. Counterirritation to the back of the neck and cold to the head may also be used. Lumbar puncture is of great service. The bowels should be kept free and the diet liquid, but liberal in quantity (hot milk, eggs, broths). In the alcoholic cases the inunctions should be omitted and strychnin in full doses (gr. $\frac{1}{60}$ every three hours) given.

ACUTE SPINAL LEPTOMENINGITIS

(*Acute Spinal Meningitis*)

Etiology.—This is always micro-organismal, and a great variety of bacteria have been discovered. It is rare unless associated with cerebral meningitis and the causes are similar (p. 1057).

Pathology.—The vessels are injected, the membrane becomes cloudy, a serofibrinous or purulent exudate either surrounds the cord or may only exist in patches, and in the more severe cases the cord itself is involved (*meningomyelitis*). The spinal meninges alone may be involved to a greater or less extent, but, as a rule, the cerebral meninges are similarly involved. Tubercles will be found in the tubercular form. It should be remembered that many cases presenting clinically the picture of meningitis show absolutely no gross *postmortem* lesions of the cerebral or spinal membranes. This may occur from any toxemia, but especially in pneumonia, typhoid fever, influenza, and rheumatism. No lesions, not even microscopic, are found. This condition is termed *meningismus*.

Symptoms.—These are chiefly pain in the back, often excruciating, with fixation, retraction of the head, tenderness on pressure along the spine, tremors or spasm of the muscles, and various sensory disturbances. Reflexes are early increased, and later diminished or absent. Should the cord be involved, paralysis, incontinence of urine and feces, and even bed-sores may develop (p. 1073). The symptoms are more fully discussed in speaking of the tuberculous and epidemic varieties.

Diagnosis.—It is often very difficult to differentiate the several varieties of spinal meningitis, and equally so to decide whether the case is actually meningeal when some other disease is present (glycyl-tryptophan test, p. 1058). The tuberculous form is readily diagnosed, especially if any collateral evidence of tuberculosis exists, and it rarely occurs except with involvement of the cerebral meninges. It is a point of some value in the diagnosis to note the absence of marked leukocytosis in the cerebrospinal fluid obtained by lumbar puncture in tuberculous and its presence in purulent meningitis. The presence of *Kernig's sign* is in favor of cerebrospinal meningitis.

Spinal paracentesis or *lumbar puncture*, first introduced by Quincke of Kiel in 1891, is a most valuable diagnostic measure and simple of application. It is performed as follows: The patient either sits up or lies upon the left side, with the back arched and the knees flexed against the abdomen. The spine of the fourth lumbar vertebra should be located (a line drawn from one posterior superior spine of the ilium to the other passes across it), and the puncture made at the level of its lower end. The needle should be inclined at an angle of about 45 degrees to the surface of the skin, and should be thrust in a distance of from $2\frac{1}{2}$ to 3 inches. The most scrupulous asepsis must be observed. The spinal fluid flows readily, either in a stream when the pressure is high,

or drop by drop if it is normal. In purulent meningitis it is cloudy, contains pus-cells, and does not reduce Fehling's solution; in tuberculous meningitis it is usually clear and does reduce Fehling's solution; in cerebral hemorrhage it may be bloody, but as admixed blood may be due to the injury of a vessel by the needle, this sign should be used with caution. The quantity obtained varies from 2 or 3 to 80 or 90 c.c. After centrifugation a differential count of white cells should be made. An excess of lymphocytes associated with symptoms of meningitis (see p. 1068) indicates a tubercular infection; an excess of polymorphonuclear cells, a pyogenic infection. Cultures should be made and the sediment or coagulum stained for bacteria. In meningismus the fluid is practically normal. Often there is great relief from the puncture, and occasionally, in serous meningitis, the patient appears to be permanently benefited.

The **prognosis** is unfavorable as a rule, particularly in the tuberculous form.

The **treatment** is the same as that of cerebrospinal meningitis (*vide* pp. 94, 1059).

CHRONIC LEPTOMENINGITIS

This disease may follow the acute form or be due to chronic alcoholism, syphilis, trauma, disease of the cord or vertebræ.

Pathology.—The pia is cloudy and swollen, and often adherent to the arachnoid, or all three membranes may be glued together. They are usually injected. Usually there is considerable proliferation of fibrous tissue. The periphery of the cord is also occasionally affected. A condition known as *circumscribed serous spinal meningitis* may be here mentioned. It may follow either traumatism or infectious diseases. When the dura is slit, its opening is filled by a more or less opaque pia that bulges forth under tension of the contained fluid which is clear.¹

Symptoms.—These are not well marked. Unless the nerve-roots are involved the symptoms are slight or none at all exist; however, pains of a radiating character, stiffness, tremors, hyperesthesia, herpes, and even paralyses, may occur. The course is slow, and may extend over many years. Idiopathic circumscribed spinal serous meningitis is described in connection with spinal tumors, as the symptoms of the two are practically the same (p. 1078).

The **prognosis** is unfavorable ultimately.

The **treatment** consists in the use of iodids and mercury internally, and the application of baths, and counterirritation along the spine.

III. DISEASES OF THE SPINAL CORD

HEMORRHAGE INTO THE SPINAL MENINGES

(*Meningeal Apoplexy; Hematorrachis*)

(a) **Extrameningeal hemorrhage** occurs when the blood is between the dura and spinal cord.

(b) **Intrameningeal hemorrhage** is that in which the bleeding takes place beneath the dura.

Large hemorrhages are more common in the extrameningeal form; they result from trauma or rupture of an aneurysm. The peridural space will

¹ Weisenburg, *Amer. Jour. Med. Sci.*, November, 1910, p. 719.

accommodate a large amount of blood without giving rise to pressure symptoms. Caries of the vertebræ or carcinoma may cause hemorrhage by erosion and rupture of a blood-vessel. The intrameningeal form may result from meningitis, from trauma, or may occur as a complication of any of the infectious or hemorrhagic diseases. In such cases the hemorrhages are small and scattered. It may also occur in convulsive disorders or in strychnin-poisoning. Rupture of an aneurysm at the base of the brain may give rise to extensive hemorrhage; blood may also pass into the spinal cerebrospinal fluid from either a ventricular or subdural cerebral hemorrhage.

Symptoms.—When the hemorrhage is large enough to cause pressure the symptoms are very acute, apoplectiform indeed, but consciousness is preserved. Generally, however, they are quite indefinite. In any case they depend upon the degree and location of the compression. At first they are irritative—viz., hyperesthesia, paresthesia, neuralgic pains that are radiating in character, muscular irritability, tremors, or contractions. If subdural, the fluid obtained by lumbar puncture will probably contain blood. Later, paralytic symptoms may develop, as anesthesia and bladder and bowel symptoms, girdle-pains, or, when the lesion is high up, interference with respiration and pupillary changes.

The **diagnosis** is often difficult, unless the onset is sudden and explosive.

The **prognosis** depends on the cause and extent of the hemorrhage. If small in amount, absorption is usually prompt, with little or no disturbance of function remaining.

The **treatment** consists of rest, ice to the spine, and morphin to relieve pain; later mercury and the iodids may be given to hasten absorption. Local measures, such as leeches, cupping, etc., or general styptics, such as ergot and calcium chlorid, are of very doubtful value; although the latter may be used if the hemorrhagic diathesis is present. In certain cases operative procedures, with a view to removing the clot, may be justifiable.

HYPEREMIA AND ANEMIA OF THE CORD

These may be due to qualitative and quantitative changes in the blood, and morbid conditions of the vessel walls. They give rise to no characteristic symptoms unless softening or degeneration occurs.

The blood-vessels may be the seat of peri- or endarteritis, and rarely miliary aneurysms may develop. Embolism and thrombosis also occur, the former much less frequently than the latter, which is prone to follow sclerotic changes in the vessels, giving rise to ischemia and ultimately to softening (p. 1071). Degenerative changes in the cord may be caused by anemia (p. 1087).

HEMORRHAGE INTO THE SPINAL CORD

(*Hematomyelia; Spinal Apoplexy*)

This is of very much less frequent occurrence than cerebral hemorrhage. It is usually due to traumatism, but may possibly follow some severe strain or overexertion, probably only when the vessels are atheromatous. Hemorrhage may occur in cases of myelitis, epidemic cerebrospinal meningitis, syringomyelia, tumors of the cord, convulsive disorders, and infectious diseases;

it is, however, usually small. If the hemorrhage is extensive, disruption of more or less cord substance necessarily follows. An area may exist large enough to cause distention of the cord without rupture, and from this extravasations may take place in the cord substance above and below. Unilateral hemorrhage may occur, the gray matter being chiefly involved. If of recent origin, fresh blood will be found *postmortem*; but if of long standing, a brown or brownish-yellow area will be noted, consisting of disintegrated blood-corpuscles, cell detritus, and hematoidin crystals.

The *symptoms* necessarily vary according to the region involved, the gray matter of the cervical region being the most frequently affected. The onset is always sudden, the symptoms rarely requiring as long as a half-hour to develop. They consist of a flaccid paralysis of the limbs below the seat of the lesion, loss of reflexes, and probably of sensibility. The urine and feces will be retained. Consciousness is not lost. If in the cervical region, contraction of the pupils and narrowing of the palpebral tissues will be observed, owing to involvement of the oculopupillary fibers at the eighth cervical and first dorsal segments (cervical sympathetic nerve). If death does not occur, the symptoms gradually more or less subside, and ultimately resemble those of acute myelitis (p. 1071). As the hemorrhage is most often in the gray matter, dissociation of sensation (preservation of tactile and loss of pain and temperature sense) will result; atrophy of the muscles supplied by the affected segments (p. 1008) will also result; below the seat of the lesion the paralysis becomes spastic with increased tendon reflexes. If one side of the cord is principally involved, the Brown-Séquard syndrome (p. 1012) results.

The *diagnosis* must be made in acute cases from meningeal hemorrhage and, if traumatic, fracture of the vertebra. The presence of severe lancinating pain, muscular twitchings, and a less degree of paralysis distinguishes the former. The latter can usually be determined by the characteristic deformity, as determined by inspection and the skiagram—hemorrhage, of course, can coexist with fracture. The residual symptoms, if the patient survive, may be mistaken for syringomyelia and myelitis; the history of traumatism and sudden onset will distinguish it from the former. In the latter it may be difficult, as hemorrhage frequently precedes the development of myelitis in traumatic cases. A history of apoplectiform onset is evidence that the primary condition at least was hemorrhagic.

The *prognosis* during the acute stage is doubtful, death may occur from exhaustion or septic infection due to bed-sores or cystitis. If this stage is survived, a considerable degree of power may return and the patient get about with a more or less spastic paraplegia, and if in the cervical region, atrophic paralysis of the arms and hands.

Treatment.—Rest, ice locally, attention to bladder and bowels, and the internal use of calcium salts and opium make up the treatment of the acute stage; afterward the treatment is similar to that of myelitis (p. 1073).

CAISSON DISEASE

(*Diver's Paralysis*)

Definition.—A paralytic condition caused by sudden transference from an abnormally great atmospheric pressure to one of normal intensity.

The **etiology** of the disease is very clear, and certain predisposing factors are worthy of note. Divers are more apt to suffer if they have been working

at extreme depths, particularly if the period of exposure to great pressure has been prolonged; very moderate pressure will sometimes produce symptoms if continued for a sufficient length of time, and short periods of rest do not prevent the development of the disease. Ordinarily, it can be said that unless the pressure exceeds two and one-half or three atmospheres no danger may be apprehended. Alcoholism is a predisposing cause.

Pathology.—Two theories have been advanced to account for the condition. One is that under the high pressure the blood becomes overcharged with nitrogen gas; when the pressure is relieved this is liberated, causing emboli, which block up the spinal vessels. The other is that the blood is driven from the surface, causing distention of the vessels with paralysis of their walls; when the air-pressure diminishes they are unable to accommodate themselves to the changed condition, and stasis with congestion and hemorrhages result. Both factors are probably accountable. Small hemorrhages and laceration of nerve-fibers have been found in the cord.

The **symptoms** vary greatly in intensity. In the mildest form they consist of *neuralgic pains in the joints*, sometimes with slight articular swelling, *headache, giddiness*, and a little *tinnitus*. These pains may become more violent, particularly in the loins, and be followed by a gradual *loss of power* and by *anesthesia* in the limbs; these symptoms may disappear in a few hours or become more severe, with the development of *complete paralysis* and interference with the action of the sphincters. This paralysis usually assumes the form of *paraplegia*; *monoplegia* and *hemiplegia* also occur, and sometimes there are complete paralysis and anesthesia of all four extremities and of the trunk. In the most severe cases *cerebral symptoms* are also present, consisting of sudden loss of consciousness, profound coma, irregular respiratory action, and finally, after a short time, death from cardiac failure.

The **diagnosis** is very easy. It is possible, however, that an attack of *apoplexy* should occur in a man who has been under water, and the patient should always be examined for the presence of this or some other organic lesion.

The **prognosis** varies with the intensity of the symptoms. The lighter forms consist merely of joint-pains and slight dizziness that usually pass away in the course of a few hours. Paraplegias or hemiplegias, developing slowly and not assuming a severe form, are also transient in character. A more severe paraplegia is usually permanent, although some improvement may be expected. The apoplectic forms are almost invariably fatal in the course of a few hours.

The **treatment** consists, first, of prophylactic measures. In all places where caisson work is carried on one or more locks should be provided in which the pressure can be gradually reduced until it is approximately that of the atmosphere. Divers should be instructed to come slowly to the surface. If the pressure exceeds three atmospheres, the maximum length of the working period should not be more than one hour, and several hours should be permitted between the descents. A chamber should also be provided in which a man who exhibits symptoms of the disease can be once more subjected to a pressure greater than that of the atmosphere, as this usually causes an arrest of the process. When, however, the condition resembles that of acute myelitis, the treatment is purely symptomatic. It consists of rest, careful hygiene, and a stimulating diet. Stimulating liniments and the rapidly interrupted faradic current may be used for the pain. If the heart is not weak, phenacetin and similar drugs may be used. If it is, strychnin and caffeine may prove useful. In the comatose cases enemas of hot coffee should be used and artificial respiration and inhalation of oxygen may be necessary. For the resulting paralysis the treatment is that employed for chronic myelitis.

BULBAR PARALYSIS

(Glossolabiolaryngeal Paralysis)

Definition.—Bulbar paralysis is usually termed a disease of the brain, but as the pons and medulla are anatomically and physiologically parts of the cord, it seems more logical to discuss it here. It is an acute or chronic disease due to involvement of the motor nuclei of the medulla oblongata, and is characterized chiefly by a difficulty of speech and of deglutition. Three varieties have been described:

1. **Sudden or apoplectiform**, this being due to hemorrhage, embolism, or thrombosis either of a branch of the basilar or inferior posterior cerebellar arteries. In the latter case anesthesia of the face, ataxia, and other symptoms occur (p. 1100). The onset is always sudden, often with vertigo, and without loss of consciousness. The power to articulate is impaired or lost. The lips and tongue are involved, and hence the pendulous lower lip, the dribbling of saliva, and the atrophy of the lingual muscles. There are dysphagia and generally frequent attacks of choking.

The *symptoms* are less characteristic than those of the degenerative form. They are less regular in type, and usually are wide-spread at first; later some improvement takes place. In other cases, after more or less of a respite, degeneration sets in and they grow progressively worse. Death, however, usually occurs speedily.

The *diagnosis* of this type is not usually difficult. "Pseudobulbar paralysis" must be borne in mind (p. 1095). There is great danger to life for some little while in these sudden cases. Later the prognosis is rather more favorable than in the other forms.

2. **Acute Inflammatory.**—Here the onset is less abrupt, requiring a few days to a week to develop, and follows either one of the infectious diseases, the excessive use of alcohol, or lead-poisoning (polio-encephalitis inferior). But for this fact the symptoms are much the same as in the preceding form. It may be associated with acute anterior poliomyelitis (p. 1068).

3. **Chronic Bulbar Paralysis.**—This condition occurs chiefly in males beyond middle life. The cause can seldom be discovered, though certain cases seem to be of toxic origin. It may develop in the course of progressive muscular atrophy, amyotrophic lateral sclerosis, and insular sclerosis.

The *symptoms* are bilateral, the tongue being usually the first to suffer. The patient may notice that he cannot speak for any length of time without fatigue, and that he will then articulate indistinctly. Soon he observes that there is a marked and progressive *impairment of speech*. The muscles of the lips and other muscles of the lower part of the face atrophy. He can no longer whistle. Speech is rendered still more defective owing to paralysis of the lips. The lower lip droops, and the saliva constantly dribbles from the mouth and may be greatly increased in amount. *Difficulty in swallowing* is always present to a greater or less degree. Owing to the lingual paralysis, the tongue can neither be protruded nor can it be used to manipulate the food and make a bolus. [It is atrophied and the mucous membrane is wrinkled. *Fibrillar tremors* are present and reactions of degeneration may occur. The *larynx* is involved, so that phonation is imperfect, but it is not so marked as the implication of other parts. Particles that enter the larynx cannot be ejected owing to motor paralysis. There are no sensory symptoms and the power of taste is normal. The mind generally remains clear, though the patient is often emotional, and cries or laughs without apparent cause. The *course* of the disease is slow, and death is usually due either to inspiration pneumonia or to interference with respiration or circulation.

The **diagnosis** is not difficult; as a rule the bilateral character of the symptoms rendering them distinctive. In the *pseudobulbar form* the limbs are often paralyzed also (double hemiplegia). The tongue is not atrophied, the muscles of the face do not show changes in their electric reaction, and there is usually a history of successive apoplectic attacks (p. 1095). *Tumors* rarely, if ever, give rise to such regular bilateral symptoms. It may also have to be distinguished from myasthenia gravis (see p. 1189).

Treatment.—The disease is incurable. Hypodermics of strychnin or of strychnin, morphin, and atropin are of value in controlling the salivary flow. Electricity is of no value. Semisolid food is probably the most readily taken, and it is often necessary either to use an esophageal tube or to employ rectal alimentation.

ACUTE ANTERIOR POLIOMYELITIS

ESSENTIAL PARALYSIS OF CHILDREN

(*Atrophic Spinal Paralysis; Infantile Paralysis*)

Definition.—An infectious febrile disease of more or less rapid onset, usually associated with muscular paralysis and atrophy, occurring chiefly in children, and most frequently in those under three years of age.

Etiology.—Flexner and Noguchi¹ have cultivated an organism which fulfils the requirements necessary to prove a germ the cause of a disease. It is filterable, exceedingly minute, and is visible under high power of the microscope. Rosenow, Towne, and Wheeler² have also isolated a peculiar streptococcus from the throats, tonsils, abscesses in tonsils, and the central nervous system of those suffering with the disease which produced paralysis in inoculated animals. They state that this organism, while larger than that discovered by Flexner and Noguchi, may be the same, the latter being the form it takes under anaërobic and certain culture conditions. Nuzum and Herzog³ have also isolated and cultivated an organism from similar material and the cerebrospinal fluid which answered the same tests. The disease has been produced in monkeys by intracerebral inoculation with an emulsion of an affected spinal cord.⁴ Monkeys have also been inoculated with the secretions from the nasopharynx of those suffering from the disease. The virus will live in the intestines and pass from the body in the feces.⁵ Washings from the nasopharynx of those brought in contact with the disease but who did not contract it have caused it in inoculated monkeys,⁶ thus acting as "carriers." Whether or not the disease is communicable by direct contact is disputed. Many authorities believe that it is, but if so it is not to the same degree as many other diseases. The virus enters the body by way of the mucous membrane of the throat and nose, and from there spreads by the lymphatics.⁷ Possibly it may enter by other avenues, but such are not now known. There is no positive knowledge that the bites of insects communicate the disease.⁸ The disease may occur at any age, but by far the greatest number of cases occur before the third year of life;

they are about equally distributed between the two sexes. Later in life the condition is more common in males, chiefly between the ages of ten and twenty-five. It is rare after this period. Epidemics occur, the first recorded one occurring in Sweden in 1881. In the United States the first occurred during the summer of 1894. Dr. Caverly, of Rutland, Vt., then reported 126 cases occurring in Otter Creek Valley, a limestone region of Vermont. The disease appears to be becoming more common and epidemics more frequent. They have been observed at various times in all parts of the world. It is especially apt to occur in warm weather. Traumatism may be a predisposing factor. The acute infectious diseases may cause a symptom group resembling the specific disease.

Pathology.—The parenchyma of the heart, liver, and kidneys are the seat of cloudy swelling, and the lymph-nodes and spleen show hyperplasia and proliferated endothelial cells.

Macroscopically, the cord and meninges are congested. A similar condition may be found in the brain cortex, basal ganglia, ventricles, cerebellum, pons, medulla, and the nerve ganglia. The entire cerebrospinal axis is edematous. Sections of the brain and cord appear translucent and edematous and punctate hemorrhages may be seen. It is important to remember that the entire nervous system except the peripheral nerves may suffer, but the cells of the peripheral motor neurons suffer most, and that the symptoms most prominent are those which follow their injury.

Microscopically, the perivascular lymph-spaces in the regions above mentioned are found filled with cells, first polymorphonuclear leukocytes, later endothelial cells and lymphocytes. The vessels are congested, their walls degenerated, with rupture of and hemorrhage from the capillaries. Degeneration and destruction of the ganglion cells and of the nerve-fibers in the anterior roots and a round-cell infiltration of the pia-arachnoid are found. These changes are most pronounced in the anterior gray matter of the lumbar and cervical enlargements, but the white matter may also be affected. The pons and medulla may also show similar changes. The meninges are first affected and the nerve-cells are involved secondarily to the changes in the blood-vessels, their loss of function and degeneration being due to lack of nutrition. In old cases round cells and connective tissue take the place of the destroyed nerve-cells and fibers.

Symptoms.—The period of incubation ranges from two to thirty days, usually not more than eight. The onset is generally acute, and may be sudden. Constitutional symptoms are present as a rule. In typical cases the sequence is as follows: Fever (usually slight), malaise, possibly vomiting (especially in children), diarrhea or constipation, headache, and restlessness. Evidences of nasopharyngeal inflammation may be present. In a few hours or after one or two days paralysis supervenes and quickly spreads, involving a greater or less area; it then remains stationary for from two to four days to from five to eight weeks, when improvement takes place, beginning in the part last affected. During this period the patient may be stuporous. In some cases, after a most trifling indisposition over night, paresis is met with in the morning. In a few weeks only that portion remains paralyzed that is to be permanently damaged. The paralysis may either ascend or descend, as in Landry's disease (p. 1070). Wasting of the muscles will be noticed in a week or two after the onset of paralysis; these become flaccid and give the reactions of degeneration. Sensory symptoms are very rarely present. The reflexes are lost,¹ both superficial and deep, and later contractures, due to the overaction of unopposed muscles, may develop and result in various deformities.

¹ In the early stages they may be increased.

The growth of bone is seriously impaired in some cases. Atypical forms occur, especially during epidemics. These are: (1) The *arrested* or *abortive type*, which consists of constitutional symptoms, possibly general hyperesthesia, but no paralysis. Such cases may transmit the disease, and will show the characteristic changes in the cerebrospinal fluid. (2) *Acute bulbar*, in which involvement of cranial nerve nuclei occurs. The seventh nerve may be the only one affected. (3) *Encephalic*, characterized by involvement of the cortical cells. (4) *Meningitic type*, in which general hyperesthesia, retraction of the head, and other meningitic symptoms occur. (5) *Neuritic type*, the symptoms of which simulate those of multiple neuritis, but in which the nerves, if examined microscopically, show no pathologic changes.¹

Diagnosis.—Usually this is not difficult except, possibly, for the first few days in some cases. Before the occurrence of paralysis in suspected cases examination of the cerebrospinal fluid, obtained by lumbar puncture, is of service. It is especially important to remember this during epidemics, and to perform the operation early in suspected cases whenever possible. By this means the abortive forms may be recognized. In this stage it may be slightly turbid, but is usually clear, contains a moderate increase of cells, mostly mononuclear, and globulin, and may show a fibrin web formation and reduces Fehling's solution. Bacteria are absent, and when paralysis ensues all of these changes soon disappear.² In the various forms of meningitis except the tubercular the fluid is cloudy, contains more protein and cells which are mostly polymorphonuclear, and does not reduce sugar well. The fluid of tubercular meningitis closely resembles that from poliomyelitis, but the cells are apt to be more numerous. It may be impossible to distinguish the two except by inoculation of animals, the tuberculin tests, and the clinical symptoms. In meningitis the fluid is much increased in amount, but otherwise negative. Neustaedter has called attention to an anemic, glistening, edematous condition of the mucous membrane of the nasopharynx, with a serous frothy transudate in the early or prodromic period.³ Close scrutiny will enable one to differentiate between this disease and a pseudopalsy the result of pain on active or passive motion, as seen in rickets, scurvy, and in hip-joint disease. From multiple neuritis it is distinguished by the absence of tenderness over the nerve-trunks and the fact that in neuritis the symptoms are progressive and not retrogressive, as they are in poliomyelitis. The symptoms of the cerebral palsies of childhood are given on p. 1101, and of transverse myelitis on p. 1072.

Prognosis.—Some impairment of motion and more or less wasting of the muscles almost invariably remain. Danger to life varies in different epidemics. In some the death-rate is less than 10 per cent., in others it may be 25 per cent. One attack confers immunity. Death may occur from either involvement of the bulbar nuclei or violence of the toxemia. Marked improvement in power may result several years after the oncoming of the disease if proper treatment is persisted in. A few cases completely recover.

Treatment.—Owing to the possibility of the disease being communicable during the acute stage, the patient should be isolated and the discharges disinfected, as in other similar diseases. The nasopharynx especially should be kept as clean as possible with washes containing menthol. Neal and Dubois claim that the greatest hope of success in combating anterior poliomyelitis lies perhaps in a prophylactic vaccination. If fever is excessive, cool sponging

or an ice-bag to the head may be employed. No procedure is of greater value than lumbar puncture. It is of especial value in the meningitic type, but is valuable in all. If done early it may stop the development of serious symptoms. It should be repeated at intervals of from one to several days, according to the condition of the patient, until acute symptoms have disappeared. The injection into the spinal canal of the blood-serum of one who has had the disease has been advocated.¹ This, of course, must be sterile, and the possibility of the donor having had syphilis must be determined by a previous Wassermann test. It need not be inactivated. The dose ranges from 5 to 20 c.c., according to the amount of cerebrospinal fluid removed (the amount injected should be less), and the procedure repeated daily according to the severity of the patient's symptoms, until several doses are given. The value of this procedure is still doubtful. Meltzer² has advised the intraspinal injection of 2 c.c. of a 1:1000 adrenalin solution every four to six hours. At the time of the first injection the spinal fluid should be withdrawn freely; at subsequent injections, unless the pressure is high, he advises that little if any fluid be withdrawn, and the adrenalin solution washed in with 2 c.c. or more (if no fluid is withdrawn) of normal salt solution. If encephalic symptoms are present the amount of adrenalin solution should be less than 2 c.c. These injections should be continued for four or five days after improvement in the paralysis has ceased. He also thinks that the inhalation of oxygen under pressure for twenty to thirty minutes every two or three hours may be of service. This is especially so when there is evidence of respiratory failure, when it should be administered "under pressure in a respiratory rhythm," combined with artificial respiration if necessary. For this purpose his apparatus should be used. During the acute stage a brisk calomel purge, followed by a saline, is of benefit; and it is necessary to support the general condition. For this reason absolute rest should be enjoined; the diet should be liquid and nourishing, and stimulants should be given freely if necessary. Hexamethylenamin probably exerts an influence in destroying the disease germ. The affected parts must be kept warm by means of cotton wool or extra clothing or artificial heat. As soon as possible the child is to be taken into the fresh air. It is of vital importance to keep up the general systemic tone, and hence the necessity for fresh air, change of scene, and for nourishing but easily digestible food. After the acute symptoms have subsided, massage and electricity should be employed, together with the administration of strychnin. In the later stages, when contractures have set in, mechanical appliances may be necessary to correct deformity and to give support. In suitable cases either nerve anastomoses or the transplantation of tendons have given good results.

CHRONIC POLIOMYELITIS IN ADULTS

That **chronic poliomyelitis** exists has been proved by Oppenheim and other observers. The symptoms resemble very much those of progressive spinal muscular atrophy (p. 1082). In this affection, however, the intrinsic muscles of the hands are usually first affected, while in chronic poliomyelitis any group may be the first to suffer.

Treatment.—Mercury or the iodids may be tried, especially if there is a history of syphilis. Electricity and massage are of the greatest value.

¹ Neustaedter and Banzhaf (*Jour. Amer. Med. Assoc.*, May 26, 1917, 1531) have had promising results with horse serum.

² *New York Med. Jour.*, August 19, 1916, p. 337.

ACUTE POSTERIOR POLIOMYELITIS

(Herpes Zoster)

The posterior root ganglia of the spinal nerves, and those found in connection with the sensory cranial nerves, are also subject to inflammation due to some infective agent. The symptoms are neuralgic pain in the course of the affected nerves, possibly anesthesia in their distribution, and herpetic eruptions. Constitutional symptoms may also be present. Herpes zoster is a type of this disease. (See also p. 1039.)

While most cases recover, it may be a serious condition. Sight may be lost if the vesicles involve the eye, and unsightly scarring is not unusual.

The treatment consists in protecting the vesicles from rupture and infection by anodyne powders or salves covered with a dressing. Anodynes internally if the pain is severe. Drugs seem to have no effect in shortening the disease, but the salicylates, quinin, and general tonics may be tried.

ACUTE ASCENDING PARALYSIS

(Landry's Paralysis)

Definition.—An acute paralysis, beginning in the legs and ascending by way of the trunk and upper extremities, and ultimately involving the *bulbar* centers. It usually runs a short course, and, as a rule, terminates in death.

Pathology.—Although in many cases neither gross nor microscopic lesions have been found either in the cells, peripheral fibers, or muscles, a number of different anatomic changes have been found in cases believed to have this disease, viz., multiple neuritis, acute diffuse myelitis, and poliomyelitis. A fluid exudation in the central canal of the cord and hyaline change in the central arteries have also been found. The symptoms are evidently due to a severe type of infection involving the peripheral motor neuron, which when very malignant causes death before visible changes occur, while in less acute cases the characteristic evidences of neuritis, myelitis, or both may be discovered.

Etiology.—No definite cause is known. It has followed cold and exposure, traumatism, and the infectious fevers, including influenza. It occurs in males chiefly between twenty and forty years.

Symptoms.—In the most acute cases there are practically no prodromal symptoms other than malaise and possibly chilly sensations. Weakness, followed in a few hours or a day or two by paralysis, develops in the lower extremities. One may be involved a few hours earlier than the other. It spreads toward, and soon involves, the trunk also, and in quick succession the arms. The third and usually fatal stage is reached when bulbar symptoms develop. Very rarely the upper extremities may be first attacked. Death may occur in forty-eight hours. The paralysis is a flaccid one; the muscles can be passively moved without offering any resistance. Wasting rarely occurs and there are no electric changes. In less acute cases a decided febrile stage precedes the onset of paralysis, chills, fever, malaise, and possibly formication or even sharp pain. In any case the later symptoms are pre-eminently or solely motor. Sensory symptoms when present are very slight. The deep reflexes are absent. The bladder and rectum are not implicated nor do bed-sores develop. As stated, when the bulb is attacked death generally follows, due to cardiac or respiratory failure or to interference with deglutition. There are no cerebral symptoms.

Course.—Death may occur in from forty-eight hours to a few weeks. A few cases of recovery have been reported (Sinkler) in some of which paralysis had been wide-spread, even reaching the bulb, judging from the labored respiration. When improvement takes place, it does so in the reverse order to the onset, so that the last part affected is the first to recover. It is much slower than the invasion.

Diagnosis.—The rapid onset of a paralysis that usually ascends, the relaxation of the muscles, slight wasting, if any, and the absence of electric changes and of sensory symptoms, with or without fever, serve to make the diagnosis and to distinguish Landry's disease from ordinary types of poliomyelitis (p. 1067), neuritis, and spinal hemorrhage. For the differential diagnosis between Landry's paralysis and acute myelitis, see page 1073.

Prognosis.—Always grave, particularly if bulbar symptoms occur, and especially if they appear early.

The **treatment** is essentially the same as that for any acute disease of the cord or nerves—*i. e.*, rest, freedom from all excitement or worry, warm baths and packs, moderate purgation, and diaphoresis; hexamethylenamin, ergot, belladonna, salicylates, and iodids internally. Should the patient survive, electricity and massage should be employed.

ACUTE MYELITIS

(*Myelitis; Acute Diffuse Myelitis; Transverse Myelitis; Myelomalacia*)

Definition and Varieties.—An inflammation, with softening of the cord, giving rise to various groups of symptoms depending upon the region or regions involved, and not, therefore, as constant in its symptomatology as the systemic nervous diseases (tabes dorsalis, lateral sclerosis). It may be acute, subacute, or chronic. If the gray matter only is involved, it is termed *polio-myelitis* (p. 1066); if a small vertical extent (several segments) of both white and gray matter, *transverse myelitis*; if an extensive area of both white and gray matter, *diffuse myelitis*; if a large area of gray matter, *central myelitis*; if in scattered areas, *disseminated myelitis*. If it follows a previous hemorrhage, *hemorrhagic myelitis*, and if it is caused by pressure, as a tumor or bone disease, *compression myelitis*.

Etiology.—Myelitis may follow exposure (especially in alcoholics), the infectious fevers, tonsillitis, and it may be due to traumatism or disease of the vertebræ (caries, malignant disease). It has followed the employment of the Pasteur treatment for rabies. Syphilis precedes it in nearly one-half of all cases. It has also been described as following peripheral neuritis, ascending neuritis, and we meet with some cases in which pregnancy seems to act as the predisposing cause. As the virus causing poliomyelitis may sometimes affect the white matter, this disease may simulate transverse or diffuse myelitis. In many of the cases occurring in those who have arterial disease the cause is thrombosis in a spinal artery, causing softening. This is known as *myelomalacia*. It may be difficult clinically to distinguish it from true myelitis. Myelitis is most common in males, generally from fifteen to thirty years of age.

Pathology.—The cord may present little or no change to the naked eye, or in the most acute cases it may be diffuent. Between these extremes many grades exist in which the pia will be found congested and adherent, the cord being more or less injected, and areas of softening and even cavities being found. Three forms of softening are spoken of by some writers—the red, yellow, and gray—depending upon the predominance of blood, fat, or connective tissue

respectively. The *postmortem* finding depends upon the duration of the disease; the more chronic the course, the greater the amount of nervous connective tissue (neuroglia), and in consequence sclerosis will be the predominant feature. The nerve-cells and fibers are found in various stages of disintegration, the former being swollen, vacuolated, granular, and their processes broken and in many cases missing; while the latter swell, the myelin breaks up, undergoes fatty change, and is removed, and the axis-cylinders finally break up and disappear. A single area of degeneration may exist centrally, in one-half of the cord, transversely, or many localized or widely disseminated areas may be found; but above and below all of them will be found degenerated fibers—ascending and descending degeneration—due to a solution of continuity between the cell body and its axis-cylinder process. Transverse myelitis, when the extent of several segments of the cord is affected, is the most common.

Symptoms.—These will vary according to the seat and extent of the lesion. In the most acute form the course of the disease is quite rapid, reminding one of hemorrhage into the cord or membranes; the onset, however, is not so explosive, and, though rapid, it is not sudden. There may be chills and fever, malaise, backache, pains in the limbs, or the first symptoms may be numbness of the limbs. In some cases, however, there is no warning. Motor weakness develops, and is rapidly followed by paralysis. Some irritative sensory symptoms appear, as hyperesthesia and paresthesia, and then more or less complete anesthesia supervenes. There is incontinence of urine and feces, and bed-sores and cystitis develop with rapidity. The temperature now rises to 105° F. (40.5° C.) or even higher, and typhoid symptoms, exhaustion, and death close the scene. I have seen a case that developed in a woman a few days after delivery and proved fatal in six days. In the majority of instances constitutional symptoms are not so marked; in fact, they are often absent, and the paralysis develops more slowly.

Acute transverse myelitis is the type most frequently met with, the lesion being generally situated in the dorsal cord. The motor symptoms generally appear before the sensory symptoms, though they may be contemporaneous. In any event, they are apt at first to be irritative. The limbs will feel tired and heavy and drag in walking, and tremors or twitching occur, even cramps, and later paralysis, partial or complete, in the region involved. The lower limbs alone may be involved, or when the lesion is in the cervical region paralysis and atrophy of the upper with a spastic condition of the lower extremities may develop. The breathing is generally diaphragmatic in cases in which the intercostal muscles are involved. If the lesion is still higher up, death will quickly take place from failure of respiration. Such cases, however, are more apt to occur in the type known as *disseminated myelitis*, in which bulbar symptoms are prone to appear. The sensory symptoms at first are those of a tingling or burning character, or formication. Later, certain or all forms of sensation may be lost, and, roughly speaking, the upper level of anesthesia corresponds to the level of the cord involved. This "boundary region" is apt to be hyperesthetic, and in it the "girdle-feeling" is experienced. The reflexes are usually lost at first; they may remain permanently absent or they may return, and become exaggerated below the lesion. The condition of the tendon reflexes may enable one to locate the position of the cord-lesion, they being lost in parts supplied by the affected segments, but increased below the seat of the lesion. Whether or not there is wasting of the muscles depends on the location of the lesion; if in the dorsal cord, as is usually the case, none will be found. When the cervical region is involved, the muscles supplied by the segments involved will atrophy and the reaction of degeneration will develop. The same thing occurs if in the lumbar cord (p. 1009). Below the seat of the lesion there is

paralysis, but no atrophy. Loss of control of the bowel and bladder may be among the earliest symptoms, though this is not the rule. While superficial ulceration may occur in any neglected case, the most marked trophic changes take place in those in which the lumbar cord is involved, either directly or by extension. In such cases, despite the most assiduous attention, extensive bed-sores develop. The course of the disease depends on the cause and extent of the lesions. Death may occur in a few weeks from exhaustion, heart or respiratory failure, or from kidney diseases secondary to cystitis. Recovery is the rule, though with more or less permanent damage due to degeneration of some of the paths of conduction.

Diagnosis.—The distinction from hemorrhage into the cord or membranes has already been mentioned (p. 1062). From Landry's paralysis it can be separated by a reference to the subjoined table:

ACUTE MYELITIS	LANDRY'S DISEASE
Paralysis is sudden and generally becomes complete.	Paralysis begins in the feet and rapidly spreads to the muscles of respiration and deglutition.
Wasting and bed-sores are marked. If atrophy occurs, reaction of degeneration is present.	Trophic disturbances are absent. No reactions of degeneration.
Early involvement of the sphincters. Girdle-pains sometimes mark the height of the lesion.	Bladder and rectum are not involved. Girdle-pains are absent.
Sensory paralysis.	No loss of sensation.

Anterior poliomyelitis is not accompanied by sensory paralysis. Bed-sores and disturbances of the sphincters do not occur. In *peripheral neuritis* pain of a shooting character and tenderness over the affected nerves is present, and is almost invariably the first symptom to appear. Motor symptoms may not appear for some days. This is not the case in myelitis. In *compression of the cord* sufficient collateral evidence, as evidence of bone disease, can usually be obtained to differentiate it from myelitis. *Hysterical paraplegia* is occasionally misleading. The character of the patient and the previous history should be thoroughly considered; moreover, in this form there are no trophic changes, and, as a rule, no bladder symptoms; at any rate, there is no cystitis. Retention of urine may occur, but not incontinence, and the Babinski reflex is absent. The diagnosis of myelitis can usually be made without great difficulty from the motor and sensory symptoms, the vesical, rectal, and trophic symptoms, and often from the presence of the girdle sensation in addition. Myelomalacia can usually not be distinguished clinically from myelitis. The symptoms occurring in an old person, without any of the causes of the latter having been operative and the existence of a previous history of syphilis, is rather in favor of the former.

Prognosis.—The most acute cases are fatal in from three days to a week. Less acute cases generally recover with more or less loss of motor power. Improvement may continue for several years.

Treatment.—Very little can be done to arrest the process in acute myelitis. Absolute rest should be enjoined, and the patient given a nutritious liquid diet with free stimulation. The patient should be placed on an air- or water-bed. Trophic changes should be looked for daily, and at the first sign of their appearance alcohol or some stimulating liniment should be employed. If the skin is broken, absolute cleanliness must be observed, and the wounds dressed antiseptically. It is well, also, to change the patient's position from time to time to avoid too long-continued pressure in any one spot. The bladder must be watched to see that retention does not occur (p. 1007), and if cystitis

develops it should be treated by the usual methods employed for that condition. Either the salicylates or hexamethylenamin should be given in infectious cases, and in specific cases salvarsan, mercury, and potassium iodid in full doses. A general tonic and supportive treatment is indicated, and later massage, electricity, and baths.

CHRONIC MYELITIS

That there are both a subacute and a chronic form of myelitis is generally conceded, though these types are not sharply circumscribed.

Etiology.—This is not clearly known; an acute attack may terminate and the tissue of the cord become sclerosed with persistence of the symptoms; or the disease may commence insidiously as the result of the existence of some chronic infectious process, such as syphilis; it may be the sequel of an acute infection, such as typhoid fever, or follow a fall or blow upon the back. The primary form is rare.

Pathology.—Histologically, the chief differences from the acute variety consist in the greater amount of sclerosis, the thickened blood-vessels with contracted lumen, and an entire absence of recent hemorrhage. In some cases also the pia is much thickened in patches and firmly adherent. The nerve-cells are either seen to be in advanced stages of degeneration or they have actually disappeared. Secondary degenerations, above and below, proceed from the primary foci.

Symptoms.—Any symptom occurring in the acute may be duplicated in the chronic form, though the onset of the latter is gradual. The symptoms are more or less obtrusive, according to the region of the cord that is affected, and it may be several years before they are fully developed. In those cases which do not follow the acute, the first symptoms complained of are usually numbness of the legs and a feeling of weakness, which gradually progresses until in some cases they may become useless. If the meninges are involved, as they frequently are (meningomyelitis), shooting pains in the extremities and a girdle sensation are complained of. The symptoms differ somewhat, according to the nature of the lesion. This is usually of the transverse variety, which, if in the dorsal region, as it usually is, causes a spastic paraplegia, with increased deep reflexes, Babinski reflex, some sphincter disturbance, and more or less complete loss of sensation to the level of the affected segments. If in the cervical enlargement, which is rare, more or less atrophic paralysis of the arms, owing to the involvement of the gray matter, with a spastic paralysis of the legs and loss of sensation to the affected segments, will be present. If in the lumbar region, the symptoms will differ somewhat, according to the segments involved. There will, however, be atrophy in certain muscles and spasticity and absence of atrophy in others (p. 1009). Owing to involvement of the posterior columns there may be more or less ataxia, so that the gait is a mixture of a spastic and ataxic type (ataxic paraplegia). The disseminated type resembles multiple sclerosis.

Diagnosis.—The gradual, and in many cases the irregular, onset characterize this disease. In its various phases it may simulate almost any spinal cord disease, and it is most apt to be confounded with tumor pressure (carius or malignant), primary lateral sclerosis, amyotrophic lateral sclerosis, and syringomyelia. *Pressure*, whether due to a tumor, to vertebral caries, or to malignant disease, is apt to cause pain radiating in character, and the last two usually present collateral evidences in the deformity and cachexia (p. 1075). The symptoms, too, in the case of tumor may, at first, be unilateral and confined

principally to the muscles and skin areas supplied by the affected segments (p. 1009). Amyotrophic lateral sclerosis is distinguished by the fibrillary tremors in the atrophied muscles, absence of sphincter involvement, and sensory symptoms. Syringomyelia is characterized by the loss of pain and temperature sense with preservation of tactile sense in certain areas.

The **prognosis** is necessarily grave. Recovery may be possible, but it is extremely rare. The process, however, may be arrested and the patient live for years, more or less helpless.

Treatment.—More can be expected from general hygienic measures than from the use of drugs. In the early stages rest is indicated, but it is well also to employ passive exercise to prevent, if possible, a too great contraction of the muscles. As soon as expedient—each case being judged on its merits—the patient should be taken out of doors. Change of air and of scene is advisable, as are also baths and massage. Mild counterirritation may be applied to the spine, but care should be taken to avoid the areas of anesthesia. General tonics—iron, quinin, arsenic, and strychnin—should be given, also mercury and the iodids. The greatest possible care of the bladder should be taken in order to avoid cystitis. Good results have been obtained by Bailey and Elsberg¹ from the performance of what they term “spinal decompression.” This consists in opening the spinal dura over the seat of the lesion and then closing the wound in the usual manner.

COMPRESSION OF THE SPINAL CORD

(*Compression Myelitis*)

It is of importance to be able to recognize this condition. To be sure, it is not always possible to diagnose it with certainty, but when there is a reasonable surety the question of operation may arise.

Etiology.—We may classify the causes of compression under three headings—(a) traumatism (fracture), (b) inflammatory disease (caries of the spine, due to tuberculosis or syphilis), and (c) neoplasms (including various tumors, gummata, and aneurysm); but these will receive separate consideration (*infra*).

Pathology.—The postmortem findings will depend upon the degree and duration of the pressure. More or less meningitis is often associated, especially in the cases due to vertebral caries. The cord will be more or less flattened and distorted at the seat of pressure, and in the early stages hyperemic and possibly softened. Later it is hard, sclerosed, and of a grayish color, and above and below the compressed region degenerated areas will be seen on sectioning the cord. Microscopic examination reveals various stages of degeneration of the nerve elements at the point of pressure and secondary degeneration of the various tracts. The nerve-roots will be more or less damaged by compression.

Symptoms.—These will vary according to the site of the lesion and the extent of involvement—*i. e.*, the vertical extent, the degree of pressure exerted, and the amount of inflammation present. Two groups of symptoms are present in typical cases—first, those due to involvement of the nerve-roots, and, second, those dependent upon involvement of the cord itself—*ascending and descending* degeneration. Pressure upon the *posterior roots* gives rise to *pain*, neuralgic in character and radiating along the course of the nerves. There may be *paresthesia* and *formication*. These irritative symptoms are followed sooner or later by destructive changes, and hence the anesthesia. There may be spontaneous pain in the anesthetic areas (*anesthesia dolorosa*), which areas are of

¹ *Jour. Amer. Med. Assoc.*, March 9, 1912, p. 675, and *Jour. Nerv. and Ment. Dis.*, October 1916, p. 339.

the segmental type and depend in location upon the cord segment and corresponding nerve-roots involved (Fig. 76). Pressure upon the *anterior roots* also causes irritative and paralytic symptoms, and hence the early twitching, or even spastic condition, and later the loss of power or paralysis. The muscles supplied by nerves from the affected segments waste, and qualitative and quantitative electric changes can be elicited.

The *second group* of symptoms, due to secondary degenerations, then develops, and may set in either rapidly or slowly. If myelitis promptly supervenes and is extensive, *cord symptoms* of a pronounced type develop quickly. The parts below the lesion will become weak, there will be girdle pains, and a sense of constriction or pain in the legs. Sensory paralysis is usually not so marked in this region as the motor, as the sensory tracts are less vulnerable to pressure than the motor, but hyperesthesia and hyperalgesia are present in most cases. They may, however, be absent. The reflexes, whether increased or absent, depend upon the location of the lesion (p. 1005). As the dorsal region is most commonly involved the deep reflexes of the lower limbs are increased. The Brown-Séquard syndrome may be present (p. 1012). If the cause of compression ceases to act for some time, some improvement takes place, due possibly to the subsidence of the myelitis. If the pressure is of *slow onset*, great tolerance is manifested. Usually sensation is recovered before motion. In certain cases, however, motor power is regained, while the muscular and tactile senses do not return. In such instances, in which the posterior columns bear the brunt of the trouble, inco-ordination results and there is secondary ataxia. If the disease is below the first lumbar vertebra the cauda equina only is affected (p. 1080).

Diagnosis.—If the combined symptoms of peripheral and central origin develop slowly in the order named, compression is likely. It has been asserted¹ that when the paralysis is due to pressure, actual degenerative changes not yet having taken place, that the tendon reflexes are not increased but the skin reflexes (plantar) are very much so. *Myelitis* gives rise first to cord, and only later to root symptoms; hence the difficulty in cases in which myelitis develops quickly. Extensive root-symptoms are suggestive of *meningeal involvement*. In any event, too much stress should not be placed on the nervous symptoms alone. The spine should be carefully examined and palpated for points of tenderness. Careful note should also be taken as to whether there is any limitation of movement or deformity (kyphosis). The family history may suggest *tuberculosis* (caries of the spine). A skiagraph of the spine is often valuable, as it must be borne in mind that Pott's disease may occur without spinal deformity. The cerebrospinal fluid may present peculiar changes (p. 1078). Tumor is discussed on p. 1077. The history will indicate if due to vertebral fracture.

The **prognosis** depends entirely upon the cause. Having ascertained this, it then depends upon the possibility of its removal.

Treatment.—In general, the treatment is that of myelitis. When due to tubercular disease of the vertebra, the treatment indicated is for that condition, and a surgeon should be consulted, though operative cases are the exception rather than the rule. It is well to impress upon the patient and relatives the chronicity of the condition, but faithful and persistent efforts will yield good results. Rest is of vital importance, particularly when the disease is active. The patient should be kept in bed in a recumbent position until consolidation has taken place. Extension may be necessary. Good and easily assimilable food and cod-liver oil and alteratives should be given. The nutrition of the muscles may be improved by general friction (massage). As

¹ *Jour. Amer. Med. Assoc.*, January 25, 1913, p. 269.

soon as possible a plaster jacket should be put on the patient, and he should be taken into the open air and sunlight. If a history of syphilis is obtained, that condition should be vigorously treated. In vertebral fracture the question of operation to remove the fragments of bone pressing on the cord may arise. In most cases laminectomy is advisable after shock has passed away, unless there is positive evidence that the cord is completely divided. The seat of the lesion must be determined by the methods detailed on pp. 1005-1012. When due to tumor, see page 1079.

TUMORS OF THE SPINAL CORD AND ITS MEMBRANES

Under this heading are included the granulomata, parasitic cysts, and those due to other causes, as circumscribed spinal serous meningitis as well as neoplasms proper. The classification of Bruns is a convenient one:

I. Tumors which, arising in its envelopes, secondarily affect the spinal cord.

(a) Vertebral tumors arising from the spinal column or the soft tissues immediately surrounding it.

(b) Intravertebral tumors, which may be divided into two classes, in accordance with their relation to the dura mater.

1. Extradural tumors originating in the periosteum of the vertebra, the outer layer of the dura mater, or the fatty areolar tissue of the epidural space. Those arising from the vertebra are frequently malignant, either carcinoma or sarcoma, and are usually metastatic. Myelomata also occur. Benign growths, as osteomata, exostoses, chondromata, etc., are rare.

Extradural growths comprise sarcomata, liptomata, fibromata, myxomata, and chondromata. The first two are the most common.

2. Intradural tumors originating from the inner layers of the dura, the arachnoid, the ligamentum denticulatum, the spinal roots, or the pia mater.

Intradural tumors may be either diffuse or localized. Sarcomata, which may or may not be metastatic; endotheliomata, cylindromata, fibromata, and lymphangiomata. Fibromyxomata and fibrosarcomata are frequently found in connection with the nerve-roots. Cysts are also found within the dura. Intradural growths are usually found in the lateral or posterolateral surfaces of the cord, a fact which facilitates their removal.

II. Intramedullary tumors of intrinsic spinal origin.

Intramedullary neoplasms comprise gliomata, sarcomata, angiosarcomata, gummata, and tubercles. Gliomata usually give rise to the symptom complex known as syringomyelia (p. 1088), but may be circumscribed.

Etiology.—As has been said, malignant and tubercular growths are often secondary to similar conditions elsewhere. Trauma seems to be a cause in some cases, especially non-parasitic cysts. They most frequently occur after middle life (forty to sixty). Extramedullary growths are more common than intramedullary. The former occur most frequently in the dorsal region; the latter in either the cervical or lumbar enlargement.

The **symptoms** of extramedullary growths are due to irritation of nerve-roots, especially the posterior and compression of the cord (p. 1075). There are, therefore, pain in course of the roots arising from the affected region and a gradually developing paraplegia. If the anterior roots of either enlargement are affected, clonic spasms may occur. The pain is usually shooting in char-

acter, but in between the paroxysms it may be constant. Hyperesthesia may also be present in the skin area supplied by the affected nerves. According to Starr, the order in which the symptoms arise is commonly: (1) Peculiar pains of limited distribution; (2) increase of reflexes below the lesion; (3) paraplegia; (4) loss of sensibility; (5) loss of subjacent reflexes. The pain, as well as evidences of compression, may at first be unilateral and the Brown-Séquard syndrome (p. 1012) may be present. As the growth enlarges they become bilateral. In some cases ataxic symptoms with increased reflexes may be more prominent than paralysis.¹ Segmental areas of anesthesia usually soon develop.

The symptoms of intramedullary tumors depend on their location; if within the gray matter, the symptoms are those of syringomyelia (p. 1088), otherwise they resemble those of a slowly developing myelitis, motion being lost before sensation. Pain is not apt to be a prominent symptom until the periphery is reached. The Brown-Séquard syndrome frequently occurs. The functions of the different segments of the cord are given on page 1009. Interference with these functions points to the particular part of the cord involved.

*Circumscribed spinal serous meningitis*² causes symptoms so much resembling tumor that it may be mentioned here. The dura is usually found very tense and bluish in color, but no macroscopic lesion is found. When opened the fluid escapes under marked pressure. The symptoms are usually sensory, especially intense pain of a segmental distribution first appearing before other symptoms develop, which are those of pressure, as in tumor. A peculiarity is that the symptoms are apt to vary from time to time, according as the pressure of the fluid increases or diminishes.

Course.—Tumors usually grow slowly, and therefore the symptoms are gradual in their development. Ordinarily there are periods of arrest or even improvement that are followed subsequently by further advance. The *duration* of spinal tumors is variable. Those of malignant nature or rapid growth may produce death in a short time; those that simply exert pressure and enlarge very slowly may not produce total disability for several years. In general, it may be said that from five to ten years is the ordinary limit after the first appearance of motor disturbance. Some tumors, however, particularly lipomata, produce only slight disturbances throughout life, or else no symptoms at all, remaining entirely latent.

The **diagnosis** involves three points: first, the recognition of the presence of the tumor; second, of its site; and third, of its nature. The prodromal symptoms of spinal tumor are often confounded with *neuralgia* or *lumbago*. It is sometimes possible to make a **differential diagnosis** by means of the presence, in neuralgic conditions, especially of intercostal nature, of the sensitive points along the course of the ribs, and of the existence, in the case of tumor, of exaggerated knee-jerks and sensitiveness over certain portions of the vertebral column. In the paraplegic condition it may be confounded with a *neuritis*, but in this there is tenderness over the nerve-trunks, absence of reflexes in the paralyzed parts. Sensory paralysis, if it exists, is not confined to the distribution of individual nerves, but is of the segmental type (Fig. 76), and the sphincters are not disturbed. The cerebrospinal fluid may present peculiar changes in compression of the spinal cord by tumor or otherwise. These are a great increase in the protein content, a yellow color of the fluid, and sometimes coagulation of it. The cells are not increased unless meningeal irritation is present. These changes if present are characteristic. Lesions of the cauda equina may be difficult to differentiate (p. 1080).

¹ Potts, *Jour. Nerv. and Ment. Dis.*, October, 1910, p. 621.

² *Amer. Jour. Med. Sci.*, November, 1910, p. 719.

The *intrinsic diseases* of the spinal canal give rise to much greater difficulty, especially *myelitis* and *pachymeningitis cervicalis*. From the former the correct diagnosis may sometimes be suspected, because in tumor there are severe radiating pains and the symptoms are more pronounced on one side than on the other, and are apt to be more gradual in their development. Moreover, the symptoms of segmentary involvement are sharper and the root symptoms more characteristic. From *pachymeningitis cervicalis* a tumor in the cervical region can be usually distinguished by the fact that the radiating pains are less severe and the symptoms not so distinctly bilateral. It may be impossible to distinguish a central tumor from *syringomyelia* unless the symptoms of root pressure are quite distinct. *Pott's disease*, in its early stage, may also give rise to some difficulty. However, the rapid development of the kyphosis, and particularly the pain that is elicited by sudden pressure upon the head, renders it possible, after a reasonable period of observation, to recognize the true nature of the case (p. 1075).

The *diagnosis of the position of the tumor* has been largely discussed in the Symptomatology. In general, this is determined by determining the existence of symptoms dependent upon interference with the functions of certain segments of the cord (p. 1009, Fig. 76) plus disturbance of the functions of tracts of the cord, causing symptoms in parts innervated by the segments below those affected (*vide* Compression of Spinal Cord). The symptom-complex may, however, be considerably disturbed by the presence of multiple tumors. In these cases the majority ordinarily remain latent. It may also be said that the presence of root pains suggests a meningeal seat, while pronounced paraplegia, dissociation of sensation, or the Brown-Séquard symptom-complex points to the presence of a tumor in the substance of the cord itself. (See table on p. 1009.)

Finally, the recognition of the *nature of the growth* can often be made from the history of the existence of the tumor or an infectious process in other parts of the body; the rapidity of the growth; the age of the patient; and occasionally from the results of an exploratory operation. It must be remembered, however, that it does not always follow that a tumor in the spinal canal is similar to that found elsewhere.

The **prognosis** depends upon the severity of the symptoms, the rapidity of their development, and the nature of the growth, if this should be known. Complete subsidence of all the symptoms may occur, even after a spastic paraplegia has existed. Of course this is only likely in those cases in which the tumor can be removed by operation or absorbed through the action of drugs.

The **treatment** depends wholly upon the recognition of the nature of the tumor; if this be syphilitic, salvarsan or neosalvarsan, mercury, and potassium iodid should be given in full doses. If, on the other hand, it is not specific, and especially if extradural, operation would seem to offer a possibility of cure. This has been done successfully a number of times. Intramedullary growths may also be removed. In such cases a two-stage operation is necessary, allowing the tumor to extrude itself after the cord has been exposed.¹ Early operation in cases of circumscribed spinal serous meningitis has given most excellent results. As the prognosis is, in general, unfavorable as to cure and often gloomy as to life, the clinician should not hesitate to recommend surgical interference. When the tumor is known to be malignant, the pain may be relieved by cutting the anterolateral columns of the cord.

¹ *Jour. Nerv. and Ment. Dis.*, August, 1916, p. 97.

LESIONS OF THE CONUS MEDULLARIS, EPICONUS, AND THE CAUDA EQUINA

As symptoms produced by lesions of these regions frequently resemble each other, they are described together.

The conus medullaris comprises that portion of the cord extending from the filum terminale to and including the third sacral segment. Lesions in this region are characterized by the absence of paralysis of the limbs and by paralysis of the sphincters of the bladder and rectum with loss of sexual power. There is also a saddle-shaped area of anesthesia involving the skin about the anus, perineum, posterior part of the scrotum, penis, and the mucous membrane of the urethra and anus. The testicle is sensitive, its nerve supply originating higher up (Fig. 76, p. 1009).

That part of the cord comprised between the fourth and fifth lumbar, as the upper and the second and third sacral segments as the lower limit, is known as the *epiconus*. A lesion here causes loss of Achilles' jerks, preservation of knee-jerks, intact sphincters, motor paralysis, most marked in the peroneal muscles, with atrophy and reactions of degeneration and a steppage gait. Sensory paralysis will be found in the distribution of the affected segments (Fig. 76).

As the spinal cord terminates at the second lumbar vertebra, tumors or injuries below this point produce symptoms only in so far as they compress or destroy the lumbar and sacral roots (cauda equina). This destruction may be partial or complete. If partial, there are *paralyses* of various groups of muscles and circumscribed areas of anesthesia, with radiating pain in the course of the affected roots. This, especially in the sciatic nerves, may precede by a considerable period the development of other symptoms. There may or may not be a disturbance of the functions of the bladder and sphincters. If all of the nerve-roots are involved, there are complete anesthesia, complete paraplegia, flaccid in character, with reactions of degeneration in the muscles, loss of the knee-jerk and Achilles' jerk, absence of the Babinski jerk, and rectal and vesical incontinence. In some cases there may be isolated paralysis of the bladder and rectum. These lesions may consist of tumors, such as are found in the membranes of the cord or on the nerve-roots, and it should be noted that, probably on account of greater space for their development, tumors in this situation are apt to be larger than those in other parts of the spinal canal. They may also consist of fractures or lesions occurring as a result of congenital anomalies, such as spina bifida. If fracture and dislocation of the vertebræ are present the diagnosis between a lesion involving the lower part of the cord and one involving the cauda equina is easily made, as in the latter case the location could be below the first lumbar vertebra. If due to hemorrhage or tumor it may be more difficult. If due to the former the symptoms would likely develop more gradually than when the spinal cord is affected (p. 1062). Shooting pains in the course of any of the nerves arising in the sacral segments, pain preceding for some time the development of other symptoms, and an irregular development of the motor symptoms are in favor of a lesion involving the cauda equina. If tumor is suspected, the treatment is similar to that of spinal tumors (p. 1079). In conus lesions the incontinence of urine may be relieved by anastomosing the first lumbar and third and fourth sacral roots.¹

¹ Frazier and Mills, *Jour. Amer. Med. Assoc.*, December 21, 1912, p. 2202.

PRIMARY LATERAL SCLEROSIS

By this is meant a primary degeneration of the central motor neurons. It is a system disease (p. 1012) affecting the central motor neuron and is a rare condition, most cases so called being due to a secondary degeneration caused by a lesion cutting the tracts somewhere. A few cases have been reported in which no such lesion could be found. The *hereditary type*¹ is probably the most common. The only pathologic change observed is in the pyramidal tracts of the anterior and lateral regions.

Etiology.—It is most apt to occur when there is a *neuropathic family tendency* or congenital weakness. *Age*, generally between twenty-five and forty, exerts an etiologic influence. *Exposure, acute disease, and traumatism* are all predisposing causes. *Syphilis* has been said to predispose to the condition, but if so, it is rather rare. Most cases presenting this symptom-complex are due to a secondary degeneration of the pyramidal tracts, caused by some lesion, as a mild myelitis, higher up. Vertebral disease may also cause similar symptoms. A number of cases have been reported occurring in a number of generations of a family (*hereditary spastic spinal paralysis*). In these cases the symptoms may appear in childhood (pp. 1082, 1086, 1101, 1117).

Symptoms.—In typical cases the onset is slow. The patient complains of feeling tired, and is less capable of exertion than formerly. Weakness of the legs develops, and with it increasing difficulty in walking. Even at an early stage some rigidity of the muscles will be present when the limb is extended; later this becomes a prominent symptom. The spasm is at first of little moment. It may only be noticed in the morning. When the disease has advanced, however, it becomes pronounced, so that it may not be possible to flex the limb, or, if flexed and an effort is made to extend it, it will often spring forward like a knife-blade in clasp-like rapidity. This spasticity is often so marked that in walking, so long as the ball of the foot touches the ground, clonic contractions occur; these also appear when the individual is in a sitting posture unless his legs are extended. The gait is characteristic; the legs are stiff, and move with an evident effort, while the toes scrape the ground. In some cases the adductor spasm is so great that the legs not only cannot be separated, but are actually overlapped in walking (*cross-leg progression*). In course of time the power of walking may be lost. The flexor muscles are usually weakened. The knee-jerk is very much exaggerated, a mere tap causing a sharp, quick response. Ankle-clonus can always be elicited. The Babinski reflex is present. Pains and other sensory manifestations are often absent, though dull and fleeting pains in the back and limbs may be complained of. The arms are frequently unaffected. The sphincters are rarely involved, and ocular symptoms do not occur. Seguin states that the ability to retain the urine is lessened and precipitate micturition results.

The **diagnosis** is not difficult. Certain hysteric cases may occasionally simulate it very closely, but these do not present the characteristic spasticity of the true form, nor the knee-jerk increased quite as much, ankle-clonus is either slight or absent, and the Babinski reflex is not present. Then, too, in hysteria spots of anesthesia are commonly met with. In myelitis there is usually more or less sensory paralysis and involvement of the sphincters; if, however, it is very mild in type, the diagnosis is most difficult. The possibility of caries of the vertebræ must be borne in mind when the symptoms are developing (p. 1075). The congenital type, due to cerebral lesions, is described on p. 1101. Hydrocephalus may also be mistaken (p. 1113).

Treatment consists of maintaining the general health, warm baths for the

¹ Rhein, *Jour. Nerv. and Ment. Dis.*, August, 1916, p. 115.

spasticity, and antisyphilitic medication if there is a history of that disease. In the hereditary form benefit has been obtained by tenotomies, followed by electricity. Cutting the posterior nerve-roots may also be considered if spasticity and not weakness is the dominant condition,¹ as may also spinal decompression (p. 1075).

PROGRESSIVE SPINAL MUSCULAR ATROPHY

(*Amyotrophia Spinalis Progressiva*; *Type of Duchenne-Aran*)

Definition.—A system disease (p. 1012) of the peripheral motor neurons and the muscles they supply, usually beginning in the cervical region.

Pathology.—There is atrophy of the anterior cornua of the cord, affecting chiefly the ganglion cells, degeneration of the nerve-fibers and of the muscles. Occasionally there are small areas of sclerosis that may involve the pyramidal columns for a short distance.

Etiology.—The disease appears to be hereditary in a few cases, and in these may develop in childhood (Werdnig and Hoffman type). A commonly accepted predisposing cause is prolonged severe muscular exertion. Syphilis may also be a factor. Many cases are probably due to congenital weakness of this part of the nervous system. It is most common in males, and most frequently appears during the third decade of life.

Symptomatology.—The first changes usually appear in the *thenar and hypothenar eminences* of the hands, but may begin in other muscles. These become flat and soft; there are loss of power, some stiffness, and inability to perform delicate coördinated movements; the thumb assumes a position parallel to the other fingers (*ape-hand*); the interossei muscles waste and grooves appear between the metacarpal bones. The degenerative changes do not ascend by continuity, the deltoid usually being affected immediately after the muscles of the hand. If the two hands have not been affected simultaneously, the other now begins to show characteristic changes. In the lower limbs the quadriceps femoris is usually the first muscle attacked. The disease gradually involves one group of muscles after another until a large part of the muscular system is affected. All the affected muscles exhibit the fibrillary twitchings and the wasting. Hypertrophy never occurs and the *paralysis* is always flaccid. The fibrillary twitchings are characteristic, but not pathognomonic. They are not always constant, but may be developed by slightly irritating the muscle. At first there is usually quantitative diminution of the response to the faradic and galvanic currents, but as the disease progresses the reaction of degeneration becomes completely developed. The *reflexes* diminish in proportion to the atrophy of the muscles, and ultimately disappear completely; the patients gradually become almost incapable of voluntary motion; but for a time they learn to overcome their disabilities by the compensatory use of other groups of muscles. In the late stage the diaphragm becomes paralyzed and bulbar symptoms appear (p. 1065); usually the patients die from inspiration pneumonia. Rare and probably accidental symptoms are disturbances of the pupillary reflexes and increase in the secretion of sweat.

Differential Diagnosis.—In *chronic anteropoliomyelitis* groups of muscles are affected without any particular order, certain groups of muscles becoming paralyzed suddenly, followed by the gradual involvement of other muscles; in *amyotrophic lateral sclerosis* the spastic symptoms are present; in

¹ *University of Penna. Med. Bull.*, January, 1910, p. 314; *New York Med. Jour.*, January 29, 1910, p. 215.

syringomyelia and *pachymeningitis cervicalis hypertrophica* disturbance of sensation, pain, and trophic lesions occur; in *Pott's disease* affecting the lower cervical region there are tenderness over the spine and sensory disturbances; in *peripheral neuritis* pain and tenderness over the nerve-trunks are present; in *arthritic atrophy* joint symptoms are present; and in the peculiar *muscle atrophies* following excessive use of certain groups of muscles rapid improvement occurs when the cause is removed and the symptoms are confined to the muscles originally affected (either median or ulnar distribution) (p. 1053). The muscular dystrophies are described on page 1183.

Prognosis.—This is unfavorable as to cure. The course is exceedingly slow, and the patients often live for a number of years after the first symptoms have appeared. They are, however, exceedingly liable to pulmonary complications, particularly a fatal form of bronchitis.

Treatment.—Prophylactic measures, such as the avoidance of prolonged excessive work, are rarely possible. Retardation may possibly be obtained by the systematic use of electricity, massage, and gymnastics. Gowers advocates the hypodermic injection of strychnin nitrate in ascending doses, commencing with $\frac{1}{100}$ gr. and rapidly increasing to $\frac{1}{40}$; one injection should be given daily. The general nutrition should be kept at the highest possible point.

AMYOTROPHIC LATERAL SCLEROSIS

(Charcot's Disease)

Definition.—A system disease (p. 1012) of both central and peripheral motor neurons, affecting, therefore, the entire motor tract from the cerebral cortex to the muscles, characterized by loss of power, spastic symptoms, and muscular atrophy. The first clear and thorough description of the clinical symptoms and pathologic anatomy was given by Charcot in 1872.

Etiology.—The disease is more frequent in males and usually begins in early adult life. Exposure has sometimes been noted in the previous history. Many cases are probably due to congenital weakness of the motor tract (abiotrophy). Syphilis may be a cause.

Pathology.—The pyramidal tracts are degenerated, the process commencing either in the cortex, crura, or medulla, and extending to the termination of the neurons in the cord. The ganglion cells of the anterior cornua are atrophic, there is degeneration of the anterior roots and of the muscle-fibers, the blood-vessels in the affected parts are dilated, and in the early stages granular cells are present.

Symptoms.—Three stages are generally recognized: (1) The involvement of the upper extremities. (2) The participation of the lower extremities. (3) The appearance of bulbar symptoms. At first there are weakness of the upper arms, atrophy of the muscles, and moderate exaggeration of the reflexes; in the course of a few months the symptoms of spastic paraplegia develop, all the reflexes are greatly increased, and there are chin- and ankle-clonus, the Babinski reflex, and dragging of the feet. The wasted muscles show fibrillary twitchings and give the reactions of degeneration. Contractures then occur, the forearms are flexed on the arms, the hands are held in pronation, and the proximal phalanges of the fingers bent backward, giving rise to the so-called *claw-hand*. From time to time there are tonic spasms in the muscles, particularly in the calves. Sensation is not disturbed, excepting for the occurrence of occasional slight paresthesia, and the sphincters continue to functionate

normally. Finally, the bulbar symptoms appear, and there is paralysis of the lower part of the face, which becomes rigid and expressionless, with the mouth partly open and saliva dribbling from the angles. Deglutition and articulation become difficult or impossible, and death finally occurs from exhaustion or inspiration pneumonia. Atypical cases occur, in which either the lower extremities are first involved or the paralytic symptoms are more prominent than the spastic symptoms, or the bulbar symptoms appear very early. The symptoms at first may be unilateral (*infra*). The course is steadily progressive, and death usually occurs within a few years.

The **differential diagnosis** is to be made from *multiple sclerosis* by the absence of nystagmus, of the intention-tremor, and of sensory disturbances, and by the degenerative changes in the muscles; from *transverse myelitis* by the absence of sphincter disturbance, sensory paralysis, and of pain; from *progressive spinal muscular atrophy* by the presence of spastic symptoms; from *syringomyelia* by the absence of sensory disturbances, trophic lesions of the skin and joints, and the greater regularity of the course; from *pressure upon the spinal cord* by the absence of pain, sensory paralysis, and sphincter disturbance.

Prognosis.—It will be understood from the foregoing description that death is the invariable termination. The course is progressive, although sometimes very deliberate, and even temporary amelioration rarely occurs.

Treatment.—The patient should be rendered as comfortable as possible, excessive physical exercise avoided, and the general nutrition increased.

UNILATERAL ASCENDING AND UNILATERAL DESCENDING PARALYSIS

Unilateral ascending paralysis, first described as an entity by Mills, is of possibly various pathology and is characterized by paresis commencing in one leg and extending to the arm on the same side. The paresis may be flaccid (Patrick), with loss of the reflexes, or spastic (Mills, Potts, etc.), with increased knee-jerks, ankle-clonus, and the Babinski phenomenon. In time complete paralysis may develop. Degeneration of the motor tract has been found. According to Mills¹ it may be produced: (1) By primary degeneration of the pyramidal tracts, to which may be added other degenerative lesions; (2) as the early stage of multiple sclerosis; (3) as the form assumed by unilateral amyotrophic lateral sclerosis; (4) as the order of progression in unilateral paralysis agitans; (5) as the expression of a focal lesion either cerebral or spinal; (6) as a clinical type in cerebrospinal syphilis; (7) as a peripheral or hysteric affection. The treatment depends upon the cause.

INTERMITTENT PARAPLEGIA

(*Intermittent Claudication*)

Three forms of this affection have been described, *i. e.*: (1) Those due to an arteritis of the vessels supplying the peripheral nerves; (2) those caused by a spasm of these arteries; (3) those due to similar phenomena occurring in spinal arteries. The symptoms consist of muscular cramps and weakness, usually but not always in one or both legs, occurring after moderate exertion. In the first type there is often loss of pulsation in the posterior tibial and dorsalis pedis arteries, in the third the sphincters are affected and cramps do not occur (p. 1091). The treatment is that of arteriosclerosis.

¹ *Jour. Nerv. and Ment. Dis.*, April, 1900, and Proceedings Neurological Section of Amer. Med. Assoc., 1906, p. 166.

HEREDITARY ATAXIA

This may be divided into two types, viz.: the spinal type, or Friedreich's disease, and the cerebellar.

FRIEDREICH'S DISEASE

(*Friedreich's Ataxia*)

Definition.—An hereditary disease, first described in 1861 by Friedreich. The symptoms are primarily manifested in early life, and the disease is characterized by ataxia, defective speech, nystagmus, absence of the knee-jerk, and more or less secondary deformity, as spinal curvature or talipes.

Etiology.—Family tendency (heredity) has a strong influence. A single case, however, may develop in a family. It is due to an inherited and inherent lack of vitality in certain parts of the nervous system (abiotrophy).

Age.—Most commonly the disease appears between the third and twelfth years, though it may appear earlier or later.

Infectious fevers (in particular) and other acute diseases frequently precede the evolution of this complaint. Trauma and many other conditions have been described as exciting causes.

Pathology.—The cord frequently is smaller than normal, and at times there is some thickening of the membranes over the posterior aspect. Microscopically are found degeneration of the posterior columns, more marked in the column of Goll, of the crossed and direct pyramidal tracts, the direct cerebellar tract, and that of Gowers. In the columns of Clarke are found atrophy of the cells with loss of fibers. In some cases the posterior roots may also be found degenerated, also the cells in the anterior horns and the peripheral nerves. The cerebellum is frequently smaller than normal, and degeneration of the cells composing the dentate nucleus occurs. The cells of Purkinje are also atrophied in some cases. Changes have also been found in the cerebrum consisting of atrophy of the gyri and changes in the cerebral cortical cells. Atrophy and disappearance of the cells of the posterior root ganglia have also at times been observed. Changes in the muscles similar to those found in the dystrophies (p. 1183) may occur. The degeneration in the posterior columns is more marked usually than in other parts, the pyramidal tracts being next in severity.

Symptoms.—The earliest evidence of the disease is impaired co-ordination, first in the legs, and later in the arms; it is most marked when the eyes are closed. Attention is often called to this symptom by the fact that the child stumbles, ambles and staggers, and cannot walk properly. The gait, however, lacks the pronounced stamp of true ataxia. In many cases the great toes are turned upward. Some affected children never learn to walk. Romberg's symptom is generally present. Movements of the arms, when these are ataxic, are irregular and jerky, and jerky movements of the head may also be observed. Bilateral nystagmus develops and the speech becomes affected. At first there is a mere impediment (a stuttering), but later syllables or even whole words are omitted and an unintelligible jargon results. The knee-jerks are almost always absent. There is no optic atrophy,¹ nor are any sensory symptoms present as a rule. In some cases interference with sensation similar to that found in tabes (p. 1128) may be present. The sphincters are not involved. There are no trophic changes in the skin or the joints and no visceral crises. Vasomotor symptoms—flushing, sweating—are sometimes observed. There is usually no mental change.

¹ See Hereditary Cerebellar Ataxia, p. 1086.

Talipes and spinal curvature are generally met with after the disease has existed for some time. In old cases muscular weakness and wasting are present, but the muscles do not give the reactions of degeneration.

The **course** is always slow. It may last for many years, thirty or even more.

Diagnosis.—Usually this is not difficult, and especially when more than one case exists in a family. The age, inco-ordination, shambling gait, nystagmus, scanning speech, and deformity are strikingly characteristic.

Differential Diagnosis.—*Tabes dorsalis* appears later in life, and the preataxic stage (pain, absent knee-jerk, and ocular symptoms) is generally well marked. It is absent in hereditary ataxia, nor does the latter present the sensory and visceral symptoms met with in the former. The gait is very different and the Argyll Robertson pupillary changes are never present.

Ataxic paraplegia shows an exaggerated knee-jerk, the presence of ankle-clonus, and an absence of the ocular symptoms, nystagmus, and the scanning speech. A rare family disease has been described by Purves Stewart in which ataxic paraplegia associated with optic atrophy appeared at the age of seven years or earlier. He termed it "hereditary amaurotic ataxic paraplegia."

Disseminated Sclerosis.—In this disease the tendon-jerks are usually increased, optic atrophy, indicated by a pallor of the temporal halves of the disks, is present; the speech is more likely to be sing-song instead of thick and indistinct, and epileptiform and apoplectic attacks are liable to occur, and the disease usually comes on later in life (twenty to thirty years).

The **prognosis** is necessarily bad. The disease is progressive, though it does not kill directly. It may last thirty years or more.

Treatment.—Little or nothing can be accomplished. It is well to employ measures to improve the nutrition of the patient.

HEREDITARY CEREBELLAR ATAXIA

(*Marie and Nonne*)

In this type the most pronounced pathologic change in most cases is an atrophy of the cerebellum, in others defective development of the tracts in the cord leading to the cerebellum has been found. The etiology and symptoms are similar to those of Friedreich's disease, except that it usually develops somewhat later in life, the knee-jerks are present or increased, and optic nerve atrophy, diplopia, and Argyll Robertson pupil may be found.

ATAXIC PARAPLEGIA

(*Posterolateral Sclerosis*)

This name was given by Gowers to a condition in which spastic paraplegia and ataxia coexist, owing to simultaneous involvement of the lateral and posterior columns. A similar condition may follow an acute myelitis, representing the chronic type of that disease (p. 1074). Disseminated sclerosis may possibly present the same symptoms. The type Gowers describes occurs chiefly in males of middle age. Traumatism and exposure seem to predispose to the disease, as does syphilis very rarely.

Symptoms.—These develop insidiously. The patient tires rapidly, and some impairment of the power of walking is observed. In turning quickly he stumbles, and there is difficulty in walking in the dark, or even in standing when the feet are close together. The reflexes are increased at an early date,

and spasticity supervenes and is progressive, though it never becomes as marked as in uncombined lateral sclerosis. The gait is somewhat similar to that met with in locomotor ataxia, but it lacks the forcible stamp present in *that disease*. When the arms are involved the same ataxia, with weakness, spasticity, and increased reflexes, is met with. Sensory symptoms are generally absent and fulgurant pains are never present. When pain occurs at all, it is of a dull character and often in the sacral region. Optic atrophy does not occur. Sexual power is lost. The sphincters are not usually involved, though retention of urine may occur. Ultimately, the case generally partakes more of the nature of a lateral sclerosis, but the features of a posterior sclerosis may rarely predominate. Mental symptoms often develop in the late stages. The so-called Erb's type of syphilis of the cord produces a very similar group of symptoms. In this, however, there is incontinence of urine and sometimes of feces.

The *diagnosis* is easy in typical cases. The ataxia, with myotatic irritability and spasticity in the absence of sensory and ocular symptoms, is characteristic.

The *treatment* consists in maintaining the general health by proper hygiene, food, etc. If due to syphilis, a vigorous antisyphilitic treatment is necessary (p. 1123).

COMBINED SYSTEM SCLEROSIS

(*Subacute Combined Sclerosis of the Spinal Cord; Diffuse Degeneration of the Cord*)

This affection, while described by many as a true combined sclerosis or system disease (p. 1012), is more correctly classified as a diffuse process, as has been done by Putnam and Taylor.¹ It was first described by Lichtheim in 1887 in cases due to pernicious anemia. Putnam, in 1891, described cases due to other causes, viz.: influenza, chronic diarrhea, lead-poisoning, and malaria. It occurs most frequently between thirty and sixty, and always follows some chronic wasting disease or toxic condition. It has been described in pellagra.²

The posterior columns are usually first and most involved. The lateral columns, especially the crossed pyramidal tracts, are also soon affected. Other tracts may become affected later, as do also the cells in the anterior horns and, in some cases, the anterior nerve-roots. The blood-vessels in the affected areas are engorged, their walls thickened.

The initial symptom is usually a persistent paresthesia, usually of the feet; with this some weakness, rigidity, and possibly ataxia will be found. Later the arms become similarly affected. At this time the tendon-jerks will usually be found increased. There may also be pain in the back and limbs. Later the muscles become flaccid and the deep reflexes lost. Late in the course of the disease loss of sensation and muscular atrophy may also occur and elevation of temperature and delirium.

The *diagnosis* is based upon the presence of the above symptoms occurring in one suffering from any of the causes mentioned.

The *prognosis* is bad, death usually occurring in from six months to three years.

The *treatment* consists of general measures to combat the cause, if known, and improve the general health. If anemia exists, iron and arsenic should be given in full doses.

¹ *Jour. Nerv. and Ment. Dis.*, January, 1901, p. 1.

² *Amer. Jour. Med. Sci.*, January, 1911, p. 94.

SYRINGOMYELIA

Definition.—A neuroglial overgrowth of more or less vertical extent, and situated in the gray matter of the cord in the neighborhood of the central canal. Its symptomatology is not constant, but the following have come to be looked upon as typical of most cases, viz.: progressive muscular atrophy, trophic and vasomotor disturbances, and dissociation of sensation (*i. e.*, impairment or loss of temperature and pain sense, with retention of the tactile and muscular sense).

Etiology.—The symptoms usually develop during the second or third decades. The exciting cause is uncertain. Traumatism by producing hemorrhage into the gray matter possibly may cause some cases. Many sufferers from this disease have congenital anomalies of various sorts, as abnormal smallness, disproportionately large hands and feet, varieties of club-feet, etc. Syphilis plays no direct part, but may have some influence by its causation of diseased blood-vessels.

Pathology.—The usual seat of the process is in the cervicodorsal region, but it may be in other regions or extend throughout the length of the cord, even into the lower part of the pons (syringobulbia), and very rarely, as shown by Spiller, into the lateral ventricle (syringo-encephalomyelia). It consists of an overgrowth of neuroglial tissue (gliomatosis) in the region of the central canal of the cord. This breaks down and forms a cavity, which usually extends irregularly in a transverse direction backward into the posterior horns, or may extend into the anterior. The cavity is lined with a varying thickness of gliomatous tissue. Secondary degenerations occur in the white matter, either ascending or descending, according to the tracts cut off. In most cases the condition results from a congenital anomaly of the central embryonal tissue, resulting during the early years of adult life in a slow-growing hyperplasia, having some of the characteristics of a benign neoplasm and a marked tendency toward the formation of cavities.

Symptoms.—Owing to the fact that different levels of the cord are involved, and that the extent claimed by the process varies in different cases, it will readily be understood that no account, however concise, will fit every case. The disease is of *slow onset*. The commonest situation of the cavity is the lower cervical region; when this is the case the earliest symptoms appear in the hands, there is a numbness, loss of the pain and temperature senses, usually in an area bounded by a horizontal line surrounding the limb (glove anesthesia), and preservation of the touch sense. This constitutes the *dissociation of sensation*, perhaps the most characteristic symptom of the disease. The first symptom usually noticed is weakness and atrophy of the muscles of the hands, which show changes in the electric reactions and fibrillary tremors, as in progressive spinal muscular atrophy. The atrophy may begin in other groups, according to the location of the lesion. Vasomotor and usually trophic changes occur in the ends of the fingers, especially multiple painless whitlows. Neuralgic pains and often exaggeration of the tendon reflexes are present in the arms. At the same time the syndrome of the transverse lesion of the spinal cord develops there is spastic paresis of the legs and disturbance of the functions of the bladder and rectum. As the disease progresses the symptoms become more general. The pain and temperature sensations are lost over large areas, the tactile and muscular sensations are preserved; there may, however, be areas in which all forms of sensation are lost. The trophic lesions are various; Charcot's joint or a dry arthritis may occur, there may be extensive bed-sores, or slight injuries may lead to chronic sores. Vasomotor disturbances are common, especially in the secretion of sweat. As a result of unequal in-

volvement of the muscles of the back lateral curvature of the spine occurs. Not infrequently, as a result of the involvement of the posterior column, incoordination, with loss of knee-jerks, similar to that observed in *tabes dorsalis*, may develop.

As the morbid process extends upward the centers in the medulla become involved, giving rise to bulbar symptoms, such as paralyses of the cranial nerves and disturbances of the urinary secretion. These are usually terminal signs. The symptoms, of course, vary with the position of the lesion in the cord, and in rare cases they may commence in the legs or indicate primary involvement of the medulla.

The disease originally described by Morvan of Brittany in 1883 should be included here. He had observed many cases prior to that time, but his attention was specially called to the matter by a case of whitlow which he incised, but to his surprise no pain whatever was experienced. He described *the disease as affecting the upper extremities*, with neuralgia, progressive paresis and wasting, dissociated anesthesia, and later painless whitlows and necrosis of the phalanges. Joffroy and Achard have made three autopsies upon cases dying of this disease, and in each syringomyelia was found. In Gombault's case neuritis was present. The current view is that *Morvan's disease* is a variety of syringomyelia.

Diagnosis.—The loss of pain and thermic sense, with preservation of the muscular and tactile senses, in association with the muscular wasting, which is most marked in the upper extremities; and with the spasticity of the lower extremities, and the trophic changes, especially in the fingers, constitute a group of symptoms that has come to be regarded as typical.

Differential Diagnosis.—*Hypertrophic cervical pachymeningitis* may be mistaken for this disease, and *vice versâ*. In this case, however, the pain is usually greater, the tactile sense is apt to be lost, and possibly the other senses also; but there is not the dissociation met with in syringomyelia. *Amyotrophic lateral sclerosis* presents neither sensory nor trophic symptoms other than the muscular wasting. *Disseminated sclerosis* is characterized by intention tremor, disturbance of speech, nystagmus, while sensory symptoms are rare. Hemorrhage into the gray matter of the cord may cause a similar symptom-complex; in this, however, the onset is acute, and usually follows traumatism. The neural form of *leprosy* may present a clinical picture that is difficult to differentiate. There are dissociation of sensation, trophic changes in the fingers, and muscular degeneration. In leprosy, however, nodular thickening of the nerves may be felt. The facial nerve is often affected first and the bacillus of leprosy can be found in the nasal mucus. Spasticity of the lower limbs does not occur.

The **prognosis** is always unfavorable, though the disease runs a very chronic course, lasting even fifteen or twenty years.

Treatment.—Nothing can be done except by attention to hygienic and dietetic details.

IV. DISEASES OF THE BRAIN

DISTURBANCES OF CIRCULATION OF THE BRAIN AND MENINGES

Meningeal Hemorrhage.—Hemorrhage may be (1) extradural—(a) traumatic and (b) due to rupture of a vessel by erosion, the result of caries; or (2) intradural—into the so-called arachnoid sac—(a) traumatic; (b) due to

injuries at birth (p. 1101); (c) due to pachymeningitis interna; (d) met with in general paralysis of the insane; (e) occurring in the course of anemia, scurvy, or some other profoundly altered blood condition; (f) in cardiac, renal, or pulmonary disease; (g) the result of strain—*e. g.*, whooping-cough.

The **symptoms** will depend upon the circumstances, whether the amount of blood is small or large, whether the onset is *gradual* or *abrupt*; they may be further obscured by the primary disease or by *shock*, if the cause is some trauma. In the slight forms absolutely nothing characteristic exists. In others there are *headache, vertigo, vomiting*, and possibly *mental confusion, convulsions*, or *coma*; in fact, the ordinary symptoms of apoplexy. The blood-pressure is increased. Cases due to traumatism are of most importance, both from a diagnostic and therapeutic point of view. If extradural, the hemorrhage is usually from a branch of the middle meningeal. When such is the case the symptoms are characteristic. They consist of a varying period, in extreme cases a day or more, in which, with the exception of a brief period of evidences of concussion, there are no symptoms, the patient possibly going about his business. Then he gradually becomes more and more stupid, muscular twitching, and some degree of paralysis upon the side opposite the seat of hemorrhage, and if the posterior branch is the one affected, sensory symptoms appear. A choked disk and Babinski reflex may also be found on this side and a dilated pupil upon the side of the hemorrhage (Hutchinson's pupil). When the hemorrhage is subdural the symptoms usually appear more quickly and the paralysis is more profound. In these cases blood will be found in the cerebrospinal fluid.

The **treatment** is that of cerebral hemorrhage except in those due to traumatism, when opening the skull over the seat of hemorrhage should at once be done. Cushing has recently done this in infantile cases with success.

HYPEREMIA

Definition.—An abnormal increase in the amount of blood in the cerebral capillaries. The condition is not in any way associated with the primary phenomena of inflammation.

What has already been mentioned in the case of hyperemia of the cord is equally true in this case—*viz.*, that while congestion undoubtedly may take place, there is nothing symptomatically pathognomonic in the fact, and hence we do not recognize it as a definite clinical entity. The transient apoplectic-form seizures, which may occur during the course of paresis, brain tumors, and multiple sclerosis, have been ascribed to a sudden congestion; in other words, a localized active hyperemia. They should be treated by slight elevation of and cold applications to the head, mild purgation, and bromids internally.

Passive congestion is met with in cases of obstruction of the cerebral sinuses and veins, and is due to pressure on the superior cava or the innominate or jugular veins by tumors or aneurysms; also in suffocation and strangling, in cases of excessive strain, and in tricuspid insufficiency.

In passive congestion the veins and sinuses are engorged and more or less edema may be present. It may be suspected if in cases of mitral and tricuspid valvular disease of the heart chronic headache and hebetude occur.

The **treatment** in such cases will consist in endeavoring to restore the circulation to as near the normal condition as possible (p. 621).

ANEMIA

Definition.—A condition in which an insufficient amount of blood circulates in the cerebral capillaries.

It is due to exhausting discharges (diarrhea), an abnormally slow pulse or weak heart, to hemorrhage, obstructive endarteritis of the vessels supplying the brain, to syncopal attacks and dilatation of the intestinal vessels, owing to the too rapid withdrawal of ascitic fluid.

Disease of the blood itself may also cause the symptoms attributed to anemia of the brain.

Symptoms.—The most exaggerated type is met with after a profuse hemorrhage. There are *pallor, weakness, vertigo, headache, flashes of light, subjective noises, rapid respiration, cool skin*, possibly profuse sweating, and in extreme cases *coma, convulsions, and death*. We are more familiar with the ordinary fainting attack. When cerebral anemia is brought about more slowly, "irritable weakness" results. The patient is either *somnolent, dull and apathetic*, or he may be a victim of *insomnia*. *Headache, vertigo, tinnitus aurium, muscæ volitantes*, and lowered muscular power are present. The patient becomes irritable on the slightest provocation. Marshall Hall has described a group of symptoms as "hydrocephaloid," from their resemblance to hydrocephalus; they occur especially in young children after diarrhea. There are *pallor, hebetude, contracted pupils, and depressed fontanels*. The somnolence may deepen into a coma that often becomes more profound, until death results.

The transient attacks of paralysis and loss of consciousness which occur in those suffering from arterial sclerosis are due probably to a localized anemia caused by spasm of the vessels supplying the particular part of the brain affected.

The **treatment** varies with the cause. The recumbent posture is always indicated, and in some cases it is necessary to depress the head, administer stimulants, and even transfuse or inject a normal saline solution. Ordinarily it consists of improving the tone of the circulation and quality of the blood. In the transient apoplexies caused by arteriosclerosis, nitroglycerin in full doses is of service. A light and easily assimilable diet should be given during convalescence.

EDEMA OF THE BRAIN

Definition.—An infiltration of serum into the subarachnoid space and a greater or less increase of ventricular fluid, with or without infiltration into the brain substance.

Pathology.—The fluid is chiefly in the meshes and beneath the membrane. The ventricular fluid is increased in amount; the brain substance is pale, and in some cases infiltrated and softened. Microscopically, lacunæ may be seen in the cerebral tissue, the perivascular spaces are dilated, and some slight degree of nerve-cell degeneration is often present.

Etiology.—Edema is met with in Bright's disease, in senile cerebral atrophy, and as a result of passive hyperemia.

Symptoms.—In general, the symptoms are those of *anemia*, though nothing definite is known of them. Since the condition is always secondary, it may be that symptoms directly referable to the edema are masked by the primary condition. Cases of apoplexy are seen occasionally in which the only post-mortem finding is an effusion of fluid into the pia and ventricles. This has been termed "serous apoplexy." (See also Serous Meningitis, p. 1059.)

The **treatment** is that of the primary condition. Lumbar puncture may be employed.

VASCULAR DEGENERATION

Arterial.—The cerebral arteries undergo a more or less decided degenerative change in the majority of people past middle life (Bichat said seven-tenths).

It is met with much earlier, however, as a result of disease. Bright's disease, rheumatism, gout, alcoholism—in fact, any irritation of the vessel wall, whether autogenous, the result of faulty metabolism, or whether introduced from without, as alcohol—is capable of bringing about a change of the inner seat of the vessel, to which Virchow gave the name *endarteritis deformans*. The circle of Willis and its branches are the most frequent seats. Various stages may be met with in different vessels or even in the same vessel—viz.: hyaline degeneration, fatty degeneration, liquefaction necrosis, atheromatous ulcers, and calcification.

Syphilitic arteritis is not a true degenerative process. It is rather a proliferative process in which both intima and adventitia are involved. Arterial degeneration is the cause of many diseases of the nervous system; for instance, cerebral apoplexy, myelomalacia (p. 1071), neuritis (p. 1023). A condition resembling multiple sclerosis, due to disseminated areas of softening, may also occur. A symptom group, characteristic of arteriosclerosis of the cerebrospinal vessels, consists of headache, vertigo, inability to stand well with the eyes closed, a gait consisting of short, shuffling steps, laughing and crying without cause, increased knee-jerks, and mental failure. Senile dementia is also so caused (p. 1117). Degeneration of the vessels of the limbs and cord may cause pseudoparalysis, as intermittent claudication (p. 1084). Spasms of degenerated vessels are liable to occur in the brain, also causing transient apoplectic attacks (p. 1091). Also such symptomatic conditions as headache, neuralgias, vertigo, tremor, and epileptiform convulsions.

Venous.—The veins are less liable to disease than the arteries, possibly because they are more yielding, yet the same pathologic changes may be met with in them. They are more commonly damaged by extension of inflammation from neighboring tissues or by pressure.

Aneurysm.—Dilatation of a vessel results from any of the causes above mentioned. The aneurysms may be very small—miliary—or often as large as a filbert-nut, and rarely as large as a hen's egg. They occur more commonly in males than in females. The middle cerebrals and basilar are most frequently attacked, and next come the internal carotid, the vertebral, and the anterior and posterior cerebrals. Miliary aneurysms are frequently found in enormous numbers upon the basilar branches of the cerebral arteries.

Symptoms of Aneurysm.—There may be none; but in any case they are due to pressure exerted by the mass, and are therefore comparable to tumors of the brain. In many cases the first evidence of any trouble is an *apoplectic attack*, and it is scarcely necessary to add that this is usually fatal. In other cases *headache*, *vertigo*, and *optic neuritis* are present, and more rarely a *subjective murmur*. Still more rarely an *objective murmur* may exist.

APOPLEXY

Definition.—As defined by Dana, "apoplexy is a clinical term used to indicate a condition characterized by sudden paralysis, usually attended with loss of consciousness, and due either to the breaking or blocking up of a blood-vessel in the brain." Thus we have hemorrhagic apoplexy, due to the rupture of a blood-vessel (intracranial hemorrhage), and embolic or thrombotic apoplexy, due to either an embolus lodging in or a thrombus forming in a cerebral vessel (acute cerebral softening).

CEREBRAL HEMORRHAGE

Definition.—Hemorrhage into the brain-substance: bleeding into the meninges is generally embraced in the definition (p. 1089).

Pathology and Etiology.—At the time of birth and during the first ten years of childhood there is some tendency to cerebral hemorrhage (see p. 1101). From this period to the age of forty the liability is small; after this, it progressively increases. The predisposing causes are alcoholism, syphilis, and gout. Hereditary influence may also be a factor, as may also the infectious fevers. Rarely it complicates scurvy and purpura hemorrhagica. The exciting causes are lifting heavy weights, straining at stool, coitus, and mental excitement; but hemorrhages occur in which no exciting cause can be determined. These causes are usually only operative in those predisposed. Transient apoplectic attacks, due to sudden congestion, may occur in multiple sclerosis, brain tumor, and paresis. In intracerebral hemorrhage the blood will be found to have infiltrated the brain substance, and, if extensive, it may have penetrated into the ventricle. In such cases the white matter is torn asunder, leaving a ragged space that is more or less filled with recent clot and fragmentary gray matter; if the ventricles have been entered, blood may escape from the lowest into the subarachnoid space. In less severe cases the territory involved is less extensive, and the blood may occupy a single space or several small spaces, forming mere separations of the nerve-fibers. Other changes take place according to the duration of the case. The blood changes color and gradually grows lighter, while reactive inflammation about the lesion results in the formation of a wall. The cyst—for such it has become through fatty degeneration of its contents—may remain as such or, when the lesion is a small one, connective tissue may form within and a scar result. The larger arteries are generally atheromatous, and an aneurysm is occasionally met with. The actual cause of the hemorrhage in most cases is the rupture of a miliary aneurysm, which is a tiny dilatation upon a small vessel. Many of these can usually be seen on the degenerated vessels of a brain in which such rupture has occurred. The vessels otherwise present the changes of arteriosclerosis. A vessel may, however, rupture when miliary aneurysms are not present. Hyaline degeneration may in some cases be the condition present. Rupture may also occur in an area of softening due to extension to the vessel wall of some neighboring form of inflammation. Such cases appear often to be due to injury to the head, the hemorrhage occurring some little time after the reception of the injury (delayed apoplexy).¹ It is very seldom that the actual source of the hemorrhage can be discovered.

Secondary degeneration follows a lesion occurring in the motor region (the cortex or internal capsule), so that sclerotic changes can be traced from the cortex through the corona radiata, internal capsule, crura, pons, and medulla, to the termination of the fibers in the cord.

Andral states that varicose veins occur in the pia, and that they occasionally rupture. Capillary hemorrhage may follow the plugging of a large vein, and of the larger vessels any one or more may be involved, but it has been observed that hemorrhage tends to take place at particular places. In more than one-half of all cases the lenticulostriate artery (Charcot's artery of cerebral hemorrhage) gives way, and damages the lenticular nucleus and internal capsule. Other regions in the order in which hemorrhage occurs are as follows: centrum ovale, cortex, pons, peduncle, cerebellum, optic thalamus, and the posterior and anterior parts of the hemispheres. Hemorrhage into the cerebrum occurs twenty times more often than hemorrhage into the cerebellum; it may

¹ Allen, *Jour. Nerv. and Ment. Dis.*, October, 1908, p. 763.

take place into the brain substance, into the ventricles, or into the meninges, the latter form having already been considered. Ventricular hemorrhage in a great number of cases is caused by a more or less extensive laceration of brain matter, thus permitting the blood to escape into the ventricles. Not only the lateral ventricles, but the third and fourth also may contain blood.

Symptoms.—As in the great majority of cases the motor tract is damaged, the following description is of a hemorrhage in that region. It must be remembered that other parts of the brain may be the seat of the lesion (p. 1095). Generally, the patient is seized without any warning, but in other cases *head-ache*, *depression*, and more or less *paresthesia* precede an attack. The loss of consciousness is usually the first manifestation, though for a few moments before, motor weakness, with or without spasmodic movements,¹ may exist. In very slight attacks consciousness may be preserved throughout or there may be a feeling of vertigo or mental confusion. The symptoms are in direct proportion to the extent and position of the hemorrhage. The patient falls, the face is usually congested, one side often expressionless, and the cheek flaps during respiration. Breathing is stertorous and, in grave cases, of the Cheyne-Stokes type, the pulse is generally feeble for a few moments, but soon becomes full and bounding in character. The blood-pressure in most cases is high, and a choked disk may be present on the side of the hemorrhage. The pupils vary, but are usually contracted. There is frequently a relaxation of the sphincters, and on raising the limbs it will be found that those of one side offer absolutely no resistance. The *temperature*, especially on the paralyzed side, is slightly lowered at first, but after a few hours rises to, or just above, normal. In grave cases it will either remain low or will mount up to 106° F. (41.1° C.) or even higher. Such cases are usually fatal. *Conjugate deviation* of the head and eyes takes place in marked cases; the deviation during the early stages may be toward the paralyzed side, as irritation causes a spasm of the muscles; for the same reason there may be early rigidity of all the muscles of the paralyzed side, but after the irritation subsides (a few hours to a day or two), the deviation is toward the lesion and away from the paralyzed side; in pontine hemorrhage the opposite to this occurs, as it is here due to involvement of the sixth nucleus, after decussation has occurred (p. 1033). As a rule, the symptoms that we group under the term “apoplexy”—viz.: loss of consciousness, motor power, and sensation, with or without relaxation of the sphincters—pass off in twelve to twenty-four hours. In fatal cases the coma deepens, but death rarely ensues under twelve hours. In hemorrhage into the medulla or ventricles it may be more rapid.

During the first few days (stage of irritation) after the onset *febrile reaction* sets in, with irritative symptoms due to the inflammatory changes occurring about the original lesion. There are fever, sometimes delirium, twitchings or spasmodic movements of a more pronounced type, and sometimes rigidity in the affected limbs. The temperature of the paralyzed side is often from $\frac{1}{2}$ to 2 degrees higher than the temperature on the sound side. At first all reflexes may be lost, but the tendon reflexes usually soon return, and the Babinski phenomenon (extension of the toes when the sole of the foot is irritated) very soon appears. Difficulty in swallowing and thickness and indistinctness of speech, due to muscular paralysis, are usually present at first, but, as a rule, disappear. This must be distinguished from aphasia (p. 1000), which may result if the lesion is in the left side of the brain. Death may take place during this stage. Cases are generally fatal also in which a second “stroke” follows closely upon the first, indicating a fresh hemorrhage. After

¹ Convulsions at the onset of hemorrhage are rare except in children. When they do occur, they indicate that it is probably cortical.

the reactionary period a stationary period follows; sooner or later control of the damaged members is then gradually, but not perfectly, regained. The degree of recovery is dependent upon the resumption of function of slightly damaged tissue or upon the compensatory activity of the other side of the brain. In certain cases the structural damage has been too great, and permanent paralysis remains, with rigidity, slight wasting, secondary contractures, and increased deep reflexes.

Ingravescent Apoplexy.—In certain cases the onset is slow, consciousness being lost gradually. Coma deepens, and the case, as a rule, terminates fatally.

Ventricular Hemorrhage.—This may be primary or secondary. The symptoms are very severe and death soon occurs. Blood may be found in the cerebrospinal fluid obtained by lumbar puncture.

Hemiplegia.—When this is complete, one side of the face and the arm and leg of one side, generally the same, are all involved (see Pontine Hemorrhage). The facial palsy is not complete, the frontalis and orbicularis oculi escaping. The tongue when protruded deviates toward the paralyzed side. As a rule, the arm is affected to a greater extent than the leg. The trunk muscles, those of the upper part of the face (p. 1038), and muscles of swallowing and speech nearly always escape (see p. 997). If a second lesion later involves the other side, bulbar symptoms, as difficulty in swallowing, indistinctness or loss of speech, and complete paralysis of the tongue, develop with more or less severity (pseudobulbar palsy). The history and absence of atrophy of the tongue distinguishes this from true bulbar palsy (p. 1065). The paralysis is usually spastic, and, therefore, the tendon reflexes on the paralyzed side are increased, there are patellar and ankle-clonus, and the Babinski phenomenon. The tricipital and bicipital reflexes and the scapulohumeral reflex are easily elicited. The reflexes upon the unaffected side are also exaggerated, but the pathologic forms are rarely present. If the *lenticular nucleus* alone is involved spasticity occurs without paralysis. If the pyramidal tract is completely destroyed, the paralysis is flaccid and the deep reflexes will be absent (p. 991). The abdominal, cremasteric, and other skin reflexes are lost on the affected side.

Sensation is, of course, absent during the period of unconsciousness. Subsequent sensory disturbances are not constant for all cases. In some cases permanent anesthesia for all forms of sensation upon the affected side persists, with loss of the skin reflexes. This indicates a lesion in the posterior part of posterior limb of the capsule, and lateral homonymous hemianopsia is usually associated. Occasionally only dissociation of sensation is present, tactile sensation being preserved, while muscular and thermal sensation are lost or diminished. The stereognostic sense is often seriously disturbed in these cases.

The special senses may be temporarily perverted or their functions in abeyance, but rarely do permanent disturbances occur.

Pontine Hemorrhage.—This is indicated by marked contraction of the pupils, temperature, and paralysis of cranial nerves upon the side of the hemorrhage and of the arm and leg upon the other (crossed paralysis). Bulbar symptoms may remain permanently.

Crossed Hemiplegia.—When a lesion occurs in the lower part of the pons the fibers of the facial nerve that are involved have already decussated; hence facial palsy occurs on the same side as the lesion. The fibers coming from the cortex are implicated before their decussation, so that paralysis of the limbs occurs on the side opposite to the lesion. Lesion of the crus may lead to oculomotor palsy of the same side, and palsy of the face, arm, and leg of the opposite side.

Reference to pp. 995-1000 will indicate the symptoms which may occur when a hemorrhage occurs in other parts of the brain.

Serous Apoplexy.—The cases present clinical evidences of apoplexy, but the only *postmortem* finding is an excess of serum, and this is in no way responsible for the apoplexy. These cases probably belong in the same category as those just mentioned, but occur in old persons whose brains have atrophied.

Course and Termination.—As previously intimated, the course depends on the position and extent of the lesion. The prognosis is always serious and death may take place in a few hours. Hemorrhage into the medulla may prove fatal more quickly. In the milder cases perfect recovery may take place in a few days or weeks. Coma persisting longer than two days, high temperature, and the development of bed-sores are bad prognostic signs. Generally, when little or no improvement occurs in two or three months, permanent changes result. The facial muscles soon recover, and next the leg. At first the patient is able merely to move the toes. Daily improvement then follows until he can support his weight; dragging of the feet rarely disappears absolutely. In the meantime a less pronounced change for the better has been taking place in the arm. This member very rarely recovers to the same extent as the leg, and secondary contractures develop in time, the hand and arm becoming flexed, while the leg is extended. The hand is usually bluish and cold, and swells if kept in a dependent position. Some ataxia may be noticed if motion is possible. Pain in the affected limbs sometimes occurs; in the majority of such cases a lesion has been found in or near the optic thalamus. Other later manifestations that are only occasionally met with are athetosis, posthemiplegic chorea (p. 1102), and tremors. Varying degrees of mental deterioration may develop and epileptiform convulsions occur.

There is no degeneration of the affected muscles as a rule; nor are there electric changes except during the irritative period, when the response to stimulation is heightened. Occasionally marked atrophy occurs, and is due in some cases, as Charcot has shown, to changes in the cells of the anterior horns. In others no such change is found, and we are forced to regard the wasting as cerebral.

Differential Diagnosis.—Apoplexy is to be distinguished from other conditions causing unconsciousness, such as traumatism to the head, cardiac syncope, epilepsy, alcohol- or opium-poisoning, insolation, and uremia. If some previous history can be obtained, the difficulty of the diagnosis is lessened, though it may still be great. If there is evidence of a blow upon the head, the possibility of meningeal hemorrhage must be considered (p. 1089). In simple concussion there are evidences of shock without any paralysis; in *syncopal attacks* the pulse is very feeble and the face is pale, respiration being shallow and often suspended. The sphincters are hardly ever relaxed; the reflexes are usually preserved and the skin is often moist. In *epilepsy* scarring of the tongue may be present, and there is a history of previous attacks, or, failing to obtain this, one can usually learn that a convulsion has immediately preceded the coma. With *alcoholism* the case is more difficult. The odor of alcohol on the breath is of no value, as spirits may have been given by a bystander; moreover, hemorrhage is common in alcoholics (*vide* table of differential diagnosis). In *opium-poisoning* the coma comes on gradually, and when not too profound the patient can be aroused when shaken or shouted at. The respirations, which are very slow and deep at other times, become somewhat quicker and shallower when he is aroused. In *insolation* the temperature suffices, as a rule, though, as stated, high temperature may occur in apoplexy. The presence of albumin is not conclusive evidence of *uremic poisoning* unless the

centrifuge and the microscope reveal the presence of casts or other indications of renal change; even then the case may be one of apoplexy in a subject of nephritis. It is important to remember also that uremia may cause a hemiplegia, which, as a rule, is not persistent. In the case of *diabetic coma* the presence of sugar in the urine serves to make the diagnosis. When we meet with a comatose case in which there is absolutely no resistance when the limbs of one side are raised, while those of the other still exhibit some tonic, particularly if the deep reflexes are exaggerated on the flaccid side, and a Babinski reflex and conjugate deviation of the head and eyes present, the probability is that it is an apoplectic attack. It is of great importance to tell whether the condition is due to hemorrhage, embolism, or thrombosis, although at times this may be impossible. The tabulated points of distinction given below may afford aid:

EMBOLISM

Early adult life.

Previous development of cardiac disease following acute rheumatism, sepsis, chronic valvular disease, aneurysm, pregnancy.

During the attack there is an absence of congestion of the face; the pulse is normal; in cardiac affections it is accelerated and irregular.

Temperature normal or but slightly disturbed.

The attack, as a rule, is short; if there is a protracted embolic infarction, the duration is long; usually the circulation adjusts itself promptly.

Hemiplegia is right-sided usually. Paralysis may occur first, followed by convulsions and coma.

Ophthalmoscopic Examination

At times the ophthalmoscope reveals either a recent or an old embolus in the arteria centralis retinae.

THROMBOSIS

Prodromes, as transient attacks of weakness, numbness, vertigo and headache, frequent.

Consciousness frequently preserved.

Age of patient greater (after fifty), except in syphilitic cases, when it may occur in early adult life.

Paralysis may develop slowly, sometimes several taking hours to become complete.

Temperature changes not so marked (initial fall followed by rise).

Attacks occur while patient is at rest (during sleep).

Pulse weak, breathing quiet. Face not flushed. Vessels atheromatous.

Pupillary disturbances not marked.

HEMORRHAGE

Late adult life; in early life rare.

Cardiac hypertrophy, arteriosclerosis, increased arterial tension. In children, previous infectious disease.

History that the patient up to the time of attack was well; also the finding of casts in urine and other symptoms of chronic nephritis.

During the attack there are noted flushes (reddish) of the face, pulsating carotids, and slow pulse.

Temperature during the attack is subnormal, followed by a rise, especially on paralyzed side.

The duration is, as a rule, longer. Coma of long duration (about two days) gives a very unfavorable prognosis.

Remote effects quite frequent; alteration in the urine—albuminuria, polyuria.

HEMORRHAGE

Prodromes not very frequent.

Usually lost.

More apt to occur between forty and fifty.

Develops at once.

Temperature changes marked.

Attack occurs during physical exertion.

Pulse slow and full, blood-pressure increased, breathing stertorous, face flushed.

Pupils unequal or contracted.

It is not an uncommon occurrence to have patients brought to a hospital dazed and smelling of liquor. These should always be carefully watched, for mistakes readily occur, and many such cases have been condemned to a prison-cell when they were really suffering from cerebral hemorrhage.

Treatment.—If a diagnosis of hemorrhage cannot be positively made, care must be taken not to do harm; therefore the treatment should be expectant. The patient should be kept as quiet as possible and in the recumbent position, with the head somewhat elevated, and preferably on the side, to prevent the paralyzed tongue from falling back into the throat. The clothing about the neck should be loosened to prevent constriction. An ice-bag may be put to the head and hot bricks or a hot-water bottle to the feet, while sinapisms may be placed on the back of the neck or on other parts of the body. The bowels should be made to move freely; a cathartic may be exhibited by the mouth (croton oil, gr. j or ij), and at the same time an enema may be given. If the patient can swallow, calcium salts may be given to increase the coagulability of the blood. Nitroglycerin or veratrum viride may be given to reduce the blood-pressure. Venesection is sometimes beneficial, especially if it is known that the patient has been having a high blood-pressure previous to the attack. When the pulse is very slow and the blood-pressure either very high (280 mm. or over) or progressively increasing, Cushing¹ has advised doing a decompression on the side of the hemorrhage. Marie advocates doing it over the sound side.² In this connection it is well to remember that a moderate increase of blood-pressure is beneficial, as it is due to the increased effort of nature to get blood to the vital centers in the medulla which otherwise become anemic, due to its compression against the foramen magnum by the increased intracranial pressure. When consciousness returns the patient should be kept absolutely quiet for several days and only liquid food permitted. Later an endeavor should be made to keep up the tone of the affected muscles and to prevent deformity by massage and electricity. The general arterial disease should also be treated by appropriate hygiene, the use of the iodids, etc.

EMBOLISM AND THROMBOSIS

(*Acute Cerebral Softening*)

Embolism.—Definition and Etiology.—The obstruction of arteries or capillaries by material brought to the spot from some other part by the blood-current. The material, generally fibrin, usually comes from the heart, and is either a vegetation of a recent endocarditis or, more commonly, of chronic valvular disease; it may possibly be a fragment of the valve plus the fibrin in ulcerative endocarditis. In the latter case the plug is generally septic, giving rise to suppurative processes. An embolus may be washed from the auricular recesses, from an aneurysm of the aorta or carotid, or from atheromatous patches; rarely from the pulmonary veins.

In puerperal women, and in certain febrile processes (diphtheria and pneumonia) the coagulability of the blood is increased. Heart-clots form, and fragments may be washed into the cerebral vessels. Owing to the direction of the vessels the embolus most frequently enters the left carotid, whence it usually passes to the left middle cerebral. Almost any cerebral artery may be obstructed, but the cerebellar very rarely. Embolism occurs most frequently between the tenth and fortieth years of life. The middle cerebrals are most frequently involved, and next in order the internal carotid and anterior cerebrals.

Pathology.—The region of the brain that is cut off from its blood-supply by the embolus undergoes softening. The cortical changes are less marked

¹ *Amer. Jour. Med. Sci.*, June, 1903. ² *Progressive Med.*, September, 1914, p. 293.

than those of the central ganglia, since in the former case more or less anastomosis exists, and none in the latter. When the embolus is septic one or more metastatic abscesses result. The degree of softening varies in different cases within wide limits. There may be nothing more than a slight diminution in the consistence, the affected area being somewhat paler than normal, or absolute dissolution may occur, the myelin breaking up into granules, while the tissue becomes infiltrated with serum, and the vessels undergo hyaline or more often fatty change. The color of the part varies with the amount of blood. In recent cases it is red. As the hemoglobin is absorbed a yellow color appears, and soon predominates. Red and yellow softening are found chiefly in the cortex. The so-called white softening is met with particularly in the white matter. A variety of red softening in which numerous small hemorrhages exist has been termed "capillary apoplexy," while *plaques jaunes* is the term given by the French to a form of yellow softening often seen in the cortex of old people. The ultimate changes depend in a great measure upon the extent of the lesion. If this is small, the granular debris is absorbed, and the proliferation of connective tissue results in the formation of a scar. On the other hand, if large the solid elements are removed, and the cavity that remains contains more or less fluid (a cyst). In many instances fibers, trabeculae, and even vessels that have escaped destruction pass through the cyst.

Thrombosis.—Definition.—Obstruction of a vessel due to clotting *in situ*. This may occur (a) in the arteries or (b) in the veins and sinuses.

IN THE ARTERIES.—Etiology.—Thrombosis results from disease of the vessel wall, atheroma, endarteritis, or syphilitic arteritis, extension from surrounding diseased areas, traumatism, in aneurysms, in depraved blood states, and at the seat of lodgment of an embolus. Thrombosis of a cerebral vessel may rarely follow ligation of the carotid. In general we may say thrombosis results from (1) changes in the vessel wall, (2) retardation of the blood-current, and (3) hypercoagulability of the blood. It occurs most frequently in the middle cerebral, basilar, internal carotid, and vertebral arteries.

Pathology.—The changes in the brain tissue are precisely those described under Embolism. Within the vessel a clot is found adherent to the vessel wall, and extending from the nearest large branch on the proximal side to the contracted branches on the distal side. If of recent and rapid formation, it is always of a red color. The slower the formation, the paler the color. Such clots are often laminated. The ultimate changes are contraction and atrophy, or, more rarely, calcification, or even softening and removal, the vessel again becoming patulous.

IN THE VEINS AND SINUSES.—Etiology.—Thrombosis may be (1) primary, due to general causes, or (2) the result of local changes.

Primary thrombosis is less common than the secondary variety. It is met with in marasmic children (one of the causes of infantile hemiplegia—Gowers), in which the clot is called marantic thrombosis, cachexia, phthisis, carcinoma, and in blood dyscrasias (anemia, chlorosis).

Secondary thrombosis usually results from an extension of neighboring forms of inflammation, caries of the bone, middle-ear disease, or meningitis. It may also be due to fracture of the skull or compression of a sinus by a tumor.

Pathology.—In primary thrombosis the most common seat is the superior longitudinal sinus. From this it spreads into the veins of both sides, and frequently also into the lateral sinuses of one or both sides. In secondary thrombosis the sinus nearest the local disease suffers. The veins emptying into the sinus involved become distended, often rupture, and in consequence the brain tissue and pia become infiltrated. When the veins of Galen are blocked serum escapes into the ventricles. Red, yellow, and white softening is met with as a

final result of the extravasation. Secondary thrombi are usually septic, and give rise to abscess formation.

Symptoms.—Following Embolism or Thrombosis of Arteries.—The symptoms necessarily depend upon the position and extent of the lesion. Often it is discovered *postmortem*, not having been suspected during life. We meet with many such cases occurring in late adult life. Then, too, extensive lesions may occur in those portions of the brain that never yield any localizing symptoms—the frontal region, for instance. Apart from the etiologic differences the clinical pictures of embolism and thrombosis differ as follows: In the former the *onset* is sudden, without premonitory signs, and is in many cases accompanied by loss of consciousness. In addition to symptoms arising directly through implication of the particular part involved, there are those of *shock*. In the less severe cases consciousness soon returns and the apoplectic symptoms pass off. When more severe, *coma* supervenes and may prove fatal. When hyperemia occurs in or about the motor region the irritation may give rise to *convulsions*. In other cases *delirium* is a prominent feature; hence three varieties of softening are described by some writers—the *apoplectic*, *convulsive*, and *delirious*—from the prevailing feature. Thrombosis may commence abruptly, but, as a rule, the onset is slow, the patient meanwhile complaining of vague pains, numbness, tingling, headache, and vertigo. It is observed that a gradually increasing impairment of the mind is going on, and that motor weakness, slight at first, increases until the function is lost. The special symptoms are, as stated, dependent upon the location of the obstruction. If this is in the middle cerebral artery, the most common seat, there will be *hemiplegia*. The trunk may be spared and one of its branches stopped. The latter run to the third frontal, ascending parietal, supramarginal, angular, and temporal gyri. Thus, then, we can account for the aphasia so often met with in these cases by the plugging of the branch that supplies the third frontal convolution of the left side. If both middle cerebrals are plugged, symptoms develop that are indistinguishable from hemorrhage into the ventricles. This condition is generally fatal. Thrombotic obstruction of the anterior and posterior cerebral arteries rarely causes symptoms, owing to compensatory circulation. “Hebétude and dulness of intellect may occur” (Osler), with obstruction of the anterior cerebral. Hemianopsia may arise from a lesion of the posterior cerebral, since it supplies the cuneus. Plugging of a vertebral artery causes symptoms of acute bulbar palsy, as does also that of the posterior inferior cerebellar artery, which is a branch of the vertebral,¹ in this the symptoms develop suddenly without loss of consciousness. There may or may not be slight weakness of the limbs of the side opposite the lesion which, if present, soon disappears. Pain and temperature sensations are also diminished in these limbs. On the side of the lesion there will be loss of pain and temperature sense and sometimes pain and paresthesia in the distribution of the fifth nerve, ataxia of the limbs, and paralysis of the muscles of deglutition, larynx, and soft palate.

Cerebellar softening is rare. There may be no symptoms if only one hemisphere is involved; otherwise they are similar to those of cerebellar disease due to other lesions.

Thrombosis in veins and sinuses cause variable symptoms. Those directly due to the vascular disturbance are severe headache, optic neuritis, delirium or convulsions, and, later, great depression. Hemiplegia may result. When the superior longitudinal sinus is affected, epistaxis is common, while in lateral sinus involvement postauricular edema occurs. If the cavernous sinus is affected there are exophthalmos and ophthalmoplegia on the affected side, with edema of the orbital and frontal regions. In secondary cases, moreover,

¹ Spiller, *Jour. Nerv. and Ment. Dis.*, June, 1908.

we have to reckon with the cause. Since this is so often septic, septicemic symptoms are the rule.

Diagnosis.—This must be made, if possible, from hemorrhage; the points are given on p. 1097. If it cannot be made with certainty, treatment should be very guarded, as treatment for hemorrhage would do harm in thrombosis, and *vice versa*.

Prognosis.—This is somewhat better than in hemorrhage, death not being so liable to occur and the resultant disability less.

Treatment.—*Of Embolism and Thrombosis of Arteries.*—Very little can be done in brain softening. In the early stages, however, while it is absolutely impossible to repair the tissue already damaged, an effort should be made to prevent the spread of the process. Rest in bed with the head low should be insisted on. When shock is present, it must be met by gentle stimulation, ammonium carbonate, and even by alcohol and digitalis in some cases; hot-water bottles may be applied to the body. Citric acid, in the form of lemon-juice, may be given to prevent further coagulation. Venesection is contraindicated. The bowels should be made to move gently and purgation should be avoided. Nitroglycerin and small doses of the iodids are useful in thrombosis. If the blood-pressure is low, caffein may be added. Later, as stated, symptoms of irritation often appear. In such cases the bromids should be given, and also a diaphoretic mixture, or ice should be placed to the head. In any case in which syphilis, rheumatism, gout, chorea, or other malady capable of causing or adding to the trouble exists, the original disease should be treated promptly and thoroughly. In the meantime efforts should be made to improve the patient's general tone by the strict observance of hygienic and dietetic rules.

Of Thrombosis of Veins and Sinuses.—Treatment in these cases depends largely on the cause. In the primary form it is that of the systemic disease. Good, wholesome, and easily assimilable food should be given, together with a tonic treatment. In secondary thrombosis careful search should be made for pent-up inflammatory products, which should be liberated at the earliest possible moment. The brilliant results of operative interference in some apparently hopeless cases should suggest its employment whenever there is good reason for suspecting septic sinus thrombosis. The emunctories must act freely. Counterirritation applied to the neck is of questionable value, but internally quinin, iron, and strychnin, and, if stimulation is necessary, ammonia and alcohol, will all be useful.

CEREBRAL PALSIES OF CHILDREN

The paralysis may involve all four extremities (diplegia), or be paraplegic or hemiplegic in its distribution.

Etiology.—They may be congenital or develop during the first few years of life, usually within the first two. The former, in the great majority of instances, are due to meningeal hemorrhage, sometimes venous, occurring during birth. In such cases there is often a history of difficult or forceps delivery; it may occur, however, during easy labors. When due to this cause, the symptoms are frequently diplegic, but may be either hemiplegic or paraplegic. Some are possibly due to a fetal meningo-encephalitis; another cause may be lack of development of the motor tracts, and in such cases a history of premature labor may be obtained. Either neurotic taints, alcoholism, or syphilis in the parents may have some influence in the causation. The congenital cases

have been known as *Little's disease* and *birth palsy*. Jaundice in the newborn is also a cause.

The hemiplegic form is most frequent in the latter group. These cases usually follow the infectious diseases, and are due in some instances to either hemorrhage, thrombosis, or embolism in a branch of the middle cerebral artery; others may be due to a cortical polio-encephalitis (Strümpell) (p. 1106).

Pathology.—If the patient live for a number of years, the following lesions may be found: atrophy and sclerosis, either of a group of convolutions, an entire lobe, or the hemisphere is most frequent. The affected parts are firm and hard, and the convolutions smaller than the normal. The sclerosis may be diffuse, and there may be nodular projections (hypertrophic sclerosis).

Next most frequently is found *porencephalus*, by which is meant loss of substance, forming cavities and cysts on the surface of the brain which may extend into the ventricle. Porencephalus may be due either to hemorrhage occurring at birth, lack of development, or the lesions of apoplexy (embolism, thrombosis, hemorrhage), which may occur after birth. The primary lesion in the cases of atrophy and sclerosis is doubtful. Strümpell attributed them to cortical polio-encephalitis.

Symptoms.—It is important if possible to recognize the occurrence of meningeal hemorrhage during birth, as treatment then may be of service. The symptoms are convulsions, asphyxia, tense and non-pulsating fontanelles, slowing of the pulse, inequality of the pupils, an intense choked disk, and blood in the cerebrospinal fluid. In newborn children presenting any of these lumbar puncture should be resorted to at once, as it is not only a valuable diagnostic measure, but a therapeutic one as well. Usually the symptoms are not noticed until the child is several months old, when it will be observed that he is unable to sit up, and that the head rolls about, owing to weakness of the neck muscles. When it is time for him to walk, he does not attempt to do so, and examination will show more or less rigidity of the limbs. Later, when the child does walk, the gait will be more or less spastic, sometimes so much so that the knees rub against each other, and in extreme cases one leg may be crossed over the other (cross-legged progression). The deep reflexes are increased unless the spasticity is so great as to prevent contraction of the muscles, and the Babinski phenomenon is present. The arms are also rigid, but usually do not suffer so much as the legs. The face is rarely affected. In the hemiplegic cases the affected side does not develop as well as the normal one, and the limbs are often shorter and the muscles smaller. They are firm, however, and the presence of the reflexes and normal electric reactions will distinguish the condition from a true atrophy due to peripheral neuron disease.

Foerster has described a form of cerebral diplegia in which there is hypotonia of the muscles without atrophy and changes in electric irritability. As the child grows, ataxia of the cerebellar type develops, the knee-jerks may be either increased, diminished, or lost, and a Babinski reflex may or may not be present. Mental deficiency is present. He termed this condition the *atonic atasic type of infantile cerebral paralysis*.¹ It must be distinguished from amyotonia congenita (p. 1188).

When hemiplegia follows an infectious disease there are usually convulsions, with or without loss of consciousness, followed by paralysis of a similar type to that above described.

Many of these cases show mental impairment and suffer from epileptiform convulsions. They are specially prone to develop spasmodic conditions, such as *posthemiplegic chorea* and *athetosis*. The former consists of choreiform movements developing in the paralyzed limbs. There is also a condition con-

¹ *Amer. Jour. of Dis. of Children*, June, 1913, p. 425.

sisting of intermittent tonic spasms affecting groups of muscles called hemi-hypertonia postapoplectica.¹ Athetosis consists of peculiar slow; worm-like movements, in some cases only of the fingers and toes; in others the arms and legs are also affected, and more rarely the muscles of the face. There is a marked tendency in the movements to overextension, and they are increased by attempts to move the limbs. When the face is affected various grimaces and contortions occur. In some cases these movements are the most prominent feature of the case, the motor paralysis being slight.

Diagnosis.—This should not be difficult if attention is paid to the history and symptoms. Paralysis due to neuritis or anterior poliomyelitis is distinguished by muscular atrophy, absent reflexes, etc. The paraplegic type might be mistaken for the hereditary spinal form (p. 1081). The history of the development of this condition and absence of cerebral symptoms easily distinguish the two. Athetosis may be mistaken for chorea; the history and presence of evidence of disease of the pyramidal tracts and rhythmic character of the movements are sufficient to make the distinction. Forms of diffuse sclerosis of the brain have also been described in young children some of which are due to hereditary syphilis. Another type described by Krabbe² is a family disease, the symptoms of which appear at about the age of five months and are characterized by intense spasticity, tonic spasms aggravated by peripheral irritation, and sometimes nystagmus and atrophy of the optic nerve. Death occurs in five or six months. Another type resembles multiple sclerosis (p. 1117).

Prognosis and Treatment.—This, as regards duration of life, is good; as regards disability and cure, is bad. The symptoms may be relieved. If the diagnosis of hemorrhage during labor is suspected, lumbar puncture should be done, if confirmed and improvement is not caused by the puncture the skull may be opened and the clots removed, as has been successfully done by Cushing.³ If spasticity is much greater than paralysis, relief may be obtained by cutting some of the posterior nerve-roots, as recommended for lateral sclerosis (p. 1082). Usually the treatment consists in passive movements and electricity applied to the extensor muscles to overcome the spasticity. Tenotomies and tendon transplantations may also be necessary. Sharpe and Farrell⁴ have performed cerebral decompression in a number of cases with encouraging results. The cases so operated upon were those in which there was a history of difficult labor and in whom ophthalmoscopic examination showed evidences of intracranial pressure. The failure of mental power, if it exists, must be treated, if not too extreme, by proper educational measures, and the epileptiform convulsions, if they occur, by the measures recommended for that disease (p. 1137).

PROGRESSIVE LENTICULAR DEGENERATION

This is a rare condition described by Wilson.⁵ It may attack several members of a family, but is not hereditary. It always occurs in young people, and may be either acute or chronic. The symptoms consist of bilateral tremor of the limbs which is increased by volitional movement (sometimes the head also is affected); spasticity of the limbs and face; dysphagia and dysarthria and finally anarthria; sometimes causeless laughter and emotionalism; difficulty in maintaining the equilibrium owing to the spasticity; sometimes transitory mental symptoms. There is no real motor weakness, and the reflexes are

⁵ *Brain*, 1912, p. 295.

normal. Cirrhosis of the liver is always associated, but no evidence of disease of the liver is present during life. Death occurs in from six months to five years, and in all the cases examined a bilateral symmetric softening of the lenticular nucleus was found. Wilson believes it to be due to a toxin which probably has some relation to the cirrhosis of the liver. In this connection the softening of the lenticular nuclei, due to carbon monoxid poisoning, is of interest.¹ These cases, the symptoms of which may appear several days after the patient has apparently recovered, have spasticity of the limbs and stupor, the reflexes, however, may be increased and the Babinski phenomenon present.² (See also Pseudosclerosis, p. 1120.)

INFLAMMATION OF THE BRAIN

(*Encephalitis*)

Definition.—Encephalitis, strictly speaking, is an inflammation of the brain substance, and does not include inflammation of the meninges, though in many instances the two conditions coexist as the result of a common cause, or one may precede and give rise to the other. Encephalitis is met with in two forms—(a) Suppurative and (b) hemorrhagic.

SUPPURATIVE ENCEPHALITIS

(*Abscess*)

Pathology.—In very acute cases no time is given for encapsulation; when of longer duration, however, the abscess is well circumscribed, having a well-defined wall, within which there are cell-detritus, pus, and sometimes more or less altered blood. It may be offensive. About it the brain substance is generally softened and edematous. The abscess is generally single except in pyemic cases, and varies greatly in size in different instances.

Etiology.—Abscess of the brain is a more or less circumscribed process due to: (1) *Injury.*—In the majority of cases of abscess following head injuries either a compound fracture of the skull exists, with or without *hernia cerebri* (fungus cerebri), or a punctured wound has been made. Less commonly it may follow a simple fracture, and rarely it is said to occur when neither a fracture nor even an abrasion of the scalp has been produced. Meningitis is an almost invariable concomitant. (2) *Extension from some neighboring inflammatory focus*, as from orbital, nasal, or aural disease, in which the bones have usually become affected. (3) *Pyemia*, in which case the abscesses are apt to be small and multiple. It is also met with occasionally in gangrene of the lung, bronchiectasis, ulcerative endocarditis, suppurative hepatitis, or bone disease, and rarely in chronic septic processes. (4) *Congenital Heart Disease.*—Little is known of this condition. Northrup, Packard, Sir Dyce Duckworth, and Osler have reported such cases. (5) *Obstruction of an artery, vein, or sinus*, whether of spontaneous origin or the result of ligature, may give rise to abscess. Generally, however, the cerebral change is that of softening, and not of true suppuration. (6) *Intracranial tumors.* (7) *Infectious fevers.* Inflammation of the middle and internal ear is the most common cause, especially if the tympanum and mastoid cells are affected. Most cases occur between the ages of ten and thirty.

Symptoms.—These vary greatly according to the nature, situation, and size of the abscess, and are frequently masked or confused by the coexistence

¹ Dana, *Jour. Nerv. and Ment. Dis.*, 1908, p. 65.

² McConnell and Spiller, *Jour. Amer. Med. Assoc.*, December 14, 1912, p. 2122.

of various complications, such as injury to the head, meningitis, septicemia, or an infectious disease. In acute abscess there are the symptoms of acute septic infection, to which are added those of focal disease of the brain. As the abscess is secondary, the septic manifestations usually appear first. They are, of course, chills, fever, leukocytosis, etc. Often the primary focus can be recognized as endocarditis or pneumonia. The febrile process continues, there is usually severe delirium, and finally the symptoms of brain disease develop, either slowly or abruptly. The general symptoms are headache, vertigo, vomiting, and convulsions, all of which are very constant and develop early; later, depending upon the situation of the abscess, motor and sensory disturbances appear. The most common are hemiplegia, clonic spasms, irregular involuntary movements, aphasia, hemiparesis, and hemianopsia. Kernig's sign may be present if the motor region is involved, and the reflexes are usually greatly exaggerated. Congestion of the eye-grounds is common, but choked disks are rare. The course is rapid and severe.

Chronic abscess develops, as a rule, insidiously; of the general symptoms, fever of a hectic type is most important, and there is usually a moderate leukocytosis. The pulse may be very slow. Headache, often severe and localized, is common, and there may be frequent vomiting. There is often vertigo, occasionally convulsions, and sometimes choked disks. Cachexia may also occur. The focal symptoms are of the utmost importance. The commonest is hemiparesis of the opposite side, but hemianopsia, hemihypesthesia, or unilateral loss of the muscle sense, and astereognosis may also be present. A peculiar feature of chronic abscess is the slowly progressive character of the symptoms, indicating extension forward or backward in the line of least resistance, and not increasing pressure in one place, as in the case of tumor. Occasionally the abscess ruptures spontaneously into one of the cavities of the head (nasal, aural), and temporary relief may be experienced. An abscess may be "latent" in almost any region, these latent abscesses being typified in certain cases of congenital heart disease. I do not think they were suspected during life in any of the cases reported thus far, and therefore optic neuritis has not been looked for. When the abscess is due to ear disease, phlebitis of the lateral and superior petrosal sinuses frequently coexists; in such cases there will be edema about the ear and neck and hardness of the jugular veins.

Diagnosis.—In the acute cases following injury little difficulty presents as a rule, though even in this group a latent period may exist. With such a history, however, the onset of headache, fever, delirium, and convulsive movements is decidedly suspicious, and, should optic neuritis also exist, practically no doubt can remain. When aural or nasal disease exists the head symptoms should be carefully studied, since they are prone to develop in ear disease soon after a cessation in the discharge. A slow pulse associated with fever is very characteristic of abscess.

Differential Diagnosis.—Brain tumor usually runs a more chronic course, and is seldom accompanied by fever, at least not until its final stage. The causes of abscess are absent except in the case of tubercular tumors, when abscess may be associated. It may be impossible to differentiate cerebral abscess from meningitis, and the two conditions often coexist, as already stated.

The **prognosis** is always grave.

Treatment.—When an abscess is diagnosed immediate operation is indicated. Suspected cases may be treated symptomatically unless focal symptoms develop. It must be remembered, however, that in a great many cases no localizing symptoms appear, and, since we know that most abscesses occur either in the temporosphenoidal lobe or in the cerebellum, when we have reason to suspect the presence of one, these regions should be explored.

ACUTE HEMORRHAGIC ENCEPHALITIS

Definition and Varieties.—This is a condition characterized by foci of inflammation scattered throughout the gray matter of the brain that are not accompanied by suppuration. The cortex alone may be affected (encephalitis of Strümpell), and a certain number of cases of cerebral palsy in children (p. 1101) are due to the process being localized in the motor region. Adults also may be attacked. The gray matter about the aqueduct of Sylvius, with involvement of the nuclei of motor nerves of the eye, is a frequent seat (polio-encephalitis superior of Wernicke). The nuclei of other motor cranial nerves may be affected (acute bulbar palsy or polio-encephalitis inferior). The cerebellum also may be involved. These forms may occur either separately or combined.

Etiology.—These are chiefly chronic alcoholism and the acute infectious diseases, especially influenza and the virus of acute anterior poliomyelitis (p. 1068). Lead-, gasoline-, ptomain-poisoning, and trauma also may be causes. It is more common in children and young adults.

Morbid Anatomy.—This consists of hyperemia, hemorrhage, round-cell infiltration, degenerated blood-vessels and nerve-cells in the affected areas.

Symptoms.—General symptoms, as headache, convulsions, vertigo, stupor, delirium, rigidity of the neck, more or less elevation of temperature, sometimes preceded by chills, may be present. The focal symptoms depend on the areas involved. The symptoms of acute polio-encephalitis superior and inferior are given on pages 1035 and 1065. If the motor cortex is involved, there may be convulsions of the jacksonian type, paralysis, either monoplegic, hemiplegic, or diplegic, with increased reflexes and the Babinski phenomenon. Ataxia, hemianesthesia, aphasia, and optic neuritis may also be present. Either the symptoms of poliomyelitis or a general diffuse myelitis may coexist.

Diagnosis.—Any combination of the above symptoms following one of the causes given, especially if any of the general symptoms are also present, would be suggestive. Sometimes they resemble those of multiple sclerosis. In the latter there would be absence of fever and the onset would be more gradual. Meningitis might be confounded, especially in the early stages. Lumbar puncture might be of service in distinguishing the two (pp. 1060, 1123).

Prognosis.—This is grave, but recovery may occur. In those that do, some permanent paralysis or epilepsy may remain.

Treatment.—This consists of ice-bags to the head, purgation with calomel, hexamethylenamin in full doses, and bromids and other sedatives if there are restlessness and delirium. Otherwise the treatment is symptomatic. (See also the Treatment of Acute Anterior Poliomyelitis.)

INTRACRANIAL GROWTHS

(Brain Tumors)

Owing to their close relationship, new growths, both of the brain and membranes, are here considered.

Pathology.—Rindfleisch has classified intracranial tumors according to the tissue from which they spring, thus:

1. Having their origin in the *membranes*, either extracerebral or intraventricular; these include tubercle, gumma, carcinoma, sarcoma, myxoma, lipoma, cholesteatoma, and psammona; small fibroids have also been described.

Enchondroma and osteoma may arise from the falx or from the bones of the skull.

2. From *blood-vessels*: to this group belong aneurysms, tubercles, and gummata.

3. Originating in the *neuroglial tissue*: glioma.

4. Originating in the *connective tissue*: sarcoma.

I will here consider these new growths in the order of frequency with which they are met:

1. **Tubercle** is most common in children and young adults, and is generally multiple (see Tuberculosis, p. 272).

2. **Sarcoma** is usually of the round- or spindle-celled variety; there may also be melanotic lympho- or fibrosarcomata. Sarcomata are apt to diffuse themselves through the brain substance quite rapidly.

3. **Glioma**.—Infiltrating tumors, generally single, and showing no definite line of demarcation from the surrounding brain structure. They may be soft, even telangiectatic, or quite firm. They often run a very chronic course.

4. **Gummata** are generally small and often multiple. They spring from the membranes or the adventitia of blood-vessels, or from connective-tissue septa. Frequently they are attached to the periosteum of the skull.

5. **Carcinomata** are secondary growths, and are generally small and round, but in some cases they perforate the bones of the skull, producing a fungus hematoides.

6. **Fibromata** are not common. They either grow in the membranes or aid in the formation of a mixed tumor, as fibrosarcoma. Other tumors met with less frequently are as follows: 7. **Osteoma**. 8. **Enchondroma**. 9. **Myxoma**. 10. **Lipoma**. 11. **Angioma**. 12. **Cholesteatoma**.

13. **Hydatids** are rare, especially in America. They may develop in any part of the brain or its membranes, and are said to occur most frequently in children. 14. **Cysticerci** may also occur in the brain or its membranes.

15. **Brain-cysts** are probably most often due to absorption of areas of softening from any cause, but they also occur between the dura and skull, as has been described. The lack of cerebral substance, due either to imperfect development or to atrophy following vascular obstruction or injury at birth, has been termed "porencephalia" by Heschl.

Etiology.—Age and sex are the chief factors; tuberculosis is far more common in children than in adults, while gummata when found appear almost invariably in adults, as do malignant growths. As a whole, new growths are more common between the twentieth and fortieth years, and males are more often affected than females. Traumatism seems to be an exciting cause in some instances.

Symptoms.—These are: (1) General and (2) focal.

General Symptoms.—*Headache* varies in degree and character; it is not of any value as a localizing symptom, nor is tenderness on pressure. Tenderness upon percussion, however, is often detected in the neighborhood of the tumor.

Vertigo in a mild form is quite a common symptom. In cerebellar cases it is often very marked.

Vomiting occurs in most cases, and generally bears no relation to the time of taking food; this constitutes an important point in the diagnosis. The vomiting is apt to be exaggerated in cerebellar tumor.

Papilledema or choked disk (p. 1029) is present, according to Gowers, in four-fifths of all cases; in 82 per cent. according to Oppenheim, and in two-thirds according to Knapp. It occurs most frequently and early in tumors beneath the tentorium. It may develop rapidly and lead to complete blindness by the development of consecutive atrophy, or, more slowly, and even

show very little if any loss of sight for a long time. It is usually bilateral, but often more pronounced on one side than the other. In many cases this is on the side of the growth. In rare cases there is progressive atrophy of the nerves without swelling. Headache, vomiting, and *choked disk* are "classical symptoms" of brain tumor, and when met with simultaneously are quite characteristic. Reversal and interlacing of the color fields may also be met with (p. 1156).

Mental disturbance is very common. Dulness and stupor are most reliable evidences of intracranial growth, and especially when occurring with any of the above symptoms. The patient may be emotional or hysteric. Pseudo-apoplexy may occur as the result either of the growth or of hemorrhage taking place about it.

Convulsions are focal, either jacksonian (p. 996) or general, depending on the location of the lesion.

Constitutional and other symptoms may include progressive weakness, loss of appetite and of flesh, amenorrhea, infantilism, pupillary changes, and changes in the pulse, respiration, etc., and possibly slight fever. In certain tumors in the basal ganglia hyperpyrexia occurs. High fever is often significant of meningeal inflammation, as in syphilitic cases.

The **focal symptoms** are of two kinds: first, those due to direct local action (irritation or compression), and second, those due to changes occurring about growth—indirect irritation, hemorrhage or softening, or merely congestion; thus can intermission or remission in symptoms be explained. The pages devoted to cerebral localization should also be consulted. The chief regional symptoms are as follows in—

(a) Tumors in the *prefrontal region*. *Headache*, not limited to the frontal region, with more or less mental impairment and drowsiness (though this is not constant by any means); and perhaps a disturbance of the sense of smell. No motor or sensory symptoms are present, as a rule, although vertigo and ataxia of the cerebellar type have been observed. The tumor may, however, grow backward, and either encroach on the motor region or cause motor symptoms indirectly. Downward growth would result in aphasia. A tendency to punning or joking (*witzelsucht*) has been noticed in some cases. Motor apraxia is sometimes present. On the side of the lesion there is often retrobulbar neuritis and rebounding pupil followed by optic atrophy, while papilledema is present on the other side.

(b) Tumors in the *motor region*. The early symptoms are irritative and, later, paralytic. The former give rise to *spasm*, which is often very localized at first, possibly in a few muscles (jacksonian epilepsy). The point of origin and direction of spread of the spasm are valuable localizing symptoms. Sooner or later destruction of the area causes *paralysis*. We may have spasm in one limb and monoplegia of the other on the same side. It may be necessary at times to decide if a growth involved the cortex primarily or is subcortical. In the former case muscular spasm usually occurs before paralysis, while in the latter paralysis appears first, the jacksonian attack not occurring until the tumor has extended to the cortex. Involvement of the left third frontal region causes motor aphasia.

(c) Tumors in the *parietal lobes*. There is usually ataxia of the limbs of the opposite side and astereognosis (pp. 997, 1004); later on homonymous hemianopsia, and if the ascending parietal convolution (Fig. 67) is involved, diminution of tactile sensibility may be present. When the posterior part of the left side is involved (angular or supramarginal gyri) we may meet with word-blindness or mind-blindness.

(d) Tumors in the *temporal lobes* may be latent, or there may be disturbances

of taste and smell, as hallucinations or uncinat fits (p. 998). If the posterior part of the first convolution of the left side is involved, we have word-deafness or other psychical disturbance of hearing, giving rise to auditory aphasia. (See p. 1002.)

(e) Tumors in the *occipital lobes*. A unilateral tumor produces lateral homonymous hemianopsia, in which the Wernicke hemianopic pupillary inaction sign is absent, while a bilateral lesion may cause blindness. In certain cases, too, mind-blindness results, or "soul-blindness," as it was at one time called (p. 1003). Visual hallucinations, as flashes of light, may also occur.

(f) Tumors of the *corpus callosum* are often latent; they may, however, cause unilateral or bilateral motor symptoms. Often some mental aberration is noted. Motor apraxia may also be present (p. 1004).

(g) Tumors of the *corpora quadrigemina*, owing to their relations to the cerebellum, often cause symptoms similar to those caused by disease of that organ (pp. 999, 1110). There is also more or less paralysis of the motor nerves of the eye and loss of the power of associated movements of the eyes upward. There may also be lateral homonymous hemianopsia (Wernicke hemianopic pupillary inaction sign present) and deafness. There may also be weakness of the opposite side. Tumors of the *pineal gland* may cause adiposity, precocious sexual, mental, and physical development, associated with the symptoms above mentioned.

(h) Tumors of the *crus* often cause a peculiar type of crossed hemiplegia, in which the face, arm, and leg are involved on the opposite, and the muscles supplied by the third nerve (eye muscles) on the same side. There may also be hemianesthesia (syndrome of Weber).

(i) Tumors involving the *base*, when growing in the anterior fossa, give rise to exophthalmos, disturbances of smell and vision, and possibly to mental impairment. When in the middle fossa the symptoms are chiefly those of involvement of the third and fifth nerve, consisting of ptosis and other oculomotor symptoms and facial neuralgia, with anesthesia in the distribution of the fifth nerve and paralysis of its motor branch. Such symptoms referable to the fifth nerve indicate tumor or other destructive disease of the gasserian ganglion. When the tumor involves the *pituitary gland*, temporal hemianopsia, amblyopia or amaurosis, optic atrophy, and frontal headache occur. If the functions of the gland are diminished, the syndrome of Fröhlich (*dystrophia adiposogenitalis*, *adiposis cerebialis*) develops. In this we may find adiposity, lack of sexual development, abnormal tolerance for sugar, lack of hair, subnormal temperature, polyuria, polydipsia, dry skin, and sometimes epileptiform convulsions. If increased function is present the symptoms are either those of giantism or acromegaly (p. 1169). When in the posterior fossa, facial neuralgia, neuroparalytic ophthalmia, or seventh or eighth nerve involvement and crossed hemiplegia are met with.

(j) Tumors in or about the *basal ganglia*, if quite small, cannot be diagnosed. When of larger size those involving the *thalamus* may cause hemiplegia and hemianesthesia by pressure upon the internal capsule, and lateral homonymous hemianopsia by pressure on the optic radiation. They may also cause obstruction and consequent distention of the ventricles (internal hydrocephalus). They may also give rise to amimia (contralateral paresis of the face only during laughing or weeping) and hemichorea or athetosis (p. 1103). If the *corpus striatum* is involved, there may be motor weakness of the hemiplegic type due to pressure on the motor-fibers passing through the internal capsule. The principal localizing symptom is muscular hypertonicity (p. 990). If due to apoplexy the symptoms would develop slowly; if to tumor, gradually.

(k) Tumors in the *cerebellum* are comparatively frequent both in children

and adults. When toward the outer surface of the lateral lobes the localizing symptoms may not be marked. By pressure upon either the aqueduct of Sylvius or foramen of Magendie they often cause internal hydrocephalus (p. 1113), and the symptoms due to that condition may complicate those due to the tumor. The symptoms of growths in this region depend upon their situation, whether in either the middle or one of the lateral lobes. Tumors in the space between the cerebellum, pons, and medulla, known as the *cerebello-pontile angle*, cause symptoms similar to growths in the lateral cerebellar lobes and may also be here considered. The principal localizing symptom of cerebellar disease is asynergia (p. 1000). Its manifestations differ somewhat according to the part of the cerebellum affected.

If the *middle lobe* or vermis alone is affected, the usual symptoms are rapidly developing—choked disk, severe headache, disordered gait (cerebellar titubation), which may be compared to that of a drunken man, vertigo (p. 1041), nystagmus (p. 1032), the Romberg symptom, weakness of the muscles of the back, and sometimes of those of the legs. Occasionally, rigidity of the muscles, retraction of the head, and tetanic-like seizures have been observed. The knee-jerks may either be increased, normal, or absent, and may vary to this extent in the same patient. Palsies of cranial nerves, especially the ocular, due to pressure and usually bilateral, may occur.

Growths involving one of the lateral lobes cause symptoms that are more marked upon the side of the lesion, and the patient usually has a tendency to fall toward this side (the opposite may occur, however). When vertigo occurs, external objects move from the side of the lesion to the opposite side, the rotation of the body being in the same direction.¹ The sixth and seventh cranial nerves are those usually affected in lesion of the lateral lobes, the paralysis being unilateral and on the homolateral side. Others may be affected. Asynergia, as shown by inability to rapidly pronate and supinate the forearm upon the side of the lesion (adiadochocinesia or adiadokokinesis of Babinski), and the straightening of the leg, after the thigh has been flexed on the body and the leg on the thigh, in a jerky inco-ordinate manner, may also be noticed on the side of the lesion. Dysmetria, demonstrated by inability to touch the end of the nose with the finger, the eyes being closed, is present on the side of the lesion. If the finger is carried past the end of the nose the symptom is termed "hypermetria." It is important to note that in cerebellar disease the finger is not carried to the nose in the jerky, tremulous way seen in multiple sclerosis, but is carried either to one side or the other of the objective point. The head is also sometimes held inclined to the shoulder of the opposite side.² Examination by the Bárány methods is important in all cases of suspected tumor of the cerebellum and vicinity, the absence of "past pointing" being especially significant of cerebellar disease (pp. 1041, 1111).

Tumors of the *cerebellopontile angle* are usually encapsulated fibromata attached to either the auditory or trigeminal nerves, usually the former. The early symptoms depend upon the cranial nerve from which the growth arises. If the auditory, there are attacks resembling those of Ménière's syndrome (p. 1042); if the trigeminal, there are neuralgic pains in the course of that nerve, with possibly sensory paralysis in its distribution. Other cranial nerves, especially the seventh, soon become affected, and the symptoms of tumor of the lateral lobe become more or less marked. The differential points between growths involving the lateral lobe, cerebellopontile angle, and pons are well given in the table of Stewart and Holmes³:

¹ Stewart and Holmes, *Brain*, 1904, p. 525.

² Batten, *Brain*, 1903, p. 71.

³ *Brain*, 1904, p. 549.

SYMPTOMS AND SIGNS	LATERAL CEREBELLAR TUMORS	EXTRACEREBELLAR TUMORS	INTRAPONTINE TUMORS
Optic neuritis.	Early and intense.	Variable.	Often absent or late.
Vertigo.	Subjective rotation of self from the side of the lesion.	Subjective rotation of self to the side of the lesion.	Indefinite.
Cranial nerves— V.	Rarely affected.	Often affected.	Affection of these nerves often bilateral. Paresis may be supranuclear or nuclear, and grouped according to nuclear arrangement. Paralysis of a nerve on one side and of an adjacent or distant nerve on the opposite side. Permanent paralysis of conjugate deviation of the eyes.
“ VI.	Weakness of conjugate deviation to side of lesion. Weakness of external rectus on side of lesion. Slow deliberate nystagmus to side of lesion.	Same as in unilateral cerebellar tumors.	
“ VII.	Paresis slight if present.	Paresis more marked.	
“ VIII.	Deafness on side of lesion incomplete and variable. Tinnitus general.	Deafness on side of lesion marked—generally complete. Tinnitus referred to ear on side of lesion.	
“ IX.	Never affected.	Occasional paresis on side of lesion.	
“ X.	“	“	
“ XI.	“	“	
“ XII.	“	Supranuclear paresis on contralateral side.	
Motor system.	Homolateral paresis, ataxia, and atonia.	Homolateral paresis and ataxia; contralateral spastic paresis common—occasionally bilateral.	Paresis often bilateral, with spasticity. Ataxia general.
Sensory system.	No change.	No change.	Occasionally hemianesthesia.
Reflexes—Tendon.	Variable, often diminished.	Generally increased, especially on contralateral side.	Increased often unequally.
Superficial.	Normal.	Often diminished on contralateral side.	Diminished often unequally.
Plantar.	Flexor.	Flexor or extensor. Extensor on contralateral or both sides.	Extensor on one or both sides.
Sphincters.	Not affected.	Rarely affected.	Generally affected.

Further help may be obtained by the employment of the Bárány tests. The differences may be tabulated as follows:

CEREBELLUM	CEREBELLOPONTILE ANGLE	PONS
Absence of “past pointing.”	<i>On side of the tumor</i> there is loss of hearing. Both horizontal and vertical semicircular canals are dead. <i>On the opposite side</i> hearing normal. Horizontal semicircular canal normal. Vertical semicircular canal is dead (p. 1041).	Either absent or perverted nystagmus, or spontaneous nystagmus upward.
Nystagmus (pp. 1032, 1042, present. Hearing good.		Vertigo present unless growth involves the cerebellar peduncles, then it is absent. Hearing good.

(l) Tumors in the *pons* produce symptoms according to their size and location. If high up, a crossed paralysis, similar to that caused by a growth in the crus, will result. When a little lower down a motor and sensory paralysis of the arm and leg of the opposite side with paralysis of the sensory portion of the cranial nerve on the same side may result. If the lower portion is affected, paralysis of the arm and leg of the opposite side with paralysis of the sixth, seventh, and eighth nerves will occur. More or less sensory paralysis may also be present. If the cerebellar peduncles are involved, forced movements and ataxia (cerebellar type) will result. If either the nucleus of the sixth nerve or the fibers of the posterior longitudinal fasciculus is involved, there will be loss of associated lateral movements of the eyeballs toward the side of the lesion, while the power of convergence remains. The absence of nystagmus (p. 1032) when the ears are tested by the Bárány methods is indicative of an intrapontine lesion, if internal ear and auditory nerve disease is excluded.

Tumors of the medulla cause symptoms of progressive bulbar palsy (p. 1065) plus more or less hemiplegia and hemianesthesia. If the growth is small, the symptoms may be more marked on one side.

Course.—Many cases run a very chronic course. Others may have existed months or years without symptoms, and then develop suddenly, owing to hemorrhage, thrombosis, or acute softening about the tumor. Either improvement may take place or the case may speedily progress to a fatal termination.

Diagnosis.—The general symptoms are usually sufficient to warrant a diagnosis. The gradual onset and progressive character without fever, in the apparent absence of any etiologic factor, are, as a rule, enough to indicate that a tumor is present, while its location can only be determined by the focal symptoms. Recently the x-ray has been used with some success for the localization of tumors that have undergone calcareous degeneration. The possibility of the symptoms being due to a syphilitic growth or basal meningitis should be borne in mind.

The **prognosis** is always grave. Syphilitic growths are the only ones amenable to medical treatment. Cortical growths, especially if in the motor region or its neighborhood, if encapsulated, are amenable to surgical treatment. Growths in both the lateral cerebellar region and cerebellopontile angle and pituitary gland have also been removed, but the operation is more serious; tubercle may recover by the growth becoming encapsulated and calcified. Nothing can be said as to the possible duration of life. Several years may elapse between the appearance of the symptoms and their fatal termination, or death may occur suddenly.

Treatment.—In any case recourse should be had to mercury and the iodids, and this treatment should be pushed, since it will certainly benefit syphilitic cases, and it is believed to be of some value even in the non-syphilitic. Other symptoms should be met as they arise. The question of operation must be considered where medical measures have proved of no avail. If the situation of the growth is favorable and the nature of the tumor is not malignant, an operation is likely to be successful. The percentage of recoveries is increasing as the technic becomes more perfect. When the growth cannot be localized, or is in a position unfavorable for operation, much benefit may be obtained by relieving pressure by the so-called operation of decompression. Blindness, which will surely result if choked disk is allowed to persist any length of time, and the severe headache may thus be prevented.¹

¹ Frazier and Spiller, *Univ. of Penna. Med. Bull.*, September, 1906; Cushing, *Jour. Amer. Med. Assoc.*, January 16, 1909, p. 184; and *Ibid.*, January 16, 1915, p. 189.

CHRONIC HYDROCEPHALUS

This affection is divided into external and internal hydrocephalus.

EXTERNAL HYDROCEPHALUS

Etiology.—External hydrocephalus may depend upon a congenital smallness of the brain or upon a congenital enlargement of the skull. The space between the brain and the bone is filled by an excess of subarachnoid fluid (*vacuum dropsy*), or there may be a wasting of the brain, such as occurs in old age or in chronic cachectic conditions.

Pathology.—When the skull is opened the bone is usually found to be thin; the dura is normal; the arachnoid is lifted from the surface of the cortex by a considerable accumulation of clear fluid of low specific gravity; the convolutions may be somewhat flattened and the cortex slightly thinned. Upon microscopic examination no changes are found in the brain substance. Sometimes the effusion is general; sometimes it is sacculated.

The **symptoms** depend upon the form. In cases in which there is hypoplasia of the brain or in which the brain has wasted, no pressure symptoms are present. All the manifestations are purely psychic in nature, and similar to those of *microcephaly* or *senile dementia*. In cases, however, in which the cranial cavity is abnormally large it is probable that the real cause resides in a congenital excess of subarachnoid fluid.

The **prognosis** is gloomy; nevertheless, it is possible that the disease may undergo spontaneous cure as a result of rupture into the nasal fossa.

The **treatment** is the same as for the internal variety (*vide infra*).

INTERNAL HYDROCEPHALUS

This is a condition in which one or more of the ventricular cavities of the brain are distended by the cerebrospinal fluid. In the *congenital form* and in that occurring in early childhood this is associated with more or less enlargement of the skull. In the later *acquired forms* the cranium does not yield so readily, and the enlargement does not exist or is slight.

The **etiology** of the *congenital form* is unknown, though the fact that it frequently occurs in several children of the same family has led to the supposition that it is dependent upon some hereditary influence. In some cases it has been referred to emotional disturbances suffered by the mother during pregnancy, and in still other cases an anatomic foundation has been discovered, such as enlargement of the pineal gland. It is generally supposed that the immediate cause is chronic endymitis.

The acquired form is usually secondary to inflammatory conditions (particularly meningitis) or to brain tumor. Some cases, however, occur in childhood that are apparently not due to either of these causes.

The **pathology** of the condition varies with its nature. In the congenital forms, upon opening the head the skull is found to be thin. The fontanels and sutures are either still open and connected only by a membrane, or closed by Wormian bones. The dura may be thickened, but usually is normal; the substance of the brain is slightly softened—although this is not invariably the case—and very much thinned. This thinning is, as a rule, particularly noticeable in the corpus callosum and commissures, which may, indeed, either be torn apart or completely atrophied. The enlargement ordinarily affects the two lateral ventricles, the third ventricle, and the aqueduct as far as its entrance into the fourth ventricle, which is commonly less involved than the other cavities. The endyma is sometimes smooth, but more often shows small

projections, which, according to Virchow, are composed of brain substance, but in some cases are due to proliferation of the glia tissue beneath the ependyma. The enlargement may not be uniform. If due to obstruction of the foramen of Monro, one or both lateral ventricles are usually enlarged, while the third ventricle either remains of normal size or is diminished. If due to enlargement of the pineal gland, the aqueduct does not show the funnel-shaped distention. Another cause upon which considerable weight has been laid is the closure of the transverse fissure between the cerebellum and medulla. The quantity of fluid may be enormous, as much as 4 or 5 liters (5 or 6 quarts) having been recorded. The thinning of the brain substance is also remarkable when one considers that a cerebrum 5 mm. ($\frac{1}{5}$ in.) in thickness is apparently able to perform a large proportion of its ordinary psychic functions. The atrophy seems to affect particularly the white substance, especially the myelin sheaths.

In cases of the *acquired form*, unless they occur early in life, the enlargement of the skull is not very noticeable; the substance of the brain shows considerable softening; the ventricles are moderately enlarged, and, particularly in the chronic forms due to tuberculosis, are considerably roughened. The most pronounced cases are those that occur when there is a tumor in the occipital fossa which compresses the veins of Galen. Basal meningitis causing an obliteration of the foramen of Magendie is also a cause. In these cases the accumulation of liquid is slower, the brain yields more gradually to pressure, and the dilatation is more pronounced. Ordinarily, there is considerable flattening of the convolutions. In a few of these cases inflammatory changes in the ependyma have led to partial obliteration of the ventricles, particularly in the anterior horns or the lateral ventricles. Occasionally also bands of organized lymph may cross the ventricles in various directions; the liquid is of higher specific gravity and contains more albumin than in the non-inflammatory varieties.

Symptoms.—The most characteristic appearance in congenital hydrocephalus is the *globular enlargement of the head*. Upon palpation the fontanels are found to be still patulous and usually bulging, and the sutures are open. The head is usually so heavy that it cannot be held upright, but falls backward or to one side. The face appears proportionately very small. *Motility* is usually disturbed, the legs are spastic, and the child either does not learn to walk at all or only long after the usual time. There are sometimes choreic movements of the upper extremities. The *eyes* frequently show nystagmus and conjugate deviation, and often there is either choked disk or atrophy of the optic nerve. Fischer has described a *systolic murmur* that can be heard if the stethoscope is placed over the anterior fontanel. Its cause is unknown. *Convulsive attacks* are common; they are epileptic in type, and, as a rule, ultimately cause death. *Intelligence* is usually considerably impaired, and sometimes the children are idiots; more often they merely show retardation of intellectual development. Occasionally—and this even in the most pronounced cases—the intelligence is well preserved. Hensch records the case of a boy three years of age whose head was 75 cm. (29.6 in.) in circumference, and who could speak both French and German. Ordinarily, the children are quiet and apathetic, but they may be querulous. *Nutrition* is commonly seriously disturbed, the children sometimes exhibiting pronounced cachexia. They may, however, be well nourished and, to a certain degree, vigorous. The symptoms of the chronic form in adults are those of brain tumor without focal symptoms.

The **diagnosis** is ordinarily very easy. Careless observation may lead to confusion with *rachitis*, but the square shape of the head and the presence of other rachitic deformities in the skeleton should lead to a prompt recognition of the true nature of the case. At times there may be difficulty in making the

diagnosis from brain tumor; x-rays may prove of service in distinguishing between the two.¹

The **prognosis** is extremely unfavorable, the majority of the children dying about the fifth year. A few cases, however, may live until they reach young adult life, and still fewer apparently recover entirely.

Treatment is, of course, difficult. Potassium iodid and mercury have been employed without much beneficial effect. Cod-liver oil may be given to stimulate nutrition, and purgatives occasionally relieve pressure symptoms temporarily. Among the mechanical precedures constant pressure upon the head seems the most valuable. This can be obtained by means of strips of adhesive plaster or by the application of an elastic band. Drainage of the ventricles has given good results in some cases.² Haynes³ suggests draining the cisterna magna into one of the cranial sinuses. A new method has been devised by Sharpe⁴ which has given encouraging results. If convulsions develop, they should be combated by bromids and purgatives.

ACUTE DELIRIUM

(*Acute Delirious Mania; Typhomania; Acute Periencephalitis; Bell's Mania*)

Definition.—An acute maniacal delirium associated with hallucinations, with a febrile course, of limited duration and of grave prognosis.

Pathology.—Visible changes are usually absent, there may be found minute pericapillary hemorrhages and degenerative changes in the ganglion cells. Sometimes injection of the pia and minute hemorrhages into the gray matter may be observed with the naked eye. Cramer has reported a case in which the pericapillary spaces of the brain were filled with mononuclear leukocytes, surrounding which were recent hemorrhages; he also noted the fact that the ganglion cells instead of exhibiting normally formed chromophilic bodies, were filled apparently with fine dust.

Etiology.—The disease occurs in either sex with about equal frequency. Predisposing conditions are neuropathic heredity, nervous disposition, the presence of other nervous diseases, particularly neurasthenia and epilepsy. alcoholic or sexual excesses, and severe prolonged anxiety. It frequently occurs apparently as the immediate result of menstruation, parturition, injuries to the head, sunstroke, acute infectious diseases, particularly pneumonia and typhoid fever, and it may develop in the course of chronic mental diseases. Occasionally, however, it appears to arise without any definite cause.

Symptoms.—The disease usually commences with certain indefinite prodromes. These consist of *restlessness*, associated either with melancholia, preoccupation, or anxiety. The *intelligence* becomes distinctly decreased; the patient loses appetite, is constipated, and commences to emaciate. During sleep unpleasant dreams or nightmares almost invariably occur. Sometimes there is a sense of impending mental disorder. This period gradually changes to one of defiance, which perhaps, even in the prodromal stage, may lead to violence and injury to those in the neighborhood. The prodromal stage rapidly passes to *acute delirium*, in which two steps may be recognized—excitation and collapse. The excited stage commences suddenly; there is great confusion; the patients ejaculate disconnected sentences or words or even syllables. There

³ *Annals of Surg.*, April, 1913, p. 449.

⁴ *Amer. Jour. Med. Sci.*, April, 1917, 563.

is great anxiety, and even fear, and the patients exhibit intense excitement, suffering very often with delusions of persecution by their environment, and nearly always have hallucinations, either of sight or sound. Often their minds are occupied by some subject that had previously caused them great anxiety—either disgrace, business, or other misfortune. The patient soon becomes restless, throws himself from one side of the bed to the other, and makes efforts to rise and escape from the room. The tongue is dry, the pulse rapid and weak. Petechiæ may appear upon the skin, and there is nearly always more or less fever, not rarely rising to 105° F. (40.5° C.) or even more. Rapid emaciation supervenes. There are all the objective symptoms of irritation of the brain—myosis and increased reflexes, and often hyperesthesia, although the patients pay little attention to any injury they may inflict upon themselves. This stage of excitation soon passes into one of *stupor* and *collapse*; fever may become even higher, and the pulse still more rapid and weaker. The patient lies in a condition of muttering delirium, with carphologia. All the symptoms are those of profound exhaustion: the eyes are hollow, the lips and teeth covered with sordes, and the emaciation extreme. The skin becomes dryer, and finally cyanotic, the pupils dilate, and there may be marked anesthesia. Death ordinarily occurs at the end of two or three days after the commencement of this condition. Occasionally the course of the disease is interrupted by intervals in which the patients exhibit more or less lucidity. The disease is related to an asthenic condition known as confusional insanity, which is due to the same causes, but in it the patients exhibit, in place of excitement, depression, with fear of poisoning and positive refusal of all food, mental confusion, disorientation, failure of memory, slight elevation of temperature, or, indeed, a subnormal temperature, and very rapid emaciation. It is most apt to occur in patients previously debilitated. In the paralytic form there is vasomotor paralysis with cyanosis, depression, and often stupor. From these the patient passes into an aglid state, in which death occurs.

The **differential diagnosis** is frequently difficult. In many infectious diseases, particularly *pneumonia* and *typhoid*, hallucinatory delirium may develop. This, of course, must be suspected in these diseases, and it is advisable, if possible, to examine the blood in all cases of acute delirium by Widal's method. In *acute mania* fever is rare, emaciation is not so rapid, and the mental symptoms are more purely psychical. In *general paralysis*, toward the end maniacal attacks may develop, but the history of the previous existence of the disease, the presence of the Argyll Robertson pupil, and the absence of fever lead one to suspect the true diagnosis. Finally, in *delirium tremens* the fine tremor of the hands and tongue, and, if possible to obtain it, a history of recent debauch should clear up the diagnosis. The course of the disease is variable; it may vary from three or four days to as many weeks. Those cases are most rapid in which excitation is most profound.

The **prognosis** in acute delirium is most unfavorable, and is more so for men (according to Krafft-Ebing) than for women. Those cases that were previously debilitated, either as a result of chronic alcoholism, or chronic exhaustive diseases, or childbirth, are the most serious. Those that develop suddenly, and from the beginning are very severe, are also nearly always fatal; if there are no lucid intervals, or if those that occur are short and imperfect, the prognosis is graver; and the same is true of those who suffer from obstinate insomnia. In confusional insanity it is better, although serious.

The **treatment** is, of course, unsatisfactory. Calomel should be administered in the earlier stages of the disease. At the same time the temperature should be combated by cool baths or packs and an ice-bag should be applied to the head. Sleep should be obtained by the use of chloral, bromid,

and the more modern hypnotics, which are to be preferred to morphin. Hyoscin seems to be particularly indicated. In the later stages of the disease stimulants should be administered freely. Excellent results have been obtained (Solivetti) by the hypodermic administration of Bonjean's ergotin. Nutrition must be maintained by forced feeding with milk, eggs, broths, etc.

SENILE DEMENTIA

This is a condition often symptomatic of sclerosis of the cerebral arteries. Cases occur, however, in which evidences of this condition are not apparent, and, of course, all those who have arteriosclerosis do not become demented. It usually comes on after fifty years of age, and is slightly more common—at least more noticeable—in the male than in the female sex. The first **symptoms** are loss of memory, especially for recent events, failure to keep engagements, and slight querulousness. These steadily progress. The patient forgets not only facts, but words, and the speech may, in consequence, resemble—to a certain extent—some of the manifestations of aphasia. At the same time judgment is impaired; the patient is irritable, occasionally ridiculous; becomes suspicious, particularly of his immediate family and friends, and is apt, at times, to become violent toward them. He becomes careless about his person and clothing, spills food while eating; often sleeps during the day, especially after eating, and may wander about the house at night. Finally, the dementia may become complete, and the patient become entirely unable to care for himself. The objective signs are usually the hardened arteries, tremor of the hands and lips, the arcus senilis, the wrinkled, dry skin with prominent veins, and the progressive emaciation. Often the urine is of low specific gravity, and contains a slight amount of albumin. Death usually occurs from some complication, such as cerebral hemorrhage or uremia, or from some intercurrent condition, such as bronchopneumonia. The **treatment** is that for arteriosclerosis.

V. DISEASES OF THE BRAIN AND CORD

MULTIPLE SCLEROSIS

(*Insular or Disseminated Sclerosis*)

Definition.—A disease due to the development of sclerotic patches, occurring in an irregular manner throughout either or both the brain and spinal cord. It is characterized by paresis, intention tremors, scanning speech, nystagmus, and mental disturbances.

Etiology.—It is not certain that there is a single cause for all cases of multiple sclerosis. Most frequently it follows some infectious condition, particularly the exanthemata, typhoid, malaria, pneumonia, and perhaps influenza and sunstroke. Focal infections should be considered. The metallic poisons, as lead, also seem to have an etiologic significance. A history of trauma, of exposure, or profound emotional shock is often obtained. Neuro-pathic heredity often exists. The majority of cases apparently begin between the ages of twenty and thirty, but children may be affected. A rare familial and hereditary disease has been described in which the symptoms resemble those of multiple sclerosis (aplasia axialis extracorticollis of Pelizaeus and

Merzbacher¹). Sex is not an important factor. The disease is far more common than was formerly believed (Taylor), as the atypical forms are often not recognized.

Pathology.—The sclerotic tissue occurs especially in the white matter, though any part of the cerebrospinal axis may suffer. The cortex is rarely implicated. The spots are usually well circumscribed, gray or grayish-red in color, and on section may be level with, raised from, or depressed beneath the normal line of section according as to whether it is in the early, hypertrophic, or cirrhotic stage. The cranial nerves may be involved at their origin, the first, second, and tenth being particularly vulnerable. The medullary sheath of nerve-fibers in the affected region degenerates early, but the axons are markedly resistant. Since they are not cut off from their trophic center, secondary degeneration is rarely met with. The blood-vessels show more or less proliferation of the adventitia, and endarteritis is not an uncommon condition. Whether this vascular change is primary or secondary is unknown. Microscopically, the sclerotic areas are made up of an overgrowth of neuroglia cells and fibers and of the ordinary connective tissue. In certain cases these patches exhibit some tendency to involve special parts of the nervous system, as the lateral or posterior columns.

Symptoms.—These may be described under two headings: first, the general symptoms, or those common to all cases of the disease, and not explicable from the position of the sclerosis; and, secondly, those dependent on the locality of the lesions. The disease is always chronic, and either remissions, or one or more intermissions occur, and in some cases may extend over several years. The first evidence of the disease is *loss of power*, first in one, then in the other, lower extremity. Later, paresis develops in the upper extremity. Sooner or later other general symptoms appear—viz., tremors, nystagmus, scanning speech, increased reflexes, and optic-nerve atrophy. The *tremor* is volitional (*intention tremor*), and when the patient is at rest no abnormal movement is manifest, as a rule. On attempting to use the hands or in walking more or less coarse tremor is observed. This may be well brought out by the finger-to-nose test. The head may be similarly involved, and some inco-ordination is commonly associated therewith. As the paresis is spastic, the tendon reflexes are increased, and even ankle-clonus and the Babinski phenomenon may be present. The abdominal reflex is often absent. In addition, a certain degree of ataxia or inco-ordination of motion is present, which is independent of the tremor. Strümpell has studied this especially. The *nystagmus* is sometimes only noticeable when the eyes are moved, but usually it is constant. It is more marked in lateral than in vertical movements. *Speech* is at first slow and drawling, and of a peculiar monotonous character; later it becomes even more deliberate, and is then spoken of as scanning, each syllable being pronounced separately with a slight rising and falling cadence. Optic-nerve atrophy is of frequent occurrence. It begins with pallor of the temporal edges of the disks, a valuable sign (Müller). Other cranial nerves, particularly the motor nerves of the eyes, may be affected, and at times are early symptoms. The sensory disturbances are less important than the motor phenomena. They consist of areas of hyperesthesia, particularly in the extremities, that are usually transient, and occasional tingling or numbness in the limbs. There is usually no wasting of, nor electric change in, the muscles, nor do bed-sores occur. Vertigo is usually present. The patients are usually emotional, and laugh or cry upon slight provocation; often the outbursts of laughter are wholly causeless. In other cases dementia, or even acute maniacal outbursts, are met with, but these are rare. During this stage epileptiform

¹ *Brain*, 1914, p. 341.

or apoplectiform attacks may occur. The symptoms directly resulting from the local lesions cannot be given in detail. Certain types result, however, that depend upon the tendency of the sclerotic areas to involve certain tracts, and these are—first, a form resembling lateral sclerosis, either bilateral or unilateral (p. 1081), due to implication of the lateral tract; and, secondly, a form similar to locomotor ataxia, in which the posterior columns especially suffer. In some of these cases the general symptoms described above are not very apparent, or only one or two of them may be present. Such are difficult of diagnosis (“formes frustes” of Charcot).

The **diagnosis** is generally easy after the disease has lasted some time. The intention tremor and the gradual and progressive loss of power, with increased reflexes, scanning speech, and mental deterioration, are sufficient. The following table gives the differential points between this disease and *paralysis agitans*, *tabes dorsalis*, and *hereditary ataxia*:

DISSEMINATED SCLEROSIS	PARALYSIS AGI- TANS	TABES DORSALIS	HEREDITARY ATAXIA
Rarely occurs in children. Generally between the twentieth and thirtieth years.	Occurs in persons over forty years of age.	Rarely before the twentieth year.	Usually before the twentieth year. Generally affects several in the same family.
No sensory symptoms, as a rule. Sight may be impaired, the hearing less frequently. The Argyll Robertson pupil is absent.	No sensory or special sense symptoms of any importance. Argyll Robertson pupil is absent.	Fulgorant pains an early symptom. Sight and hearing are commonly affected. Often diplopia and Argyll Robertson pupil are present.	Sensory symptoms are rarely present. Diplopia and Argyll Robertson pupil are absent.
Nystagmus is present, as a rule.	No nystagmus.	No nystagmus.	Nystagmus is frequent.
Reflexes are exaggerated; ankle-clonus is present. There may be muscular rigidity.	Reflexes are normal; very rarely they may be plus. Permanent muscular rigidity.	The knee-jerk, ankle-clonus, and rigidity are all absent.	The knee-jerk is lost in the course of the disease; it is rarely increased. No rigidity.
Scanning speech.	Speech is slow and deliberate on commencing a sentence, but soon it becomes hurried.	No speech defects.	Speech is slow and irregularly scanning.
A tremor is generally present on voluntary movements only. If the tremor occurs during rest, it is fine. Oscillations of the head are frequent; of the trunk, less so.	Tremor when at rest. Voluntary movement may make it cease temporarily. The head may shake, with rather a vertical than an oscillatory movement.	No tremor. Inco-ordination is marked. No oscillations of the head or trunk. Romberg's symptom is present. Trophic disturbances are common.	Inco-ordination is present, is increased by closing the eyes. Static ataxia may be noted.
Mental disturbance may occur.	No mental phenomena.	Mental disturbance is rare.	No mental disturbance.
Gait is usually spastic and paretic, and often uncertain.	The face is immobile and mask-like. The gait is propulsion, festination, retropulsion, or latero-pulsion.	The gait is stamping in character; the legs are moved stiffly. There is difficulty in urination.	The gait is swaying and irregular, like that of a drunken man. The legs are not kept wide apart as in locomotor ataxia.

The most difficult differential diagnosis is from syphilis of the central nervous system. This is characterized, as a rule, by the more rapid development, the presence either of the Argyll Robertson pupil or complete pupillary immobility, the absence of the typical group of symptoms, and the response to antisyphilitic treatment. It should not be forgotten that any of the symptoms of disseminated sclerosis may be present in cerebrospinal syphilis, and that cases of the former disease may lack one or more of the fundamental symptoms, and cases will sometimes occur in which the differential diagnosis cannot be made. Examination of the cerebrospinal fluid may be of assistance, as in syphilis a marked pleocytosis, an increase of globulin, and possibly the Wassermann reaction will be found (p. 1123). Arteriosclerosis may produce multiple areas of softening, causing a symptom group resembling multiple sclerosis. This, however, is more apt to occur in old people, while multiple sclerosis is more common in early middle life. Disseminated myelo-encephalitis (p. 1106) may also be mistaken. In this there may be fever and a history of previous infection. The affections known as pseudosclerosis and diffuse sclerosis may also resemble multiple sclerosis (*vide*).

The **course** usually extends over five to ten or even fifteen years, and death is generally the result of some intercurrent affection, though it may occur during an apoplectic or convulsive attack. Rarely it is due to failure of the heart or respiration. Remissions of considerable length of time may occur.

The **prognosis** is favorable as far as life is concerned, and some improvement may even occur, but entire recovery cannot be expected.

Treatment.—Silver nitrate, mercury, the iodids, quinin, and arsenic may be tried. Rest and easily assimilable food are of prime importance.

PSEUDOSCLEROSIS AND DIFFUSE SCLEROSIS

In 1883 Westphal described a case characterized by disturbance of speech, slowness of the movements, decrease of intelligence, increased irritability, apoplectic attacks, pronounced tremor, spasticity and increased reflexes, slight disturbance of sensation, and no involvement of the sphincters. The autopsy was entirely negative. He termed the condition *pseudosclerosis*. Since then similar cases have been reported, especially by Strümpell. Such symptoms may appear early in life and also affect more than one member of a family. They differ from those of multiple sclerosis in that usually motor weakness is not great, but spasticity is; the Babinski reflex is absent, as is usually ankle-clonus. Scanning speech does not occur, but dysarthria does. The tremor is present when the patient is at rest. In a general way these cases may resemble paralysis agitans or lenticular degeneration, and it is believed now that many of them at least are due to disease of the lenticular nucleus (pp. 999, 1103). Many other athetoid, choreiform, and spastic conditions are probably also due to disorder of this part of the nervous system. Some of these cases may be due to *diffuse sclerosis*. Usually, however, in this condition there is spastic paralysis and dementia developing gradually. The symptoms may resemble those of paresis, but the serologic changes (p. 1125) will be absent. It may occur in young children (p. 1103) and must be distinguished from the cerebral palsies of childhood (p. 1101).

Treatment is without avail.

SYPHILIS OF THE NERVOUS SYSTEM

Syphilis affects the nervous system in two ways: (1) By a round-cell exudation involving the arteries and meninges, in which the nerve-cells and fibers are involved secondarily. This causes either the so-called gummatous meningitis, localized gumma, or obliteration of the caliber of the blood-vessels (endarteritis obliterans), with resulting apoplectiform seizures and softening. This type may be termed *meningovascular* or *exudative syphilis*. (2) By causing a degeneration of nerve-cells and fibers. This type may be termed *degenerative* or *parenchymatous syphilis*. Paresis and tabes dorsalis¹ are the common examples of this type, but progressive spinal muscular atrophy, amyotrophic lateral sclerosis, lateral sclerosis, cerebral palsies of children, epilepsy, and optic atrophy may be rarely so caused.

MENINGOVASCULAR OR EXUDATIVE SYPHILIS

Etiology.—This type comprises the cases usually termed syphilis of the nervous system, or cerebrospinal syphilis. It may be due to either acquired or hereditary syphilis. When due to the former the symptoms may appear at any time after the appearance of the chancre. The usual time is from the third to the tenth year after infection, but they have occurred while the usual secondary symptoms are present. In this connection it is important to note that during the secondary period a certain proportion of cases show the characteristic changes due to syphilis of the nervous system (p. 1123) in their cerebrospinal fluid. Such cases are those which, if not then treated as cases of nervous syphilis, will probably develop that condition later.

When due to the latter, they may appear at any time after birth, and cause symptoms similar to those following acquired syphilis. Cerebral palsies (p. 1101) and epilepsy may sometimes be so caused.

Either the brain, spinal cord, or peripheral nerves may suffer alone. Usually the brain and spinal cord are both affected. The spinal nerves are not often affected, but the cranial nerves are, and symptoms attributed to cerebral syphilis may be due to their involvement.

CEREBRAL SYPHILIS

Pathology.—The essential feature is a marked round-cell and lymphocytic infiltration of the meninges and blood-vessels. When diffuse (known as gummatous meningitis), the meninges at the base are most commonly affected, especially in the region of the optic chiasm and ocular nerves. It may, however, involve the vertex alone. When localized, a gumma results. This springs from the meninges, but may extend into the brain substance. It is a tumor and causes symptoms as such. The arteries alone may suffer, their walls being infiltrated with cells and their caliber lessened or obliterated. When such occurs, areas of softening in the areas supplied by them will be found. Gunmata may develop in the adventitia, causing globular or ovoid swellings. Macroscopically, gummatous meningitis has a gelatinous, yellow appearance; in places there may be connective-tissue formation.

Symptoms.—A symptom frequently present before the development of others is headache. This is usually very intense and worse at night. In connection with this there may be somnolence, sometimes amounting to stupor, during the day. If the lesion affects the vertex, epileptiform convulsions may occur. If the lesion is localized, these may be of the jacksonian type. When the base is involved, cranial nerve palsies occur. Those most

¹ In their early stages at least these two diseases would seem also to belong to the exudative type.

commonly affected are those which move the eyeball (third, fourth, sixth). At first these palsies may be transient, appearing and disappearing from time to time. If the exudation is in the region of the optic chiasm, symptoms simulating those of pituitary tumor (p. 1109) may be caused. Optic neuritis or beginning atrophy is a frequent symptom and may be a very early one. It is well to have an ophthalmoscopic examination made from time to time in patients who have contracted syphilis. When the blood-vessels alone are diseased, apoplectic attacks, usually due to thrombosis, may occur. Such an attack in a young person, in whom embolus or a previous attack of one of the infectious fevers can be excluded, is usually due to syphilis. The symptoms of gumma depend upon its location, and are practically those of brain tumor. Diffuse meningitis may, however, be associated. Hypochondria and either mental depression or excitement may be due to syphilis.

SPINAL SYPHILIS

Pathology.—The lesions are similar to those found in cerebral syphilis.

Symptoms.—These may be those of either acute transverse or disseminated myelitis (p. 1071), or if the meninges are involved, those of meningo-myelitis. The Brown-Séquard syndrome (p. 1012) also occurs, especially if the lesion is either a gumma or small area of softening. A form of spastic paraplegia, known as Erb's type of syphilitic spinal paralysis, frequently occurs. This is characterized by slowly increasing stiffness and weakness of the legs. The gait is of the ataxic paraplegic type (p. 1086), the deep reflexes are increased, and the Babinski reflex can be elicited. More or less difficulty in either passing or holding the urine is present. Sensory symptoms are not prominent, although pain in the sacral region and paresthesia in the legs may be complained of. The lesion consists of thrombosis occurring in the vessels of the lower dorsal region of the cord, and involving principally the posterior columns and posterior part of the lateral columns. Gummatous meningitis involving the posterior roots may cause symptoms simulating tabes. Localized gumma causes symptoms similar to those of spinal tumor.

CEREBROSPINAL SYPHILIS

This consists of various combinations of the symptoms of cerebral and spinal syphilis, and is probably the most common type.

SYPHILIS OF THE PERIPHERAL NERVES

Without involvement of either the brain or cord this is not common. Either isolated primary atrophy of the optic nerves or optic neuritis may occur. The former may be an early symptom of tabes. Other nerves may be the seat of a round-cell infiltration, which causes paralysis of the muscles or skin areas supplied by them. Multiple neuritis has been described.

DIAGNOSIS

Syphilis may simulate any of the various organic diseases of the brain and cord. There is usually, however, something atypical in the development of the symptoms. There are also apt to be in the early stages transient symptoms. Headache of the type described (p. 1121) is a frequent prodrome, as may be vertigo, transient paralyses, especially of cranial nerves, epileptiform convulsions, somnolence, etc. Such symptoms may precede apoplectic attacks due to syphilitic disease of the arteries. Those who have been infected should have the eyes examined at intervals for signs of either optic neuritis or atrophy. The development of serologic tests has been of great help. In this connection

it must be borne in mind that a negative Wassermann reaction with the blood-serum does not exclude syphilis of the nervous system, and, on the other hand, a positive one does not prove that the symptoms are so caused, as a patient may have had syphilis and yet have a lesion of the nervous system due to other cause. The important tests are those with the cerebrospinal fluid, although these may sometimes be negative. Close attention to the development and character of the clinical symptoms is therefore most important. According to Kaplan, the serologic changes are as follows: Lymphocytes per cubic centimeter, 80 to 2000; Wassermann in cerebrospinal fluid, + in 65 per cent; in blood-serum, + in 80 per cent.; globulin, excess in 65 per cent. Fehling reduction of sugar, present in 95 per cent. Lange's colloidal gold test¹ is valuable. This depends on the color changes which take place when cerebrospinal fluid in ten different dilutions (1 : 10 to 1 : 5120) is added to a colloidal gold solution. These changes vary from the normal salmon red to red blue, lilac or blue, blue gray, or gray and colorless. If the normal is indicated by 0 and the decolorized solution by 5, in either cerebrospinal syphilis or tabes, the changes can be indicated as follows, 1133200000 or 1223320000. This is known as the "luetie curve." In paresis a different reaction occurs, known as the "paretic curve," and indicated as 5555431000. This may be obtained in cases in whom the usual symptoms of paresis have not developed, and is, therefore, a valuable danger-signal. Other symptoms aiding in the distinction between cerebrospinal syphilis and paresis are given on p. 1126. The distinction from true tabes is given on p. 1130.

PROGNOSIS

This is doubtful. If the diagnosis is made early and vigorous treatment given, recovery often occurs. If degeneration of nerve-cells or fibers has occurred, they cannot be replaced, and symptoms so caused will remain. The progress of the disease may, however, be stayed. The prognosis of apoplexy due to syphilis is similar to that due to it from other causes; further attacks may, however, be averted. Cerebral syphilis and acute lesions of the cord may cause death.

TREATMENT

This consists of the intensive use of either salvarsan or neosalvarsan and mercury. Swift advises that when the cerebral meninges or brain are involved to precede the use of the former by a short course of mercury by inunction or injection. It may also be well to administer iodid of potassium in full doses in the early stages. It must be borne in mind that this drug will not cure syphilis, but it is an excellent remedy to remove the exudate caused by it. Therefore it is not of as much service in the degenerative forms. Salvarsan should be given as described for tabes (p. 1131). Other treatment may be needed for the symptoms, thus papilledema due to a gumma requires a decompressive operation, as does that due to other causes. Surgical interference may sometimes be required to remove it or the thickened membranes caused by it, when they act as a tumor and can be localized. Cystitis, bed-sores, and paralysis should be treated as when they occur due to other causes.

PARENCHYMATOUS SYPHILIS

The principal manifestations of this are paresis or general paralysis of the insane and tabes dorsalis. At one time these were termed parasymphilitic diseases, and were thought to be caused by syphilis in some obscure way. The finding of the spirochetes in the brain and cord and the results of serologic tests in these diseases has proved their direct relation to the infection.

¹ *Johns Hopkins Hosp. Bull.*, 1915, xxv, p. 391.

Lateral sclerosis, amyotrophic lateral sclerosis, progressive spinal muscular atrophy, and some forms of mental deterioration in children may be sometimes so caused.

GENERAL PARALYSIS OF THE INSANE

(*General Paresis; Paresis; Chronic Diffuse Meningo-encephalitis; Dementia Paralytica*)

Definition.—A chronic disease involving the cerebrum, spinal cord, and the meninges, and characterized by a gradual loss of power, tremors, and progressive mental decay.

Pathology.—The intima and adventitia of the blood-vessels undergo proliferative changes, and the perivascular spaces are dilated and contain an excessive quantity of fluid, also cellular elements. Obliterative endarteritis occurs also. Atrophy and degeneration of the cerebrum are met with, chiefly involving the cortex, particularly that of the frontal or parietal regions and the anterior basal region. The ventricles are dilated and the ependyma is granular. The membranes are thickened and opaque, and adherent to the surface of the convolutions, so that the cortex is torn upon their removal. Hemorrhage may take place into the subdural spaces, and may vary in amount from a mere stain to the formation of a pseudomenbrane.

Secondary sclerotic and degenerative changes are found in the posterior and pyramidal tracts of the cord in most cases.

Etiology.—As in locomotor ataxia, a history of syphilitic infection is obtained in a large majority of all cases. Noguchi and Moore have demonstrated the *Spirochæta pallida* in all the layers of the brain cortex except the outer one in 12 cases out of 70 examined.¹ The condition occurs more frequently in men than in women, and usually between the thirtieth and fiftieth years. Business or domestic troubles, and, in fact, great anxiety of mind from any cause, trauma, also venereal or alcoholic excesses serve more or less directly to induce the disease. The white races, Hebrew and Caucasian, seem to be especially predisposed, the yellow and black races less so, although it is occasionally observed among the negroes of America. It is undoubtedly increasing in frequency.

Symptoms.—The **prodromal stage** may last for months, or the onset may be sudden with an apoplectiform or epileptiform seizure. When the former is the case, neurasthenic symptoms are frequent. The symptoms are both mental and physical, either of which may appear first and exist alone for some time, or they may be contemporaneous in point of onset. As a rule, some *alteration of the character* and demeanor of the patient is the first evidence of the trouble. The patient suffers from insomnia and is generally restless, as well as incapable of sustained effort. He will be forgetful and perhaps careless where he was formerly careful and attentive. The sexual desire may be excessive. The *ego* will figure prominently in his sayings and doings. Sometimes he is hypochondriacal, sometimes exalted, and feels strong and competent. Among the physical signs are frequent twitchings and *tremors* of the facial muscles, particularly of those about the mouth and the tongue. Tremors of the hand and arm seriously interfere with writing; tremor of the lips and tongue renders the *speech* thick, blurred, and hesitating, and syllables are omitted from words, or even whole words lost from sentences; and the *pupils* are frequently unequal and fail to react to light, but do in convergence and accommodation (Argyll Robertson pupil), primary optic atrophy may also be present. The tendon reflexes may either be diminished, lost, or exaggerated. The gait may be ataxic, in fact, all the symptoms of tabes may be associated with paresis (taboparesis). These symptoms extend over a variable period, with one or more remissions as

¹ *Jour. Amer. Med. Assoc.*, March 29, 1913, p. 1002.

a rule, and sometimes with a complete intermission and an apparent cure. Sooner or later, however, the next stage develops.

Stage of Excitement or Depression.—The symptoms of this stage are superadded to those of the first, which by this time have grown gradually more pronounced; *loss of power* usually is already a prominent feature. A state of excitement is most commonly met with, and is characterized by a most remarkable prodigality of thought and speech. The patient believes himself to be possessed of enormous wealth or of great rank and power. Extravagance, unsafe business ventures, and irrational generosity are common. He is boisterous, sleepless, and constantly and actively engaged in pursuing his extravagant ideas. Women are apt to believe themselves pregnant. In many cases, however, this state is characterized by nothing more than a feeling of well-being and satisfaction with one's self and freedom from care and worry when such would be justified. In other cases this delusion of grandeur (*expansive delirium*) is absent and the patient is melancholic with delusions of persecution. This is especially apt to be the case if his physical condition is lowered by some intercurrent disease. Remissions of all these symptoms are not rarely met with. These states may alternate. *Epileptiform* or *apoplectic attacks* may occur, followed by paralysis in this stage. In the large majority of cases the mental decay is progressive, until finally complete dementia is reached; the patient then becomes bedridden, bladder and rectal symptoms develop, and possibly bed-sores. Death results from exhaustion or from some intercurrent disease.

Diagnosis.—This is sometimes difficult in the earliest stages, particularly when the mental phenomena alone exist. The slight change of character and the occasional outbursts of temper or unrestrained jollity may be regarded as mere moods more or less directly dependent upon the daily routine. When mental depression exists it may be mistaken for neurasthenia. When to these symptoms are added the tremor, the defects of speech, the inequality of the pupils, and paresis, the clinical picture gradually assumes definite shape, and oftentimes, long before expansive delirium or melancholia develops, a positive diagnosis is made. The tabetic type of the disease presents many points of resemblance to *tabes dorsalis*. There are ataxia, loss of knee-jerks, disturbance of micturition, fulgurant pains, visceral anesthesia, and Biernäcki's symptom (absence of tenderness over the ulnar nerve). To these are added tremor of the lips, disturbance of speech, and the peculiar mental symptoms. In the cerebrospinal fluid obtained by lumbar puncture will be found the globulin reaction, an increased number of lymphocytes, and plasma cells, and in many cases the Wassermann reaction with both the blood-serum and cerebrospinal fluid. Lange's colloidal gold reaction is especially apt to occur in paresis (p. 1123). The percentage of positive Wassermann reactions in both blood-serum and cerebrospinal fluid is greater than in either cerebrospinal syphilis or *tabes*. The average number of lymphocytes in the fluid is less.

Differential Diagnosis.—The diseases with which it is most likely to be confounded are—(1) *Disseminated sclerosis*; (2) *paralysis agitans*; (3) *cerebral syphilis*; (4) *neurasthenia*; (5) *chronic alcoholism*; (6) *chronic lead-poisoning with cerebral symptoms*; (7) *bulbar palsy*; (8) *chronic mania*; (9) *dementia from any cause, as senile or terminal dementia*.

(1) In *disseminated sclerosis* the mental symptoms are even less obtrusive in the earlier stages, the first evidence of the disease being paresis in the lower extremities. The tremor, too, is volitional, the speech is scanning, and nystagmus is present. Mental phenomena develop late if at all, and are not expansive in nature.

(2) In *paralysis agitans* there are frequently no mental changes, and in

any case they consist of nothing more than dulness. The characteristic attitude and gait; the tremor when at rest, which sometimes ceases on movement; the speech, which is hesitating at first, then hurried; the high-pitched voice; the absence of pupillary changes—all mark paralysis agitans. Remissions are uncommon.

(3) *Cerebral syphilis* may also simulate paretic dementia. In cerebral syphilis the tremor may or may not be present, but no speech-defect occurs; and attacks of severe headache are frequent and usually severe. Palsies of cranial nerves and complete immobility of the pupils are more liable to be due to syphilis. The condition often passes into dementia, but the peculiar expansive delusions of paresis rarely, if ever, occur. Mott states that in syphilitic pseudoparesis the lymphocytes in the cerebrospinal fluid disappear under antisyphilitic treatment, but in true paresis they do not. Plasma cells are not present in the fluid in syphilis, and the lymphocytes are usually much greater in number (80 to 2000 per cubic millimeter) than in true paresis (8 to 78 per cubic millimeter). (See also p. 1123.)

(4) The characteristic physical symptoms will distinguish the two.

(5 and 6) Both of these poisons may cause symptoms resembling those of paresis. The history and occurrence of hallucinations, which are very uncommon in paresis, will often serve to differentiate the two conditions. Often, however, the diagnosis can only certainly be made when the patient recovers, which he will not do if he has true paresis.

(7) The absence of mental symptoms and the occurrence of atrophy of the tongue, paralysis of the vocal cords, etc. (p. 1045), distinguishes *bulbar palsy*.

(8) Patients with *chronic mania* do not have the peculiar physical symptoms of paresis, and there will usually be a history of a previous attack of acute mania. Spells of acute excitement may, however, occur during the course of paresis.

The presence of an increase of the lymphocytes in the cerebral spinal fluid and the Wassermann test or some of its modifications will distinguish paresis from any of the above, excepting syphilis (*supra*). There is also a possibility that a patient having alcoholic pseudoparesis may have had syphilis, which renders the examination of the cerebrospinal fluid of importance.

The **prognosis** is gloomy and recovery never occurs. The tendency is toward a fatal termination in from two to three years. In rare cases the progress may be slow or remissions may delay the termination for several years longer.

Treatment.—Drugs are of no value in a curative sense. Proper treatment may cause more frequent remissions and their longer duration. Salvarsan serum has also been injected subdurally (cerebral) and into the lateral ventricles.¹ The use of salvarsan ("606"), administered either intravenously or by the Swift-Ellis method (p. 1131), may be of service in incipient cases. Bromids, morphin, chloral, or, still better, sulfonal, trional, or hyoscin, may be used in combating the insomnia and attacks of delirium. These cases cannot be properly cared for at home; indeed, their removal to an asylum is generally imperative. The tendency to bed-sores must not be forgotten, and continuous rest in bed must, therefore, be postponed as long as possible.

TABES DORSALIS

(*Locomotor Ataxia; Posterior Sclerosis*)

Definition.—A disease, primarily of the posterior nerve-roots, with consequent secondary degeneration of the posterior columns, also degeneration

¹ *Jour. Amer. Med. Assoc.*, December 18, 1915, p. 2147.

of peripheral nerves and those of special sense, particularly the optic. It is characterized by more or less inco-ordination of movement, various sensory and trophic disturbances, and impairment of the special senses.

Etiology.—Syphilis is probably the exclusive cause. Whether the tabes occurs because the individual is predisposed or because the syphilitic virus in these cases has some peculiar predilection for the central nervous system is not determined. Some interesting evidence has been collected in favor of the latter view. There may be a history of injury, severe prolonged muscular exertion, dissipation, or sexual excess. Race appears to be of some importance, but an increasing proportion of cases is found among negroes and Jews, who were formerly considered partially immune. Males are more liable to the disease than females in the proportion of 10 to 1. About 75 per cent. of all cases commence between the ages of thirty and fifty. It may occur in childhood due to hereditary syphilis.

Pathology.—Macroscopically, it may be observed: 1. That the posterior roots are more or less atrophied and grayish in color.

2. There is a thickening and adhesion of the spinal membranes, with some degree of congestion, particularly noticeable in the posterior region (not a constant change).

3. There is a slight change in the shape of the cord, and the affected regions assume a grayish tint. Change of color is well seen after the cord is hardened. Microscopically, the first changes are found in the posterior roots, usually the lumbar, followed by sclerosis in the column of Burdach and zone of Lissauer, also most marked in the lumbar region and localized at the point of entrance of the root-fibers. Higher up the columns of Goll will be found involved. The fibers coming from the posterior roots to join the column of Clark are also sclerosed, but as the cells, as a rule, are not destroyed, the direct cerebellar tract is rarely involved. In advanced cases sclerosis of Gowers' tract may also be observed. While the disease usually first affects the lumbar nerve-roots, either the sacral, upper thoracic, cervical, or bulbar nerve-roots may be first involved, in which event the cord changes above noted will be found more marked in one of these respective areas. In addition to the cord changes degeneration of peripheral spinal nerves and of cranial nerves and their nuclei, especially the ocular, may be found. Less marked changes may also be found in the anterior nerve-roots.

Nageotte's views as to the pathogenesis of the disease are now those most generally accepted. In brief, he believes that tabes is the result of a local affection of the spinal roots at the height of the "nerfs radicaux"—*i. e.*, that part of the root from its entrance into the dura mater to the spinal ganglion. It consists of an endo- and perineuritis with interstitial and parenchymatous changes, due to a mild but chronic syphilitic meningitis. The "nerf radicaux," being a channel for the lymph circulation in the central nervous system, is believed to be a spot more vulnerable to toxic and irritating material circulating in the cerebrospinal fluid. This is further intensified by the fact that the nerve-fibers lose their neurilemma sheaths as they pass through the pia, and, hence, when damaged by the meningeal exudation, have no power of regeneration. The degeneration found in the cord is, hence, secondary, the nerve-fibers being separated from their trophic centers, the posterior ganglion.

In addition to changes in the nervous system, certain cases present some morbid condition of the osseous system, consisting of erosion of the intra-articular cartilages and atrophy and absorption of the bony articulating surfaces.

Symptoms.—These may be grouped into various stages: the prodromal, preataxic, ataxic, and paralytic. The *prodromal stage* may extend over a

number of years, the symptoms are slight, and often make very little impression upon the patient. They consist of occasional pains, usually in the legs, of transient disturbances of the ocular muscles leading to ptosis, diplopia, etc., occasionally of slight diminution of vision, most noticeable at night, of more or less pronounced impairment, very rarely exaltation, of sexual power, and neurasthenic symptoms. The symptoms become characteristic only in the *preataxic stage*. The pains in the legs become more frequent and assume the typical fulgurant or lancinating type; that is, a stabbing or boring sensation, shooting along the limbs and lasting for a brief interval of time. There is often numbness or anesthesia of the extremities and the patient feels as if walking on cotton. The pupils give the Argyll Robertson phenomenon, there is permanent myosis, nyctalopia, and the paresis of the eye muscles may be still present or may have disappeared; primary atrophy of the optic nerve will also frequently be found. There is usually some disturbance of motion, chiefly manifested at night, and ataxia may be revealed by the finer tests (having the patient hop backward on one leg). The patella and Achilles' jerks are diminished or absent. There is now distinct impairment of sexual power and difficulty in urination. Martin has described a peculiar loss of tone and muscle sense of the rectal sphincters. The sensory symptoms belong to this and the following stage.

The dominant symptom of the *ataxic stage* is the inco-ordination of movement. This gives rise to the *ataxic gait*. The legs are kept far apart and are lifted higher than is necessary from the ground, they are brought down violently, and the gait is of a peculiar stamping, irregular, slightly staggering character. Walking without the aid of a cane soon becomes impossible, and the feet are carefully watched. Ataxia of the arms occurs later and is manifested by difficulty in grasping objects or in accomplishing finer co-ordinated movements. Ataxia of the lower extremities may be tested by directing the patient to touch with his toe an object held above it, or, when lying down, to place the heel of one foot upon the knee of the other; of the upper limbs by directing him to touch rapidly the tip of the nose with the forefinger, or to spread the arms apart and bring the forefingers rapidly together. Loss of station, or *Romberg's symptom*, is tested by directing him to stand with the feet close together and to close the eyes. The swaying of the body will vary from several inches in either direction to falling over. The reflexes are now completely abolished, and there may be some wasting of the muscles, and marked muscular hypotonia, causing relaxation of the joints, will frequently be found. The sphincters are involved, there is often difficulty in voiding the urine, associated with incontinence, and, as a result of careless catheterization, cystitis is often acquired. The facial expression is peculiar, the pallor, drooping lids, small pupils, and deep lines give an impression of weariness, dulness, and apathy that is quite characteristic.

The *sensory symptoms* are various: in addition to the fulgurant pains, there may be visceral crises, characterized by sudden severe pain and disturbance of function. The most common seat is the stomach, and the crises are associated with vomiting of acid material. Crises may also involve the larynx, liver, kidneys, clitoris, bladder, and eyes. The latter is associated with pain, lacerimation, and blepharospasm. Diminished sensation affects the organs, nerves, and areas of the skin. There is loss of sensation in the testicles or breasts, and severe blows in the pit of the stomach cause no distress. *Biernacki's symptom*, loss of sensation in the ulnar nerve when pressed upon at the elbow, is present. The same phenomenon can be observed in the peroneal nerve, where it winds around the head of the fibula. These may be early symptoms. Areas of analgesia or hypalgesia, usually segmented in type, can be detected

upon the trunk or upon the extremities. Astereogenosis, or the loss of the ability to recognize objects, may be present on one or both sides, or the stereognostic sense may not be impaired. The *girdle pain* is a feeling of constriction about some part of the trunk that may be very uncomfortable. *Trophic changes* are of various kinds, painless loosening of the teeth; *arthropathies*, characterized by enlargement and erosion of the joints, which are painless; fragility of the bones leading to spontaneous fracture; herpes and perforating ulcer of the foot. The *paralytic stage* inaugurates the termination of the disease. Locomotion becomes impossible, or can only be accomplished with the aid of two canes, loss of control over the bladder is complete, the patient is querulous or even demented, and muscular wasting and bed-sores may appear. In either this or the ataxic stage the optic nerve may atrophy until blindness results, and this is often associated with a remarkable improvement in the ataxia that is at present inexplicable (ocular tabes). It is important to remember that mental symptoms may be present, as tabes and paresis (p. 1124), may be associated (taboparesis). Death usually occurs as a result of infection, either through the bladder or lungs, more rarely as the result, apparently, of exhaustion.

Atypical cases are not rare. In *cervical tabes* the ataxia may appear first in the upper extremities and may be more severe in them, and the fulgurant pains may be limited to them. Laryngeal crises are more common in this form, and neuralgic pain in the course of the fifth nerve may be present. Certain classical symptoms may not appear in the entire course of the disease. In sacral tabes the knee-jerks may be present, while the Achilles jerks are lost. It is well in all cases to have Wassermann tests made with both the blood-serum and cerebrospinal fluid, and to examine the latter for an excess of lymphocytes and the globulin reaction. The cell-count may vary from normal (indicating usually that no active process is in progress) to 95 or more. Cases in which the latter occurs are usually those in which there is an active meningeal irritation. In such cases the Wassermann test is usually positive in both serum and cerebrospinal fluid and the globulin reaction is present. In other cases the Wassermann test may only be positive with the serum and the globulin not in excess. Old cases in which the active process has subsided may give a normal serology. In doubtful cases Lange's colloidal gold reaction (p. 1123) and Noguchi's luetin test may be used.¹

Course.—The earliest symptoms are usually observed from five to twenty years after the syphilitic infection. Rarely the disease runs a very rapid course. The preataxic symptoms—pain, loss of knee-jerk, Argyll Robertson pupil, with or without ptosis and diplopia—may only exist a few weeks before inco-ordination develops. The latter will then reach its acme in twenty to thirty days. This is very unusual, however. As a rule, the first or preataxic stage extends over a period varying from months to even as long as twenty-five years. Dr. Wm. Egbert Robertson has related to me the case of a man aged fifty-eight who for fifteen years has had fulgurant pains and an absence of the knee-jerk, but neither ocular nor any other symptoms. In some cases the first stage may be unnoticed. The second or ataxic stage—that of inco-ordination—is generally slowly progressive, finally reaching a point at which it remains; rarely, more or less improvement may follow. The final stage in a few cases is only reached when the patient has become paralyzed and bedridden.

Diagnosis.—This is readily made when we have a combination of the absent knee-jerk, fulgurant pains, and the Argyll Robertson pupil.

Differential Diagnosis.—*Peripheral Neuritis.*—The symmetric distribution of symptoms, tenderness in the muscles and over the nerve-trunks, more weak-

¹ *New York Med. Jour.*, August 22, 1914, p. 349.

ness and wasting, pain (not fulgurant in type), absence of the Argyll Robertson pupil, and the history of the case are sufficient. *Alcoholic*, diabetic, and, more rarely, *arsenical neuritis* give rise to a condition closely resembling true tabes, in that there is the loss of knee-jerk, often sharp pain, and inco-ordination, though the latter symptom is never as marked as in advanced tabes. The gait, however, is totally different, and consists of the high "steppage" gait described in the discussion of Peripheral Neuritis.

Ataxic Paraplegia.—Apart from the absence of pain and anesthesia, inco-ordination is followed by a spastic condition. The knee-jerk is much exaggerated, ankle-clonus develops, and the Babinski reflex is present.

Cerebellar Disease.—The inco-ordination does not resemble that of ataxia; optic neuritis is present; also headache and vomiting appear in well-marked cases. The knee-jerk is usually present.

Ataxia may be present in *combined sclerosis*, due to anemia and infections (p. 1087), as lesions of the posterior columns are present. In this disease the Argyll Robertson pupil is absent. While paresthesia is pronounced, the characteristic pains of tabes are not complained of. The Babinski reflex will also usually be found. The history of the onset and course of the disease also differs.

Cerebrospinal syphilis may simulate tabes. Examination of the cerebrospinal fluid will usually show a much higher lymphocyte count (80 to 2000) in ordinary forms of cerebrospinal syphilis than tabes (p. 1129). The Wassermann test is positive in a larger percentage of cerebrospinal fluids and the globulin reaction greater. Argyll Robertson pupils, visceral crises, and arthropathies do not occur. Pupils that do not respond to either light or convergence are common.

The crises may be mistaken for *disease of the various organs involved*. Repeated attacks of acute pain, tabetic in character, and particularly in adult males, should, however, excite suspicion, and an absence of the knee-jerk and other characteristic evidences will always be present in ataxia.

When the chief lesion is in the dorsal region the pain may be mistaken for that of *spinal caries* or even *neuralgia* or *rheumatism*. From caries it may be differentiated by the fact that in vertebral disease the pain is more or less localized, and that it is much increased by movements. Moreover, the other symptoms of ataxia are wanting—*e. g.*, ocular troubles, inco-ordination, and absence of the knee-jerk. The latter point also holds good in cases of rheumatism and intercostal neuralgia. For the diagnosis from hereditary ataxia, *vide* p. 1086.

Prognosis.—The outlook is serious, but if the diagnosis is made early and modern methods of treatment employed there is fair hope of improvement. Complete recovery is unusual, but occurs in cases of true syphilis which simulate tabes. The disease does not cause death, at least for a long time. Cases in which the cell-count is high (p. 1129) are, as a rule, more amenable to treatment.

Treatment.—Rest (first suggested by Weir Mitchell) is imperative when the patient commences treatment, and especially when pain is an early symptom, massage and electricity being employed meanwhile to keep up the tone of the muscles. In my opinion the rest treatment retards the progress of ataxia more effectively than any other measure, but it cannot be used with the expectation of producing a cure. The bowels should be moved daily, and the urinary functions especially looked to. In certain cases catheterization is necessary. The patient should then be taught, first, what surgical cleanliness means; and second, how to use the instrument. Urotropin in doses of gr. v—0.3, three or four times daily, is a valuable prophylactic against cystitis. Counterirritation along the spine and suspension are useless. The diet should

not be heavy, and if gastric crises occur special care should be taken in this direction. Vigorous antisypilitic medication should be employed in all cases where the serologic changes peculiar to syphilis (p. 1129) are found. In old cases in which these tests prove negative such treatment is not advisable, but it should consist of measures to improve the general health and nutrition. If specific medication is used it should at first consist of salvarsan, given either intravenously or intraspinally by the Swift-Ellis method.¹ These injections should be repeated until six or eight are given at intervals of a week if given intravenously, or of two weeks if given intraspinally. Mercury should be used during the intervals. After this the spinal fluid should be examined and if the treatment is efficacious the cells should be less in number and the Wassermann reaction weaker or absent. If this result has not been obtained, further treatment should be given. After six or seven injections it is well to cease their administration for a time even if the above-mentioned changes have not occurred. Symptomatic improvement may be present even then. Some authorities believe that the intravenous injection is as useful as the intraspinal, others use the former first and if no improvement results, employ the intraspinal. Instead of salvarsanized serum, mercurialized serum² may be used for intraspinal treatment. Salvarsan and neosalvarsan have been found to relieve the pains even when no other benefit resulted. It is well to remember this: the latter method is not without danger, and should be done by one skilled in the technic. Optic atrophy is not a contraindication, in fact, it may be benefited. Nephritis and advanced arteriosclerosis are. Arsenic, chlorid of gold and soda, and nitrate of silver seem to have some influence upon the course of the disease.

The fulgurant pains, or those of the various crises, are occasionally so severe as to require codein, or even morphin, though the use of the latter agent is always to be postponed until other means are exhausted. For the former, rest in bed and bandaging the limbs may be useful. Antipyrin or salol and phenacetin may also be tried. Gastric crises may be relieved by cerium oxalate and small doses of cocain or carbolic acid. Morphin is usually required. In some cases the crises are so severe that even this fails to give relief. The cutting of the posterior roots (seventh to tenth) of the dorsal nerves (rhizotomy) has been efficacious in the relief of intractable gastric crises.³ In any case the patient should live a simple, regular life, avoiding excesses of all kinds, and particularly sexual and alcoholic indulgences.

Electricity is of service in relieving paresthesia and pain. For this purpose either a rapidly interrupted faradic, static spark or high-frequency current applied to the extremities may be tried. Hydrotherapy is a serviceable measure if judiciously employed. Neither cold nor hot baths are free from deleterious effects, but tepid baths (80° to 90° F.—26.6°–32.2° C.), combined with gentle friction of the body surface, are signally useful.

Recently it has been discovered (Frenkel) that the *ataxia* can be greatly improved by systemic exercises designed to train the muscles in co-ordinated movements. The important points are to avoid fatigue and irritation, and to increase gradually the complexity of the tasks.

VI. GENERAL AND FUNCTIONAL DISEASES

INFANTILE CONVULSIONS

(Eclampsia Infantilis)

Under this term are grouped a number of conditions, with convulsive attacks as the common symptoms.

The **causes** are: 1. Organic brain lesions (pp. 1102 and 1106). 2. Neuro-pathic tendency, that is manifested later as hysteria or epilepsy. 3. Emotional disturbances, as fright. 4. Rickets, in about 30 per cent. of all cases. 5. Acute infectious disease, especially as an initial symptom of pneumonia, and more rarely of scarlet fever, small-pox, and pernicious malarial infection. 6. Inflammation of the serous membranes, as meningitis, where the relation is direct, or pleuritis or peritonitis. 7. Kidney disease, in which they are uremic. 8. Peripheral irritation; dentition has long been supposed to be a chief factor in their causation, but it is now believed that the chief cause is the presence of rickets. Intestinal parasites have also been found, particularly the *Ascaris lumbricoides*, and the convulsions have ceased after their expulsion. 9. Debility, especially that resulting from gastro-intestinal disorders.

Pathology.—The pathologic changes may be divided into two groups: (1) Those bearing an etiologic relation to the convulsive attacks, and (2) those that are merely consecutive. Among the former are meningeal bleeding, tumor, gliosis (either hypertrophic or atrophic), and hydrocephalus. Then there are general conditions that seem to predispose to this condition or, at any rate, are frequently associated with it, such as rachitis. The consecutive lesions are hemorrhages into the meninges or into the substance of the brain and the spinal cord, an increase in the amount of cerebrospinal fluid, and congestion of the pia or the substance of the brain.

The **symptoms** of the attack vary according to its intensity. In the most severe form they resemble in all respects those of an epileptic seizure. At first the eyes deviate upward or to one or the other side, and the gaze becomes fixed and staring; next there are *twitchings of the muscles* of the face, sometimes slight and limited to one side, and sometimes general, often involving the muscles of mastication and giving rise to trismus or gnashing of the teeth. Next there are *tetanic contractions* of the extremities, the fingers being strongly flexed, the hands flexed upon the arms, and the feet in the position of pes equinus or sometimes in the dorsal flexion, and both legs and arms rigidly extended. Often the muscles of the trunk are involved, and there is either opisthotonos or respiratory cramp, with excessive hardness of the abdominal muscles. This rigid condition is interrupted at brief intervals by sudden twitchings, or occasionally the convulsion becomes clonic instead of tonic, and there are repeated extensions and contractions of the extremities, shaking of the head, and quivering of the whole body. As a result of the respiratory cramp, *cyanosis* rapidly develops and may reach an extreme degree. The forced respirations give rise to a foam that collects about the lips, and is often mixed with blood from the bitten tongue. Urine is often, and feces occasionally, passed involuntarily. In nearly all cases unconsciousness is complete. Many of the slight attacks are accompanied by a cry or by an attack of screaming. The tetanic state usually lasts for a minute or two; then there are a few clonic movements, relaxation becoming rapidly complete, and the spasm is ended by a few deep respirations. The child may return to consciousness, although it is usually drowsy or stupid, or it may pass into a deep sleep from which it cannot be aroused. Often in the latter condition attacks will recur at irregular intervals, and sometimes a single attack may continue for some time, although

from time to time there are slight twitchings followed by partial relaxation (*status eclampticus*—Lewis). The attack may come on suddenly, or, as is more frequently the case, it may be preceded by a period of restlessness and irritability. A milder form of the spasm consists of sudden fixation of the eyes, slight twitching of the body, and a peculiar dusky pallor that passes away in a few moments. In other rare cases consciousness may persist, although the patient is aphasic. Laryngismus stridulus is an analogous condition (*vide Diseases of the Larynx*, p. 497).

The **diagnosis** of the condition is very easy. The recognition of the cause, however, is very important and often difficult. Every case should first be examined for rickets, and then the gums should be investigated; also the condition of the child's nutrition and the presence of symptoms of gastric or enteric irritations. If fever exists, it is important to discover its cause. The character of the convulsion is often of value in distinguishing between the idiopathic or reflex type and that due to organic brain disease. Convulsions beginning immediately after birth, or an injury, either persisting or else disappearing gradually, are probably caused by meningeal hemorrhage (p. 1101). An attack of a jacksonian type would, of course, indicate the presence of a focal lesion; and if this be a tumor, there will probably be bulging of the anterior fontanel, severe headache, and the ophthalmoscope will reveal a neuroretinitis. If, after the attack, pareses or paralyzes are present, a focal lesion is still more likely. Hydrocephalus is usually recognized with ease. Some cases exist, however, in which it is impossible to discover any adequate cause.

The **prognosis** varies according to the etiology. In cases with organic brain disease it is unfavorable as regards cure. In those forms that precede epilepsy or functional nervous diseases the spasms usually disappear after the first dentition, and the patients appear to have recovered for a time. In those, however, in whom the symptoms are due to some peripheral irritation or to rachitis, the outlook is fair, although even these now and then develop into permanent epilepsy. The convulsions themselves are either often immediately fatal, or so exhausting to the patient that he succumbs readily to the disease that produced them. In these cases the prognosis depends upon the frequency and severity of the attacks, death usually terminating those in which the status eclampticus has been established. The prognosis for ultimate cure depends also in part upon the length of time that the condition has existed; if but for a short time before an arrest has been established, recurrence is much less likely. Gowers, however, says that even after a year's duration permanent cure may sometimes be obtained.

The **treatment** naturally falls into two parts—that of the attack and that of the interval. Unquestionably, the most efficacious antispasmodic that we possess for this condition is chloroform. A few drops may be put upon a handkerchief and held carefully over the nose and mouth of the little patient. A very small quantity usually suffices, and the effect is almost instantaneous. In addition to this, chloral and the bromids may be given by the rectum, and it is often useful to add to these one of the coal-tar antipyretics, particularly antipyrin. Formerly hot mustard-baths were much in favor, but unless they do good at once they are not likely to be of any use. In a very obstinate case under my care they were absolutely valueless, and were replaced by momentary immersion in ice-cold baths and vigorous friction, which seemed to act very favorably. If any known source of irritation is present, as an overloaded stomach, it should be relieved at once, if possible, by the stomach-tube or an emetic. An enteritis may be temporarily benefited by an enema or by a moderate dose of calomel. The treatment during the interval depends upon the nature of the cause. If rachitis exists, it should be treated according to the

principles laid down in my discussion of this disease. If denitition is suspected, the gums may be lanced, but this should only be done when they present distinct signs of irritation. Gastro-intestinal disorders of any kind should be relieved as soon as possible, and intestinal parasites must be expelled. In infectious diseases the convulsions usually disappear after the initial stages, and require no further attention. In organic brain disease, providing it be not syphilitic in nature, very little can be done. Finally, in those cases in which no cause can be discovered bromids are the only resource, and should be given in sufficient doses: from gr. iij to v (0.194–0.324) per day to children of six months, and from gr. v to x (0.324–0.648) to those between six and sixteen months.

EPILEPSY

Definition.—A condition characterized by attacks of unconsciousness, with or without convulsions. We are scarcely justified in speaking of epilepsy as a disease. It seems, in reality, to be a symptom, though in many cases (the so-called idiopathic cases) we do not know the underlying cause. The type of cases in which the unconscious period is very brief (momentary), with no convulsion following, or at most but a slight rigidity, is termed *petit mal*. The more pronounced type, with prolonged unconsciousness and severe general convulsions, constitutes *grand mal*. That form first described by Hughlings Jackson in which the convulsion is localized, and in which unconsciousness may or may not occur, is called *jacksonian*, *focal*, or *cortical epilepsy* (p. 996).

Pathology.—Epilepsy is a symptom, and the inevitable question must be, "Of what?" In certain cases this can be answered (in the organic cases), since the lesion is demonstrable; but in others (functional or idiopathic) there is no demonstrable lesion. Among the causes of the former are brain tumors, meningitis, traumatism inflicted either at birth or subsequently, atrophy and sclerosis, vascular disturbances, syphilis, and toxemia, both autogenous (which may be associated with abnormal position of different parts of the gastro-intestinal tract) and exogenous. Peripheral lesions too may give rise to it. Little can be said about the idiopathic variety, we can only enumerate causes; we do not know in any case how these act, and we do not know the ultimate pathology. Many writers apply the name "epilepsy" only to the idiopathic form, while others include all apyretic affections characterized by the occurrence of fits, whether of centric or peripheral origin. Brown-Séquard believes that the distinction between the various kinds of convulsions is artificial, and that the correct classification should be based on the knowledge of the cause.

Etiology.—The causes are (1) *predisposing*, (2) *exciting* or *determining*. Among the former, which refer particularly to the idiopathic form, are—

(a) *Age.*—Most cases develop during childhood. It has been said that when the attacks first appear after thirty-five years that they are not idiopathic.

(b) *Heredity.*—Family neuroses, such as insanity, hysteria, chorea, etc., are common, but it is decidedly more the exception than the rule to find either parent epileptic.

(c) *Alcohol.*—The causal relationship between an abuse of alcohol by the parents and epilepsy seems rather pronounced. Féré says that of 594 epileptics examined by him, 258 had parents who were hard drinkers. Echeverria refers to 572, 257 of which he believed could be traced directly to the abuse of alcohol.

(d) *Syphilis* does not predispose. When it gives rise to changes in the brain and cord, which in turn cause epilepsy, it is in reality a determining cause.

(e) *Eye-strain* is no longer regarded seriously as a predisposing influence.

The **exciting or determining causes** are traumatism to the head with or without actual lesion of the skull or brain, mental shock, various morbid conditions of the membranes of the brain or of the brain proper (*e. g.*, after hemiplegia) or peripheral irritation (dentition, worms, a cicatrix, an adherent prepuce, etc.). Not a few cases are dependent upon toxic substances in the blood, as in uremia and lead-poisoning. Excessive indulgence in alcohol or overeating often precipitates the attack. Intestinal stasis must be considered. Great emotion and nervous shock (fright) seem to be exciting causes in some cases. Pituitary insufficiency and excessive thyroid secretion have been mentioned as causes. There are cases of bradycardia in which epileptiform attacks occur (Stokes-Adams disease). Cerebral arteriosclerosis may cause the epileptiform attacks that occur in old people. The possibility of a micro-organism causing the disease has been advanced by Reed.¹

Symptoms.—Petit Mal.—In this condition the majority of cases belong to the following type: The attack begins suddenly; perhaps while talking to the patient his expression suddenly becomes blank, the face pales, the pupils dilate, and he is evidently not conscious. In a moment or two he gathers his scattered senses and picks up the thread of the conversation. Very often he is not cognizant of any lapse of time or has but a vague idea that something has occurred. If carefully observed, fine clonic movements may be detected in many cases, it may be of the facial muscles or of the hands. Convulsions never occur, the dominant feature being the unconsciousness. On regaining consciousness the patient may act strangely and appear dazed; it is seldom, however, that he falls in attacks of this kind. Occasionally a peculiar dreamy state takes the place of an ordinary attack, or the individual may be the victim of imperative ideas. Falret has described a condition (*epilepsie larvée*) known as masked epilepsy, in which maniacal outbursts or explosions of passion occur.

Grand Mal or Haut Mal.—In many cases some subjective symptom precedes the actual attack. In its most specialized form it is termed an *aura*, and includes any phenomenon, motor and sensory, that ushers in an attack. While the aura differs in different cases, it is almost invariably constant in the same case, so that one will have a subjective sensation of sound, another of light, either flashes or colors, etc. There are other signs that occasionally antedate an attack, and which may or may not precede each attack (headache, drowsiness, change of disposition, palpitation, perverted appetite, sexual or other, etc.). Many attacks begin precipitately with absolutely no previous warning. In such cases the patient may or may not utter a piercing sound (*epileptic cry*), falling at the same time, no matter where or in what position he may be. Hence the danger to which epileptics are always subjected. A peculiar onset occurs in the so-called *procurative epilepsy*, in which the patient suddenly starts off and runs some distance before the paroxysm begins.

Paroxysmal Period.—In many cases, whether preceded by an aura or not, this stage is ushered in by a *spasm* that is tonic in character. The patient falls, perhaps because of the loss of consciousness, though in those cases in which he drops precipitately he is probably thrown by the violence of the spasm. The head is usually extended, the muscles of the larynx and trunk contracted, and hence the epileptic cry and the dyspnea, while the lower limbs are generally extended, the upper semiflexed, and the fingers tightly clinched. This period of rigidity lasts but a few seconds before *clonic convulsions* appear.

Intercurrent contractions vary in different cases from very mild movements to those so severe as to toss the individual about. The face, pale at first, becomes congested, and the jaw works in churning the saliva into a froth; this is blood-tinged when the tongue is bitten. The respiration is jerky, gasping,

¹ *Jour. Amer. Med. Assoc.*, January 29, 1916, p. 336.

and there may be a loss of control of the bladder and bowels. In idiopathic cases this stage lasts from one to five or six minutes. The spasms gradually diminish, and without regaining consciousness the patient passes into a deep sleep, immediately preceded in some cases, however, by coma in which the breathing is stertorous. During the sleep, which lasts about an hour, the patient is completely relaxed. On waking he usually appears confused and complains of feeling tired. His limbs may ache for several days.

Occasionally attacks follow one another in quick succession, with no period of consciousness intervening (*status epilepticus*)—a very dangerous condition.

Postepileptic phenomena are variable. The patient may become maniacal, homicidal, or may simply be mentally deficient for a few days, with perhaps some slight speech disturbance. A condition known as epileptic automatism may follow or take the place of the convulsion. In this state the patient may go about, converse, and perform apparently purposive acts of which he has no recollection afterward. In the course of time every epileptic's brain power deteriorates. Paralysis sometimes occurs, is usually transient, and may be unilateral or bilateral.

Nocturnal Epilepsy.—In this condition the attacks occur at night, and may be entirely unknown either to the patient or his friends. He complains from time to time of feeling tired on rising in the morning, his limbs and head ache, and he is generally duller than usual; he may even be confused. Such a history is suggestive, and the suspicion is strengthened if in addition he has urinated involuntarily or if blood-spots are found on his pillow.

Jacksonian epilepsy is characterized by spasm that is generally local in character. It is not true epilepsy (p. 996).

Myoclonus epilepsy is characterized by epileptic seizures of the ordinary type, while in the interval between the attacks the patient suffers from clonic spasms of various muscles. The spasms vary in intensity from fibrillary tremors (*myokymia*) to violent spasms of the large muscles (*myoclonus*, p. 1142). It may be a family disease.¹

The so-called *uncinate fits*, which consist of hallucinations of taste, chewing movements, etc., have been described on p. 998.

Diagnosis.—When a definite history is obtainable the difficulty of the diagnosis is less, particularly if an aura occurs. The attack can be frequently diagnosed from other epileptoid conditions at the time by the explosive onset, the brief tonic and somewhat longer clonic spasm, profound unconsciousness followed by a deep sleep, and when these are present by an involuntary passage of urine, frothing at the mouth, and biting of the tongue.

Differential Diagnosis.—In *uremia* the state of the urine (catheterize if necessary), and often the odor, serve to differentiate it. Hysteria may also resemble it very closely. Gowers has tabulated the chief differences as follows:

EPILEPSY	HYSTEROID
<i>Apparent cause</i> None.	Emotion.
<i>Warning</i> Any, but especially unilateral or epigastric aura.	Palpitation, malaise, choking, bilateral foot-aura.
<i>Onset</i> Always sudden.	Often gradual.
<i>Scream</i> At onset.	During course.
<i>Convulsion</i> Rigidity followed by "jerking"; rarely rigidity alone.	Rigidity or "struggling," throwing about of limbs or head, arching of back.
<i>Pupils</i> Dilated and immobile.	Mobile and active.
<i>Biting</i> Tongue.	Lips, hands, or other people or things. Very rare.
<i>Micturition</i> Frequent.	Never.

¹ Clark, *Rev. Neurol. and Psychiat.*, July, 1907, p. 532.

EPILEPSY		HYSTEROID	
<i>Defecation</i>	Occasional.	Never.	
<i>Talking</i>	Never.	Frequent.	
<i>Duration</i>	A few minutes.	More than ten minutes, often much longer.	
<i>Restraint necessary</i>	To prevent accident.	To control violence.	
<i>Termination</i>	Spontaneous.	Spontaneous or induced (water, etc.).	

Epileptiform seizures may occur in the course of multiple sclerosis, paresis, and dementia præcox. Organic and toxic causes (p. 1134) must be eliminated before deciding that the condition is idiopathic. For this purpose a careful study of all the organs should be made. If intestinal stasis is suspected, study of the abdomen by x-rays is important.

Prognosis.—Idiopathic epilepsy very rarely is cured. In most cases it will be found that an apparent recovery is merely a prolonged intermission. Cases that are evidently symptomatic are sometimes curable if the cause can be removed. Death is seldom due directly to an attack. Fatal accidents may, however, be caused by an attack.

Treatment.—When an aura occurs, advantage may indirectly be taken of it to aid in aborting the attack. The only efficient remedy is nitrite of amyl inhaled as in angina pectoris. In jacksonian epilepsy, constriction of the limb in which the aura occurs may sometimes be sufficient. Every effort should be made to lessen the liability of danger to the patient—first from falling, and second, from the violence of the spasms. One may at times be justified in using ether or chloroform by inhalation to control the severity of the convulsions. After loosening the clothing, and putting a cork or something between the teeth to prevent biting the tongue, nothing more can be done at the time. Between the attacks special care should be taken to put the system in good condition, and all sources of worry and irritation should be removed so far as possible. Particular attention should be given to the stomach and bowels and the removal of all sources of reflex irritations, as eye-strain, adenoids, intranasal obstructions, bad teeth, adherent prepuce, etc. The food should be light and easily digestible, and systematic colonic flushing is often advantageous.

As to *medicinal measures*, the bromids are of the greatest value. The sodium and potassium salts are most commonly employed, the former, as a rule, being better borne by the stomach. They may be given in milk or in one of the medicated waters. Strontium bromid has been used rather extensively of late, and has yielded excellent results. While idiosyncrasies are met with, it may generally be given in from 10- to 20-grain doses (0.972–1.944) three or four times a day, and preferably after meals. Each case must be treated according to its special indications. Symptoms of bromism (acne, sore throat, drowsiness, and gastric disturbance) should be carefully guarded against. Should they develop, the dose of bromid must be reduced, and Fowler's solution administered for a few days. H. C. Wood recommends that the latter should be given continuously with the bromids, thereby preventing or, at all events, lessening the liability to bromism. Other remedies sometimes employed are nitroglycerin (hypodermically), cannabis indica, silver nitrate, zinc, borax, solanum or horse-nettle, chloral, antipyrin, veronal, and chloretone. If pituitary insufficiency is suspected, extracts of the gland should be given. Pancreatin has given good results in some cases. Surgical measures occasionally yield good results, this being particularly true in focal epilepsy—*i. e.*, when the cortical centers are the seat of an irritating lesion, as a tumor or depressed fracture which can be removed. Even in these cases, if the convulsions have continued for two years or over, the outlook is not good. It is a curious fact

that almost any surgical operation will diminish or check the epileptic attacks for a time, and I have known as simple a procedure as venesection to afford complete relief in a severe case for several months. The results ascribed to various operations may be explained in large part by this fact.

MIGRAINE

(*Hemicrania; Sick Headache*)

Definition.—A neurosis characterized by severe attacks of headache, often paroxysmal and more or less periodic, with disturbances of vision and with or without nausea and vomiting.

Etiology.—The condition is frequently hereditary, and in the large majority of the cases that I have seen it has been transmitted by or through the mother. It usually appears early in life. Various other neuroses are common in families subject to this condition. Females are more frequently affected than males, and migraine seems to be associated with diseases peculiar to women, especially menstrual disorders. Among the exciting causes may be mentioned gastric disturbances, dental irritation, nasopharyngeal diseases (adenoids, etc.), eye-strain, grief, emotion—in short, anything that tends to lower the physical or mental tone occurring in those hereditarily predisposed. Recently attention has been called to auto-intoxication (leukomaine poisoning) as a cause of certain cases. A gouty diathesis seems to be operative in many cases.

Pathology.—This is profoundly obscure, since no lesion has ever been discovered. It is probably an auto-intoxication associated with vasomotor disturbance, and the transient paralytic symptoms that may occur are believed to be due to arterial spasm. Very rarely the disease has been observed in some subjects to replace an attack of epilepsy or even to alternate with true epileptic attacks.

Symptoms.—As a rule, the patient can prognosticate an attack. In the cases of slow onset he may feel indisposed for some hours before, being languid, drowsy, with general discomfort and perhaps nausea. In other cases various *subjective sensations* occur, lasting from a few minutes to several hours. Of these, disturbances of vision are most common, such as flashes of light, spectra, visions of animals or weird forms, or scotoma, etc. Lateral homonymous hemianopsia has also been observed. Auditory sensations are rare, as are those of the other special senses. Transient palsies and aphasia also may appear, the latter occurring when the pain is on the right side. The palsies are often hemiplegic, being present on the side opposite to that in which the pain is. Numbness and tingling may also be symptoms. Complete oculomotor palsy, lasting several days, may occur. After these phenomena have existed for some time *headache* supervenes, when, as a rule, they cease. The pain, at least in the beginning, is usually unilateral, as the name suggests, though later it may and often does involve the entire cranium, spreading from a single point of origin—over one eye, for instance. The affected region may be tender to the touch or it may be the seat of numbness or tingling. *Nausea* and *vomiting* are common symptoms, with or without vertigo. Vasomotor symptoms are frequent, usually the face is pale (angiospastic type), but it may be flushed (angioparalytic type). A brief period of unconsciousness occurs in some cases, and spasmodic movements may also be observed occasionally. This fact is of particular interest, since it serves to support the view that migraine is in some way related to epilepsy, and, as has been stated, attacks of migraine

and epilepsy may alternate. Unlike epilepsy, migraine does not tend to impair the mental faculties, no matter how long the patient has been afflicted. During an attack, however, he may have melancholia or be incapacitated mentally and physically for two or three days.

Course.—The disease generally begins in early life, and in nearly half of the cases before the fifteenth year, recurring with a certain degree of periodicity until old age, when it often passes away. It may cease in women at the menopause, and in men between the fortieth and fiftieth years.

The **prognosis** is good as far as life is concerned. This disease is incurable, though the condition of the patient may be alleviated.

Treatment.—The management of the disease may be considered under two heads: (1) treatment of the attack, and (2) the treatment between the attacks, which necessarily includes prevention. The patient should be put to bed in a slightly darkened room, and all sources of noise and confusion should be removed as far as possible. The attack may be so severe as to justify the use of morphin hypodermically. The coal-tar derivatives have met with most favor, however, as remedial measures, and preferably antipyrin and phenacetin, though their occasional depressing effect should be borne in mind. Caffein may be given with phenacetin with advantage, and aromatic spirits of ammonia is a useful adjuvant to antipyrin.

Acetanilid may often be substituted for phenacetin with apparent advantage. In twenty-four hours this may be discontinued, and potassium bromid should be given in liq. ammon. acetatis in doses of gr. x to xv (0.648–0.972). Local applications of menthol, or fly-blisters may be employed, or even superficial points may be made with the actual cautery. The rapidly interrupted faradic current applied with a dry wire brush over the painful side of the head may give temporary relief. Washing out the lower bowel has been recommended.

In the angiospastic type full doses of nitroglycerin may be of service.

Between the attacks the general health should be carefully looked after. The so-called uric-acid diathesis is common in subjects of migraine. Haig staunchly advocates the use of salicylates in such cases in addition to the dietetic measures. Anemia should be treated by iron in some form, dialyzed or Blaud's pill. The bowels should be kept normal by means of some saline (Hunyadi, etc.), or by the fluidextract of cascara sagrada. An examination of the stomach contents often shows the existence of anacidity; when this is corrected there is usually marked improvement in the migraine. The extract of cannabis indica is employed by some over a long period of time, just as the bromids are in epilepsy. It is given in doses of gr. $\frac{1}{4}$ to $\frac{1}{2}$ (0.0162–0.0324), two or three times a day, after meals. While exercise and fresh air are admirable adjuvants to any form of treatment, it must not be forgotten that fatigue invites an attack. Proper rest, care and regularity in dieting, and the avoidance of excitement are the chief points to be observed.

ACUTE CHOREA

(*Sydenham's Chorea; St. Vitus' or St. Anthony's Dance*)

Definition.—The type of chorea described by Sydenham is a more or less acute disease, due to an infectious agent or its toxin. It has a special predilection for children, and is characterized by involuntary, irregular, non-purposive muscular movements, more or less marked mental change, by a great liability to endocarditis and a tendency to recurrence, particularly during the spring and fall. It has a close relation to acute articular rheumatism.

Pathology.—No definite lesion can be ascribed to the disease. The disease is, however, probably due to the action of a bacterial poison upon the brain cortex, which causes more or less cortical hyperemia, small hemorrhages and areas of softening, and infiltration of the perivascular spaces with round cells. In some cases at least the infection is due to the *Micrococcus viridans*. In about 25 per cent. of the cases there is an association of chorea and acute articular rheumatism.

Etiology.—(1) *Age.*—By far the greatest number of cases occur before the twentieth year, but it may develop at any age. Most cases occur between the tenth and fifteenth years.

Sex.—Females are most frequently attacked, and probably in two-thirds of all cases.

Race.—Acute chorea is rarely met with except among the white races.

Heredity.—A history of other neuroses (hysteria, epilepsy, etc.) in the ancestors may be obtained, and an unstable nervous system obtained from such stock may predispose to the disease. Children who develop chorea are especially apt to be of a nervous, excitable temperament, and may be hysteric as well as choreic. It is in cases of this type particularly that *fright* acts as an exciting cause.

Infectious Diseases.—There seems to be a relationship between some cases of chorea and other infectious diseases. This, however, is only at all marked in acute articular rheumatism and scarlatina. It is not yet proved, however, as has been claimed, that chorea and rheumatism are due to the same cause. The possibility of the infection entering through the tonsils must be considered, and these structures are frequently found enlarged and diseased.

Pregnancy is a frequent cause of chorea in adult life. When so caused, it is apt to be severe. It is most prone to develop during the earlier months, and especially in primiparæ. It often assumes the maniacal type.

The influence of *reflex irritation* is probably much overrated, whether intestinal, genital, or from ocular defects, but these may aggravate the disease.

Symptoms.—The common or ordinary form is frequently met with, especially during the spring and fall. Primary attacks may occur at any time, but recurrent outbreaks are most prone to develop in the spring. There is a slight affection manifested by restlessness, disturbed rest at night, and by irregular and purposeless *muscular movements*, that are most marked in, or entirely confined to, the upper extremities, the head, or the facial muscles; or the condition may be unilateral. They usually cease during sleep. *Endocarditis* may not give rise to characteristic signs. More or less *muscular weakness* is present and the patient tires very readily. The child's *disposition* is changed, outbursts of temper being quite common on the slightest provocation. *Fever* is absent in this form unless complications exist, though when severe joint troubles or endocarditis are present, the temperature will rise. *Anemia* is often present, and with it headaches, irritable heart, and hemic murmurs. Indeed, in some instances not even a murmur can be heard, though *postmortem* records of cases with a history of chorea show that in most of them the valves are affected. The mitral valve is most commonly involved, the endocarditis usually being of the verrucose type. There are rarely any sensory symptoms, severe pain, at all events, being extremely rare. Little dependence can be placed on complaints of tingling or burning pain unless they are voluntary, for the mental make-up of choreic patients is such that they are apt to dwell upon slight ailments suggested to them through leading questions. The reflexes do not differ from those of normal children.

There is a more severe type of chorea, in which the movements are extremely violent, causing severe injuries, even fractures, and leading in some cases to

death from exhaustion. The *psychic symptoms* are often marked, and speech may be impaired to such an extent as to render articulation unintelligible. Such a condition may occur in the first, but it is probably met with more often after one or more mild attacks. The gravest form of chorea is *chorea insaniens*, in which the movements are violent and constant. Speech is much affected, insomnia is marked, and fever and maniacal delirium develop, followed in some cases by exhaustion and death. Various forms of skin eruptions may be seen.

The **course** is from six to twelve weeks, though the most trifling cases may recover in a month or less. Others persist six months or even more. In about two-fifths of all cases there is more than one attack, while Gowers has reported one case in which there were nine recurrences. In one of my own cases two attacks occurred annually—spring and autumn—for two years. A fatal issue is very rare in children, and absolute recovery is the rule. The maniacal form, which usually develops in adults, especially in pregnant women, as previously stated, is more often fatal, though recovery is also the rule in such cases.

Diagnosis.—As a rule, this is quite simple. The age of the patient, the mode of onset, and the character of the movements suffice to prevent mistakes. It may be mistaken for hereditary chorea (p. 1142), and for the various spasmodic movements due to hysteria (p. 1144), tics (p. 1156), tortipelvis (p. 1144), and myoclonus (p. 1142), and attention has been called (p. 1103) to the possibility of mistaking athetosis and other spasmodic movements associated sometimes with cerebral palsies for it. Tremor from any cause is characterized by the rhythmic, regular character of the movements.

Treatment.—This is largely hygienic—a fact that must be strongly dwelt upon in discussing with the parent the management of the patient. The avoidance of all forms of nerve strain is of the utmost importance, and the amount of school work and home study should be carefully inquired into, and all excess absolutely prohibited. The throat should be examined, and if diseased or enlarged tonsils found, they should be removed. In the milder forms rest in bed is not imperative, but active exercise must be forbidden, since it invites cardiac troubles, the tendency to heart involvement already being great in chorea. In the more severe forms rest in bed is a *sine quâ non*. In any case an abundance of rest is called for, and when insomnia is present it should be promptly handled. An important element of the treatment that is sometimes indispensable is the change of environment, associated with rest. As a rule, the patients do best in a warm climate and at the seashore. In severe cases the bromids should first be tried internally, and a warm bath administered just before bedtime. Hyoscin hydrobromate may also prove useful to lessen the severity of the movements. In other cases morphin or chloral may be required, though it must not be forgotten that the latter is a cardiac depressant; veronal or trional should, therefore, be given the preference. The bowels must be regulated and the diet should be light and wholesome, with an abundance of fruit and fresh vegetables. Cod-liver oil is usually indicated. When anemia is present, it is to be met by the use of some one of the preparations of iron. Should reflex irritation be found to exist, it should be corrected at once. Of the therapeutics of the disease not much can be said. We have no specific, but the two most useful drugs are arsenic and some form of salicylic acid. Arsenic is best given in the form of Fowler's solution, which should be given in 3- to 5-drop doses three times a day for a few days, and then increased 1 drop *per diem* until the point of tolerance is reached or the physiologic action is manifest. The remedy is now to be continued, but in reduced dosage. Between the attacks of chorea, syrup of the iodid of iron may be given with advantage.

HUNTINGDON'S CHOREA

(Chronic Progressive Chorea; Hereditary Chorea)

Definition.—An hereditary disease affecting many members of a family, developing in early adult life, and characterized by irregular muscular contractions, inco-ordination, and progressive dementia. The disease was first definitely described by Huntingdon in 1872, but other writers had already alluded to it. Sporadic cases are reported from time to time.

Etiology.—The disease is strictly hereditary, and has been traced through five generations. The offspring of parents that escape are forever immune. It occasionally alternates with idiocy, epilepsy, and various degenerative conditions. It appears to be endemic in certain localities, and still exists upon the southern shore of Long Island, where Huntingdon first observed it.

Pathology.—The changes found consist of chronic pachy- and leptomeningitis, chronic hemorrhagic encephalitis, characterized by round-cell infiltration of the cortex, degeneration of the ganglion-cells, proliferation of the neuroglia, sclerosis of the blood-vessels with dilatation of the perivascular and lymph-spaces, and numerous hemorrhagic foci (Facklam). There are also atrophy and thinning of the cortex, slight irregular changes in the spinal cord, and multiplication of the nuclei in the muscles.

Symptomatology.—The *choreiform movements* commence insidiously and only in the rarest cases become pronounced. They are usually susceptible to voluntary inhibition and disappear during sleep. They usually appear first in one extremity and then gradually invade the other parts of the body. There is considerable *inco-ordination* of movement. The *mental symptoms* consist of progressive dementia, irritability often attaining maniacal violence, delusions of persecution, and rapid diminution of intelligence. In some cases the mental changes are very slight.

The **course** is steadily progressive, but the patient may live to an advanced age.

Diagnosis.—The only condition likely to cause confusion is senile chorea with dementia. In this the mental symptoms are usually slight and the motor symptoms more violent. The family character of the disease is also lacking. By many, however, this is supposed to be a type of Huntingdon's chorea.

Treatment is entirely symptomatic.

PARAMYOCLONUS MULTIPLEX

(Myoclonus Multiplex)

Definition.—This is a disease of unknown pathology, first described by Friedreich, and, as its name implies, characterized by clonic contractions in various groups of muscles.

Its **etiology** is obscure. Heredity unquestionably plays an important part, nearly all the patients having among their ancestry cases of one or more forms of nervous disease. Emotional disturbance, as fright, is often the exciting cause. It usually develops in early adult life, and is probably more common in males. In one case that I observed it was associated with idiocy.

The **symptoms** of the disease consist of *clonic contractions* of individual muscles, which cause either no or very little movement of the parts controlled by them, occurring chiefly in the muscles of the extremities and the trunk, and only occasionally involving the muscles of the face. These contractions

are very sudden; so much so that they have been described as lightning-like. Voluntary movement diminishes them somewhat, emotional disturbance increases them considerably, while during sleep they disappear. The power of the muscles, their size and nutrition, remain unimpaired. The *electric reactions* are normal, but electric stimuli and any cutaneous irritation are apt to precipitate an attack. The *tendon reflexes* are increased. Sometimes the patient gives vent to a peculiar *grunt*, which is probably due to involvement of the larynx and diaphragm. In some of the cases sensitive points have been found over the spinal column, and not a few have presented other stigmata of hysteria.

Varieties of this disease are myokymia or persistent quivering of the muscles (fibrillary chorea of Morvan), and fibrillary or fascicular twitchings (myoclonus fibrillaris multiplex of Kny). In these cases organic disease of the peripheral motor neuron, tuberculosis, and neurasthenia must be excluded (pp. 1082, 1083, 1162). All of these symptoms may coexist in the same case.

Pathology.—Friedreich believed that it was due to irritation of the anterior horn cells. In the case studied by Hunt nothing was found but hypertrophy of the muscle-fibers.

Diagnosis.—The essential features are sudden, quick, spontaneous, multiple contractions of individual muscles, which do not cause movement of the parts supplied by the affected muscles. This is sufficient to distinguish it from chorea. The so-called *electric choreas* of Bergeron and Henoch are probably varieties of the same disease. A similar type of movement may also be due to hysteria; when so caused, other manifestations of this disease will be found (p. 1156). It may be mistaken for one of the forms of tic. These are discussed below, where the differential points are given. Myoclonus may also occur in association with other diseases, as tuberculosis, epilepsy, and the muscular dystrophies (p. 1183). A family type has also been described by Unverricht.

In the non-hysterical form the **prognosis** is serious, very few of the cases ever showing permanent improvement.

The **treatment** consists of rest, isolation, full feeding, hypodermic injections of hyoscin, arsenic, bromids and valerian internally, and the application of electricity. The latter seems most effective when applied to the spinal column, a constant galvanic stream being employed and the anode being placed over the sensitive vertebræ. It is not unlikely, however, that these cases are of a hysteric nature.

ELECTRIC CHOREA OF DUBINI

A disease closely allied by its symptoms with the preceding, but probably of very different etiology, is the *chorea electrica of Dubini*, a disease endemic in Northern Italy. It occurs at all ages, affects both sexes, and appears to be of an infectious nature. Occasionally congestion of the meninges has been found; in other cases there are inflammatory lesions in other parts of the body, and particularly in the lungs.

Symptoms.—The disease commences with severe pains in the head, the neck, and the lumbar region. After a brief interval contractions occur in the muscles, usually appearing first in the upper extremities, but rapidly becoming general. They are almost continuous, and are separated by approximately equal intervals, so that they are distinctly rhythmic in character. From time to time there are attacks of general convulsions, that may occur as often as four times per day, and are usually followed by paresis of the limbs. There is slight hyperesthesia of the skin, and usually more or less fever.

The *prognosis* is extremely unfavorable, death occurring in 90 per cent. of the cases. The duration of the disease varies from two or three days to four or five months, death usually occurring from heart failure while the patient is comatose.

No satisfactory *treatment* has been suggested.

DYSBASIA LORDOTICA PROGRESSIVA

This affection, also termed *dystonia musculorum deformans* and *tortipelvis*, has been described by Oppenheim.¹ It occurs in children and young adults of the Jewish race. The symptoms consist of tonic and clonic spasms of the muscles around the pelvis, associated sometimes with similar twitchings of other muscles. These cause a deformity around the pelvis. Excepting the deformity the symptoms disappear when the patient is recumbent. Attempts either to stand or walk develop them. There is marked lordosis in the lower dorsal and upper lumbar regions, with prominence of the buttocks and a peculiar gait which has been termed "the monkey or dromedary gait." The muscles are often hypotonic, and tremor, choreiform and athetoid movements may be associated. Late investigations seem to show that disease of the corpus striatum may be responsible for it² (pp. 999 and 1120).

TIC

(*Habit Chorea; Habit Spasm; Tic Convulsif; Motor Tic; Palmus*)

Definition.—Meige³ has defined a tic to be "a co-ordinated purposive act, provoked in the first instance by some external cause or by an idea; repetition leads to its becoming habitual, and, finally, to its involuntary production without cause and for no purpose, at the same time as its form, intensity, and frequency are exaggerated; it thus assumes the characters of a convulsive movement, inopportune and excessive; its execution is often preceded by an irresistible impulse, its suppression associated with discomfort. The effect of distraction or of volitional effort is to diminish its activity; in sleep it disappears. It occurs in predisposed individuals, who usually show other indications of mental instability."

Etiology and Symptoms.—These have been practically described in the definition given above. A few points should be emphasized. The disease is especially apt to develop in those who possess a neuropathic ancestry, and who themselves show other evidences of a neurotic diathesis, as neurasthenia, hysteria, etc. Most cases are originally excited by an effort to relieve some peripheral irritation. Thus, a man who had a sore spot on the upper lip which he was constantly moistening with his tongue found that after the sore had healed he continued to protrude the tongue involuntarily. This protrusion has occurred more or less frequently since, until it has become an unconscious act, and at the same time the tongue is protruded much further than would occur in a normal protrusion. By concentrating his attention upon himself he could prevent this, but a marked feeling of discomfort was caused by so doing. He had had several attacks of "nervous breakdown."

¹ Fraenkel, *Jour. Nerv. and Ment. Dis.*, June, 1912, p. 361.

² Hunt, *Jour. Amer. Med. Assoc.*, November, 11, 1916, p. 1430.

³ "Tics and their Treatment," Meige and Feindel, translated by Wilson, p. 260.

Tics may develop at any age. Any group of muscles may be involved. Thus, we have facial or mimic tics, tics of the nose or sniffing tics, of the lips or sucking tics, of the jaws or biting tics, of the tongue or licking tics, of the neck or nodding tics, of the trunk muscles, of the arms, of the hands, or scratching tics, of the legs or leaping tics, of respiration or snoring, sniffing, blowing, whistling, coughing, and sobbing tics, etc. Any voluntary and purposive act may be so simulated. The movements are usually quick, and, as has been said, are imitations and exaggerations of normal acts. The predisposed may acquire the condition by imitation of one who has the disease.

Diagnosis.—In the first place, this must be made from a true spasm. A spasm, as defined by Meige (*loc. cit.*), is the motor reaction consequent on stimulation of some point in a reflex spinal or bulbospinal arc. In other words, it is due to some irritative lesion. Patrick¹ has well summarized the points of difference, part of which are here given: Tic is more common than spasm, and invariably develops in a nervous or neuropathic individual. Disposition or temperament appears to have nothing to do with spasm.

Spasm is absolutely devoid of voluntary or involuntary control, while tic, to some extent, is always under the control of the will, and always subject to involuntary control by strong emotional or intellectual pre-occupation. Spasm is an anatomic, tic a physiologic, disorder. Voluntary simulation of a true spasm is practically impossible. The patient himself can always repeat or imitate his tic movement, and another person can nearly always do so. A spasm in its incipency may be confined to part of a muscle or of the muscles taking part in a movement (fascicular contractions). A tic always involves all of the muscles taking part in any one physiologic movement. From chorea tic is readily distinguished by the co-ordinate and purposive character of the movements; from tic douloureux (p. 1017), by the absence of pain. In the so-called general tic, or Tourette's disease, there are mental symptoms (*infra*) which do not occur in the form just described.

Prognosis and Treatment.—The prognosis is doubtful as regards cure. Of course, it does not cause death. The treatment is educational—that is, training the patient to perform movements the opposite to those involved in the tic; this he can do before a mirror several times daily. In addition, measures to improve the neuropathic state—viz., fresh air, easily digested, plain food, etc.

GENERAL TIC

(*Maladie des Tics convulsif; Maladie de Gilles de la Tourette*)

Definition.—A disease apparently psychic in nature and characterized by co-ordinated spasmodic movements, explosive sounds or words, and imperative ideas, without intellectual disturbance.

The **pathology** of the disease is unknown. It occurs in those suffering from neuropathic heredity, and usually indirectly. It most frequently commences in childhood—that is, before puberty—and affects either sex.

Symptoms.—The disease generally commences in the *orbicularis palpebrarum*, the first movement being an uncontrollable winking. This, as a rule, is rapidly associated with movements of the muscles of the face, causing the patient to exhibit various *grimaces*; finally, other muscles of the body may be involved, and the patient is compelled to repeat many times some apparently purposeful and co-ordinated movement, as the brushing away of insects or the stroking of the beard. From time to time he emits sounds that may be either inarticulate cries or imitation of some animal, as the crowing of the cock or the barking of the dog, or the repetition of some obscene word (*coprolalia*). These

¹ *Jour. Nerv. and Ment. Dis.*, January, 1909, p. 1.

movements are partially under control of the will, and are diminished by occupation, but increased by emotion. At other times the patient is compelled to imitate sounds that he has just heard, no matter how unusual or unexpected (*echolalia*). A more curious symptom is the imitation of movements that he has observed (*echokinesis*), which may lead to most absurd or painful results. Still another psychic symptom is the occasional development of imperative ideas. These usually take the form of a desire to recall some unimportant word or syllable (*onomatomania*) or the performance of difficult problems in mental arithmetic (*arithmomania*). One of my patients, a boy of fourteen years, before undertaking a definite act, would repeat the words "ten, ten, ten," three times, followed by a rapid count of figures from one to ten. If riding in a public conveyance, he would do the same, endeavoring to finish before reaching a definite place, as a street corner, or before hearing the sound of the voice or whistle of the conductor if in a trolley car. A failure to accomplish the task was cause for intense mental worry. These patients are usually affected at the same time with a certain degree of melancholia or anxiety that interferes to some extent with their normal life. The disease is, as a rule, very obstinate, and ordinarily continues throughout life.

The **differential diagnosis** is not difficult, the presence of motor tic, associated with the peculiar mental symptoms, being characteristic.

The **prognosis** is unfavorable for cure; death, however, almost never occurs as the result of the disease.

The **treatment** is symptomatic, and consists in putting the patient in the most favorable physical condition possible; also hydrotherapy, change of climate, tonics, and the correction of any atonic condition, are all useful measures. Potassium bromid to a certain extent controls the paroxysms when they become very severe.

SALTATORIC SPASM

(*Jumpers; Latah*)

Definition.—This is a term applied to a peculiar clonic contraction occurring in the lower legs of a patient on attempting to stand upright. The disease was first described by Bamberger. It appears to occur more frequently in men than in women, and usually in individuals who have suffered from other functional diseases. Occasionally it appears in those who exhibit hysteric phenomena. The condition may develop after severe exertion, and sometimes appears during convalescence from an acute disease. In one of my own cases the condition suddenly arose in the course of habit chorea. Saltatoric spasm is not a clinical variety of true chorea.

Symptoms.—This condition is probably related to the tics (p. 1144). When the patient attempts to stand, violent clonic convulsions take place in the muscles of the legs, particularly of the calves. These may cause the patient simply to rise on his toes, or they may be so severe as to cause him to spring from the ground, in which case he usually falls. As soon as he lies down the spasms disappear, but they may be produced in patients lying in bed by pressing against the feet.

The **prognosis** is generally favorable. The attacks usually last for a period of from two days (Gowers) to a few weeks, but a few cases have been recorded that persisted throughout life. Gowers recommends diaphoretic treatment. Antispasmodics may also be employed, and in those cases with hysteric stigmata suggestion is useful.

PARALYSIS AGITANS

(Shaking Palsy; Parkinson's Disease)

Definition.—A chronic disease characterized by a tremor; by rigidity of the muscles; by the peculiar character of the gait, and by a progressive, but very seldom complete, loss of power.

Pathology.—Lesions that are probably only senile in type have been frequently described. These are peri- and endarteritis, irregular degenerations in the posterior columns, and numerous amyloid bodies. Camp has called attention to the constancy of changes in the muscles, and disturbance of the function of the parathyroids has been thought by some to be the cause of the trouble. Recent studies point to degeneration of cells in the corpus striatum, especially the lenticular nucleus. It is therefore probably a disease of the extrapyramidal system (p. 990).

Etiology.—Paralysis agitans is a disease of adult life, developing in the large majority of cases between the fortieth and forty-fifth years; it is met with more often in men than in women. No definite etiologic factor is known, though, as with most, if not all, nervous diseases it is predisposed to by mental strain, worry, or trouble of any kind. Some cases seem to be excited by traumatism.

Symptoms.—Usually the first evidence of the disease is *tremor*, slight at first, and in the extremities, the hand usually being the first to betray it. The movement is very characteristic, the thumb and forefinger being approximated as in the act of making a pill. At the same time the hand is semi-rotated and the forearm trembles more or less as a whole. The upper arm is either but slightly or not at all affected. The legs are also but slightly implicated. The tremor is most noticeable when the patient is sitting with one leg crossed over the other, the foot then being sure to be in more or less constant motion. When the head is involved (rather the exception than the rule) the motion is a nodding one. The tremors cease when the patient sleeps, but are continuous during waking hours, though it is not rare to meet with cases in which, during purposeful acts necessitating the use of the affected parts, the tremors diminish or even cease temporarily, to return as soon as the voluntary motion is completed. The latter movements, it will be noticed, are awkward, and as the disease advances they become more and more stiff. This *rigidity*, with its consequent impairment of activity, is another cardinal feature of the disease. The patient's movements are slow and apparently measured. There is some impairment of power also, but it is slight, and may be rather from rigidity than from a direct nerve or muscle involvement. Turning in bed unaided is difficult or impossible.

Two of the most striking symptoms of the disorder are the *gait* and *attitude* of the patient. He walks with head and body bent forward, eyes directed toward the ground a short distance ahead, and takes short, mincing, and somewhat hurried steps (*festination*), giving one the impression that he is about to fall, which he would do but for each successive step, which, as it were, gives him a fresh center of gravity. His station is equally striking. The head and back are bent forward, the feet are kept some little distance apart, and one in front of the other, while the arms are slightly flexed and pendulous. From time to time the patient will make a slight forward movement (*propulsion*), or else, if walking, bend or fall backward (*retropulsion*). The facial muscles are set, the eyebrows arched, and the whole expression is "mask-like." The general slow character of all movements, except walking, which is necessarily quicker, is imparted to the speech, though after a sentence is begun the balance may be rendered normally or even hurriedly. The voice may be high pitched.

The pulse is usually rapid; the skin flushes easily, and the patients are sensitive to cold. There are no trophic or sensory symptoms, and the reflexes are normal. Apart from the diffidence, amounting in some cases to a positive dislike for meeting people, and the melancholia occasionally induced by brooding over the affliction, there are no mental changes.

Cases occur in which the tremor is very slight or absent, the diagnosis then being based on the rigidity, attitude, and facial expression.

Course.—The disease is almost always of slow onset and of insidious progress. Often one side is involved before the other, or the two sides are unequally affected. Very rarely the earlier symptoms may develop somewhat rapidly, but in every case their further progress is slow. Disappearance of tremor, usually transient, has been observed in the side affected by a subsequent hemiplegia. The course may be interrupted from time to time; even seeming improvement may take place, but it is not maintained. The disease lasts for years, and the patient usually dies of some intercurrent disease.

The **diagnosis** is not at all difficult when the tremor, attitude, gait, and rigidity have developed. During the earlier stages it may be confounded with *multiple sclerosis*, though this condition develops earlier in life, and the volitional character of the tremor, thenystagmus, and the scanning speech should serve to differentiate it. The muscular rigidity, peculiar gait, and temporary cessation of the tremor after some muscular effort distinguishes it from senile tremor. That the rigidity is not due to disease of the central motor neuron is shown by the absence of the Babinski reflex, and, in most cases, absence of increased tendon reflexes.

Treatment.—The medical management of the disease is unsatisfactory. Graduated exercise, tepid baths, and massage should be employed to keep up the tone of the muscles. The patient should avoid excitement and over-fatigue, both mental and physical. The long-continued use of arsenic may be of service, and hyoscin hydrobromate (gr. $\frac{1}{200}$ — $\frac{1}{100}$ t. i. d.) often relieves the symptoms. Parathyroid gland (gr. $\frac{1}{20}$ of the powdered gland) three or four times daily has given good results.

OTHER FORMS OF TREMOR

1. **Hereditary tremor** has been described by C. L. Dana, who has also reported interesting cases. It may commence in infancy and continue until old age, unaccompanied by detectable lesions.

2. **Simple tremor**, lasting a longer or shorter period (oftener it is comparatively brief), is a rare condition and without serious possibilities. Its etiology is unknown, though it is sometimes aggravated by nervous shocks and other debilitating conditions.

3. **Senile Tremor.**—This is common in old persons, and rarely appears before three-score-and-ten years. It is excited by muscular motions, is always fine, and affects chiefly the hands and arms; more rarely the neck is also involved, and the head may then be seen to tremble.

4. **Toxic Tremor.**—This results from the action of alcohol, lead, mercury, tobacco, and other poisonous substances. It is usually fine and irregular (*vide* The Intoxications).

5. **Hysteric tremor** (*vide* Hysteria).

6. Tremor may also be a symptom of neurasthenia, exophthalmic goiter, and multiple sclerosis.

TETANY

Definition.—A disease of unknown cause, characterized by paroxysms of tonic cramp that usually affect the flexor muscles of the extremities, by sensory disturbances, and by a peculiar alteration of the electric reaction of the muscles.

Etiology.—Tetany may occur in epidemics, and has, therefore, been supposed to be infectious. There is some doubt, however, whether these epidemics are cases of true tetany or are hysteric in nature. There is also some evidence that it is due to an intoxication occurring in the course of some other morbid condition. Tetany is frequently associated with infectious diseases; it also occurs in connection with gastro-intestinal disorders, especially dilatation of the stomach, diarrhea, and intestinal parasites, during pregnancy and lactation, and it is associated with the myxedema that develops after the removal of the thyroid gland, in which cases it is due to the parathyroids also being removed. Exposure to cold has often preceded the disease. Occupation seems to exert a remarkable influence upon the predisposition to it, the great majority of those affected being shoemakers or tailors. In childhood males are far more frequently attacked than females, and the victims are frequently rachitic, but in adult life this proportion is reversed. Heredity may have some influence, since tetany often occurs in several members of the same family. It is much more common in the spring months, and, curiously enough, it appears to be endemic in certain localities, particularly Leipsic and Vienna. It is rare in the United States.

Pathology.—Distinct morbid lesions of the nervous system have not been found in all cases. Slight vascular changes in the brain and cord and vacuolization of the ganglion cells have been described, but these are not peculiar to this disease. It has been supposed that changes ought to be found in the motor nerves, but the most careful observers have failed to detect them. It is evidently occasioned by a toxemia which, in some cases, is due to absence or disease of the parathyroid glands. Excessive excretion of calcium salts is found in the urine.

The **symptoms** fall naturally into two groups: (1) Those of the paroxysm, and (2) those of the interval. (1) The **first symptoms** of an attack usually consist of peculiar sensory disturbances in the limbs, either tingling, formication, pain, or numbness, and these may precede the attack for some hours or even days. Stiffness of the muscles usually begins in the fingers. There may be slight clonic movements at first, but this is not frequent. The limbs are symmetrically involved. The *spasm* commences first in the hand, the fingers being straightened and flexed upon the hand, and bunched so that the hand has been likened to that of the scrivener or obstetrician. The spasm then extends to the muscles of the forearm and arm, and usually also to the feet and lower limbs. If the cramp is slight, the pain may be insignificant, but ordinarily it is severe, and is increased by attempts to overcome the contractures. The muscles are hard, painful upon pressure, and occasionally fibrillary twitchings may be observed. There is sometimes a slight edema, and often sweating of the limbs. The paroxysms may last for several minutes or for several hours or even days, and may even persist during sleep. If, however, the period is very long, remissions are usually observed. Sometimes a series of paroxysms may occur with considerable regularity. Attacks are more likely to occur at night, and they may also be brought on by prolonged and severe muscular effort, or by emotional shocks. Besides the paresthesiæ in the affected extremities, the patient may suffer from severe headache or pain in the back and neck.

(2) The **symptoms of the interval** are—*Trousseau's sign*—i. e., the possibility of causing an attack by prolonged pressure upon the main nerve-trunks or vessels of the limbs. Frankl-Hochwart has shown that pressure upon the nerves is essential; pressure upon the vessels acting secondarily if at all. *Chvostek's sign* is a peculiar excitability of the muscles of the face, so that spasms are produced if the trunks of the facial nerve are lightly percussed by a hammer. This occurs in other conditions, particularly the cachexiæ, but in most cases of tetany the spasm occurs if the skin of the face is lightly stroked; and this reaction appears to be pathognomonic. *Erb's sign* consists of a greatly increased electric excitability of the muscles, and, occasionally, of an alteration of the electric reaction, so that ACIC may be greater than KCIC. Moreover, AOTe is often obtained, and, in at least 2 cases, KOTe has also been noted. The last two reactions occur in no other condition. *Hoffman's sign* consists of an increased reaction of the sensory nerves to electric stimuli. The facies of the patient is peculiar and characteristic. The face is slightly swollen, dusky, and expressionless, but if carefully examined usually no edema can be detected. Often this swelling is also found in the hands and feet, and may be associated with distinct enlargement of the veins. Even during the interval the feet when at rest have a tendency, particularly in children, to assume a slightly inverted and extended position.

The *sensory disturbances* consist of cramp-like pains during the attack, some diminution of sensation in the affected parts, and increased sensibility of the sensory nerves. The contractures are not invariably limited to the extremities. Sometimes the muscles of the neck, back, and larynx are involved; sometimes also the diaphragm, and occasionally the compressor urethræ. Involvement of the larynx gives rise to stridulous respiration; involvement of the diaphragm to severe dyspnea; when the urethra is compressed there is retention of the urine. *Fever* occurs in about one-half the cases; it is slight and generally limited to the paroxysm. The urine usually contains a large amount of phosphates, and less frequently indican is present in excess. Partial tetany—that is, with the absence of one or more of the cardinal signs—occurs not infrequently, especially in gastro-intestinal conditions. Pain, cramp, and Trousseau's sign are usually present.

The **differential diagnosis** is very easy, as a rule, if the patient is seen during a paroxysm. The severer forms may, however, be confounded with *tetanus* or *meningitis*. Tetany can be distinguished from the former by the fact that the spasm begins at the periphery and rarely affects the muscles of the jaw. From the latter it may be diagnosed by the absence of coma and the slighter degree of fever. The diagnosis from certain forms of *ergotism* is more difficult, and can often be made only by careful attention to the etiology. The *hysteric forms* can be differentiated by finding various hysteric stigmata. An epidemic occurring among young women should give rise to a suspicion of the true nature of the malady.

Prognosis.—The duration varies from a few days to many months, the most obstinate forms being those due to thyroidectomy, in which the parathyroids have also been removed, and chronic diarrhea. The disease cannot be said to have disappeared until the characteristic symptoms of the interval (Trousseau's, Erb's and Chvostek's signs) can no longer be elicited. The prognosis is usually favorable, nearly all cases tending to spontaneous cure. Death, however, may occur from chronic diarrhea, from respiratory failure when the diaphragm is involved, and from cachexia strumipriva.

The **treatment** is purely symptomatic. The patient should be placed in the most favorable hygienic conditions and given plenty of nourishing food, especially that containing calcium salts. Full doses of these salts, as calcium

chlorid or lactophosphate, should also be given. During the spasm bromids or chloroform inhalations seem to give the best results. The most important therapeutic measure is the correction of the underlying cause. Thus, in children rachitis is almost invariably associated with tetany, and the most efficient remedies are iron and cod-liver oil. Intestinal disorders should be treated according to the principles laid down in the discussion of these diseases. The form due to removal of the thyroid gland usually disappears under a course of parathyroid medication, while that occurring during pregnancy usually persists until delivery.

PERIODIC PARALYSIS

(*Family Periodic Paralysis*)

Definition.—A disease characterized by paroxysmal attacks of complete paralysis, and alteration in the electric reactions, occurring in many members of a family.

Pathology.—In excised fragments of muscle Goldflam and Oppenheim found hypertrophy of the fibers and slight vacuolation, without multiplication of the nuclei or proliferation of the connective tissue. In most cases no changes have been found, and the condition has been supposed to be an auto-intoxication, associated with a lowered condition of metabolism. In a case observed by Mailhouse there was a diminished excretion of calcium and magnesium salts in the urine, and he mentions the possibility of the paralysis being due to their inhibitory influence upon nerve and muscle when retained within the body.

Etiology.—The disease is purely hereditary. Both sexes are affected. The attacks appear to be more frequent in summer, and often seem to occur either after overfilling the stomach or excessive muscular exertion.

Symptoms.—The attacks are preceded by *prodromes* in the form of vague discomfort or paresthesia. The patient then usually falls asleep and awakens completely paralyzed. Speech, deglutition, and the sphincters are unaffected. During the attack there is often transient *albuminuria*, with blood-cells in the urine. The *reflexes* are abolished, and the muscles either do not react well or not at all to the electric current. The *paralysis* lasts from twelve hours to three days, and then there is an outbreak of perspiration, with gradual recovery, the muscles of the head first regaining power. During the interval the muscles react to electricity and the reflexes return. Dilatation of the heart has existed during an attack, to disappear during the interval. A few cases have been associated with migraine.

Prognosis.—The disease does not usually kill; but there appears to be no tendency to recover, and a few cases have died during the attack.

Treatment.—This involves only caring for the children during the attack. Large doses of potassium citrate have been beneficial.

HYSTERIA

Definition.—A state in which ideas control the body and produce morbid changes in its functions (Moebius).

Pathology.—In it there is a constitutional tendency, often congenital, to excessive reaction to emotional stimuli, which may be trivial. This leads to hypersuggestibility, the suggestion being either formed within the mind of the patient or received from without. By such suggestions the symptoms are produced and by them also they may be made to disappear. The symptoms,

it may be said, are due to a dissociation of the personality in which ideas existing in the subconscious, but not recognized, become predominant.

Etiology.—There are a large number of predisposing and exciting factors, all of which, however, may be grouped under a few dominant heads. Thus among the former must be mentioned, pre-eminently, *heredity*. The investigations of many neurologists and alienists of divers lands have gone far to demonstrate that at the foundation of the vast majority, if not of all, of the hysterics is to be discovered an inherited neurotic tendency or temperament. The family histories of these patients generally reveal a large number of consanguineous, neurotic, or hysteric individuals. It is apparently in close relationship with the various psychoses and major neuroses (epilepsy, chorea, tetany), and with the so-called rheumatic diathesis.

In the process of transmission one generation may entirely escape the pernicious influence, and successive generations may manifest strikingly different evidences of the disease, in one the neurotic and in another the psychic element predominating. A curious phenomenon that is worthy of mention is the apparent *contagiousness* of hysteria; moreover, the baleful influence one neurotic individual exerts over the unfortunates of this temperament explains the so-called "hysteric epidemics" that have swept over communities, and even over vast tracts of land or entire countries, at different periods of the world's history. Similar, though limited, outbreaks may still be seen in the nervous wards of hospitals or in religious and political conventions, and these depend largely upon the general prevalence of the neurotic disposition untempered by a virile will-power.

The hysteric temperament may be, and often is, fostered by improper and pernicious modes of life, especially by luxurious and sensuous living and by the habit of gratifying every desire of the will during early life. It is manifested at this early stage of the individual's existence by hypersensitiveness, brilliancy, undue enthusiasm, and a more or less erratic turn of mind.

Contrary to the prevailing opinion, hysteria is not limited to the female sex, although they are the chief sufferers from the more dramatic forms. Instances of a most rebellious nature not infrequently occur in the opposite sex.

Age.—The condition is generally encountered between the ages of fifteen and thirty years, although it is observed in young children. After the latter age the frequency of the disease rapidly diminishes.

Anything which tends to lower the nutrition and nervous stability, as improper hygienic surroundings or the existence of neurasthenia (p. 1161), and the influence of certain chronic toxemias, as alcohol, mercury, morphin, and lead, may predispose to it.

The *exciting causes* of hysteria may be grouped as follows:

(1) Most commonly it follows some profound emotion or mental or moral shock. Thus, in neurotic males it may be excited by excessive and protracted business worry or excitement, or by active competition in certain lines of occupation, or by some heavy and unexpected monetary reversal. In females it is not uncommon as a sequel to the establishment of puberty and the menstrual function, or to the physiologic arrest of menstruation at the period of the climacteric. Especially is it prone to develop in young and illegitimately pregnant women, or during the first pregnancy in newly married women of a neurotic temperment. Great religious excitement during the progress of a revival wave and profound political upheavals have been most potent in establishing the disease in numerous instances; and other profound mental impressions, of fear, grief, or great and unexpected joy, have assumed the exciting rôle. In this connection the theories of Breur and Freud, now receiving considerable attention, but only accepted by a comparatively few, should

be mentioned,¹ but in the space at hand it is impossible to give them in detail. They teach that hysteria is always due to a physical or psychic trauma, which may have occurred some time before the symptoms develop. According to Freud, the trauma practically always is sexual in nature. Thus there develop in the period before puberty definite sexual activities, which are mostly of a perverse nature. These activities do not, as a rule, lead to a definite neurosis up to the time of puberty, which, in the psychic sphere, appears earlier than in the physical; but sexual fantasy maintains a perverse direction by reason of the infantile sexual activities. On constitutional (affect) grounds the increased fantasy of the hysteric leads to the formation of complexes which are not taken up by the personality, and, by reason of shame or disgust, remain buried in the subconscious mind. There therefore results a conflict between the characteristic normal libido and the sexual repressions of these buried infantile perversions. These conflicts give rise to the hysteric symptoms.¹

(2) Extreme physical prostration, the result of some very acute or much protracted chronic disease, may exert an etiologic effect. Thus, some of the most marked and intractable forms of the disease have resulted from the specific fevers (typhoid, typhus, and the other exanthemata), while it is not rare in a varying degree in the final stages of tuberculosis, chronic nephritis, and other grave constitutional affections of long standing.

(3) The so-called "traumatic hysteria" has come to occupy a prominent place in the etiologic category of the disease. Especially do we find the incurable varieties of hysteria resulting from a slight or, it may be, a more severe traumatism. It must be remembered that a considerable period of time may intervene between the date of the injury and the appearance of the initial hysteric symptoms, so that in all cases it becomes of the utmost importance to make a careful study of the patient's history for signs of traumatism, however remote. It has also been noted that oft-repeated minor traumatism may finally result in some hysteric manifestations.

(4) Finally, in a limited number of cases coitus interruptus, sexual excesses, and masturbation are the influential factors in the production of hysteria. These sexual cases, though few in number, do exist, and are especially to be found among the class of so-called sexual perverts.

Clinical History.—Clinically, hysteria presents three well-marked stages, known respectively as the *prodromal*, the *convulsive*, and the *latent*. The latter is also designated as the *interconvulsive stage* or the *period of the stigmata*, and during this period the number of the symptoms and their complexity almost baffle attempts at classification; they can, however, best be portrayed by presenting them under the heads of the various systems (*vide infra*).

(1) **The Prodromal Stage.**—The prodromes are invariably present, and at times they are more marked than at others. They are evident alike to both patient and physician, and are largely psychic in nature. Prominently among these is an abnormal desire for notoriety and sympathy. There may be noted a marked mental depression associated with introspection, and, it may be, with a form of mild mania or of melancholia. A condition of aprosexia develops, and the patient becomes irritable, restless, and discontented. There may also be disturbances of the gastro-intestinal tract—viz., anorexia, nausea, vomiting, constipation, and perversions of taste. These phenomena persist for several days and are followed by emotional disturbances—spasms of hysteric laughing and crying—that immediately precede the *aura*, which is as marked a feature in hysteria as in epilepsy. It may assume one of a number of forms, but more

¹ *Psychoanalysis*, Brill, W. B. Saunders Co.

² Jelliffe, *Osler's Modern Medicine*, vol. vii., p. 816.

commonly it has an ovarian, a cervical, a cerebral, or a surface or cutaneous origin (unilateral). Very frequently the convulsion is preceded by a condition of extreme sensitiveness and pain in one or both ovarian regions, so that the lightest touch at a point on the abdominal surface 1 inch above Poupart's ligament, and midway between the pubis and the anterior superior iliac spine, will elicit exquisite tenderness. This is so constant and characteristic that many patients can invariably predict the onset of the convulsion. Not infrequently the aura begins in the neck, the patient experiencing a sensation as of a ball lodging in the throat (*globus hystericus*): this is due to a spasmodic contraction of the muscles of the pharynx and esophagus, and is accompanied by tachycardia and a sense of suffocation. If the aura originate above the scalp, it is characterized by the sudden appearance, generally in the top of the head, of a severe neuralgic pain, as if produced by the entrance of a nail (*clavus hystericus*); this is frequently associated with vertigo and tinnitus aurium. The aura, finally, may appear in the form of spots of cutaneous tenderness, mainly localized upon the trunk, to which areas has been given the name of *hysterogenous zones*.

(2) **The Hysteric Convulsion.**—Closely following upon the footsteps of these prodromes, and immediately following the aura, the hysteric convulsion may appear. Most commonly this is epileptoid in nature; rarely it assumes a less common type. Hence it becomes necessary to describe several of the forms of the convulsions—viz.: (a) the *epileptoid* (hystero-epilepsy); (b) the *gymnastic* (clownism); (c) the *emotional cataleptic*, or *dramatic*; and (d) the *delirious*. All of these forms may be present in the same attack, the one passing quickly into the other, or, as in the abortive cases, one or the other form will predominate. Briefly described, the characteristic features are as follows:

(a) *Epileptoid (Hystero-epilepsy).*—Immediately upon the appearance of the aura the patient commonly emits a shriek and falls upon the floor or in some convenient place, taking special care to do herself no injury: this is in strong contradistinction to the true epileptic spasm. The head and limbs are thrown about by more or less violent clonic muscular spasms, and at times a condition of opisthotonos or other trunkal contortion (emprosthotonos, pleurosthotonos) may be noticed; these muscular movements, however, are more or less volitional, and are not the aimless movements of the true epileptic. In some cases there is merely a tonic spasm or muscular rigidity. The patient may or may not foam at the mouth. There is a constant twitching of the eyelids and the eyes are rolled about, but apparently retain a more or less observant expression. Consciousness, as a rule, is not fully lost. The facial muscles are distorted, rapid changes of expression being noted (*hysteric trismus*), and respiration is somewhat impeded. As the convulsion passes off the movements gradually subside, and the patient generally sinks into a state of quiescence or, it may be, into a light sleep. This may be followed by complete temporary recovery, or the epileptoid may pass into one of the other forms of the convulsive seizure. The duration of the spasm as described is usually longer than that of a true epileptic seizure. This form, more or less severe, is the one usually seen in this country.

(b) *The Gymnastic Form (Clownish).*—This stage is characterized by violent and grotesque muscular movements. Here are to be grouped all of the more curious manifestations of the disease recorded in the history of medicine. The most difficult feats of the contortionist are performed with apparent ease; the patient may suddenly begin to dance or jump at a most astonishing rate, persisting in the movements until she drops from pure physical exhaustion. The so-called religious ceremonies of the Shakers of Lebanon, Pennsylvania, and of the Jumpers of the Middle Ages are manifestations of this form of

hysteria. In children the attack may appear as the so-called *beast mimicry*, in which the movements or sounds of the lower animals may be simulated; such is also the explanation of the condition known as *spurious hydrophobia*. Consciousness is never lost during this period.

(c) *The Emotional Cataleptic, or Dramatic Form*.—In this form the patient seems to suffer from delusions or hallucinations that are apparently the outcome of the preceding condition. The emotion that is most developed in the patient's moral constitution now dominates his spasmodic actions. As Lloyd aptly expresses it: "The third period of the hysteric convulsion is one of dramatic representation of emotional images, and these are of countless varieties, according to time and person." All of the manifestations of the cataleptic state are present. Sensation is largely abolished, consciousness is retained, and the patient is usually able to recall events that have transpired during the period. Especially common now is the assumption of dramatic and passionate attitudes, which, as described by Richer, include "the attitude of the cross, of defence, of menace, of appeal, of lubricity; of ecstasy, of dread of animals (as rats), of scorn," and the like. The body of the patient retains, at times for indefinite periods, whatever position is first assumed (*hysteric catalepsy*). In some cases the patient falls into a condition of apparent sleep or narcolepsy (*hysteric sleep, hysteric somnolence, hysteric trance*) of varying degrees of intensity; this may persist for any period of time, from an hour or two up to weeks, months, or even years. In these extreme cases, while the patient at first appears to be in a normal sleep, sooner or later the body assumes a corpse-like appearance, with pale, waxy skin, almost imperceptible respiration and cardiac action, and a subnormal temperature.

(d) *The Stage of Delirium*.—The final stage of the hysteric convulsion is but a continuation of the preceding period, with, however, a cessation of the muscular movement to a great extent. The tendency now is to delirium of a mild type, tinged with more or less melancholia. Consciousness is maintained throughout this stage, and there now appear some curious motor phenomena that may persist for days or weeks. These may consist in the abolishment of muscular power in various portions of the body. Very often associated with these motor phenomena is noted a condition of mutism that lasts for indefinite periods of time.

Hysteric paralyses occur, and may simulate any form of the organic paralyses (monoplegia, hemiplegia, paraplegia). In many cases the patient is left with a more or less permanent spasm of a single set of muscles or of associated sets. These so-called *hysteric contractures* may affect any portion of the body. One arm may be bent at the elbow or one leg at the knee; in the former case the fingers are rigidly contracted and embrace the thumb, which is crossed upon the palm, while in the latter the toes are strongly flexed upon the plantar surface and the foot is inverted. The ankle- and knee-jerk persist. In other cases a curious spastic gait is produced that closely simulates that of spinal sclerosis. The muscles of the hips, shoulder, back, and neck (*hysteric torticollis*) may share in the process. In women the muscles of the diaphragm and abdominal walls may be involved (*hysteric pseudocyesis*). *Hysteric rotary spasm, hysteric athetosis, and hysteric tremor* are all dependent upon a spasmodic action of the muscles affected. The convulsive seizure generally is of *short duration*, lasting but fifteen to thirty minutes. Occasionally, however, there is developed a prolonged convulsive status, during which time the patient continually falls from one convulsion into another, until one hundred or more may be recorded and the excess of nervous power is exhausted.

(3) *The Latent or Interconvulsive Stage, or Period of the Stigmata*.—After the convulsive attack the patient enters upon a more or less prolonged

interval of comparative quiet; this is characterized, however, by numberless and varied phenomena—the *hysteric stigmata*. The whole course of the affection may be comprised in this period, convulsions being absent. As I have already stated, these can best be described under the heads of the various systems:

(a) **The Nervous System.**—This presents the most characteristic hysteric stigmata. They are generally grouped into the three classes of *motor*, *sensory*, and *psychic*.

The *motor symptoms* have already been referred to in part in the description of the hysteric convulsion. They embrace every variety of muscular pathology, from obdurate paralysis to and including tremor, which may be either fine or coarse, inco-ordination, and tonic spasm or contraction. The hysteric paralyses, as stated, may be absolute or partial, and either general or limited to groups or to individual muscles, and may simulate any variety of true paralysis of organic origin. There is usually noted an exaggeration of the reflexes of the affected side; muscular wasting, if present, is very slight and due to disuse; usually it is absent. It is not at all uncommon to find associated contractures and sensory phenomena. The paralyzed limb or limbs show evidences of circulatory disturbances, as edema and bluish discoloration. In the paraplegic cases it is unusual for trophic disturbances (bed-sores) to appear. Paralysis of muscles supplied by motor cranial nerves, especially those of the larynx and pharynx, may occur; with these exceptions it is usually a pseudoparalysis due to spasm. Hysteric tremors are not infrequent, and are usually well marked and persistent. They are generally associated with contractures and other hysteric stigmata. Choreiform movements may be simulated, but they are usually more quick and rhythmic than true chorea. It is important to remember that hysteria may coexist with chorea; also, that apparently true choreic movements may arise from imitation, in which event it is justifiable to term them hysteric.

Hysteric inco-ordination (*hysteric ataxia*) has also been termed *astasia-abasia*; it is one of the rarest of the motor phenomena of hysteria. The name implies an inability to stand or walk, although muscular power in the legs and trunk is retained, and they can be moved perfectly well when the patient is at rest. *Hysteric contractures* may occur as distinct phenomena or may be associated with some form of hysteric paralysis. Usually the contractures occur with startling abruptness, and are most intense and persistent. They may persist during sleep, but disappear under the influence of an anesthetic. There may be associated sensory phenomena. The toes and the fingers are most frequently the seat of contracture, but the muscles of the face and neck may likewise share in the affection.

Sensory Symptoms.—The anesthetic, hysteric, and paresthetic varieties are noted. The anesthesia may be general or it may involve but half of the body or scattered areas of the cutaneous surface. *Segmental anesthesia* is the term applied to that condition in which a limb or a portion of a limb is involved. Not only is the skin affected, but often the deeper tissues as well, and there is generally some vasomotor involvement, as is shown by the fact that punctures by a needle are not followed by bleeding. There is often associated an anesthesia of one or more of the special senses (*hysteric amaurosis* or *blindness*, *hysteric deafness*, and *hysteric anosmia*). The anesthesia is severe, as a rule, immediately after a hysteric convulsion, but it may be entirely absent throughout a given case of hysteria. There is often contraction of the field of vision or inversion of the color fields, the red being more extensive than the blue. This may also be due to brain tumor.

Hysteric hyperesthesia is also a frequent clinical manifestation, and is generally confined to limited areas, as the ovarian, mammary, or spinal regions,

or to one of the larger joints (*hysteric joint*), simulating organic disease of the part. Pressure upon these areas may precipitate paroxysmal attacks, and they have been termed hysterogenic zones. These conditions can be recognized by etherizing the patient, when perfect mobility of the affected joint is noted. When one of the mammæ is involved, the organ becomes exceedingly painful to the touch and slightly edematous (*hysteric breast*). *Hysteric paresthesiæ* include the common varieties of formication, dead fingers, and the like.

Psychic Symptoms.—These form some of the most interesting and remarkable of the manifestations of the disease. Lethargy or a tendency to sleep may exist, the periods of which may follow or alternate with the crises. The sleep in this condition is peculiar because complete muscular relaxation does not exist, as is the case in ordinary sleep. There may also be mental depression and unrest, melancholia, and a notable lack of volitional power whereby the patient becomes especially open to the suggestions of the hypnotist. Double consciousness or somnambulism is a peculiar state, often following a grand crisis, but occasionally arising independently. The morbid period may last for a few minutes or hours or may extend for days or months. During its continuance the patient may be excited and more or less abnormal, or an apparently normal person of altered character. The most remarkable feature is the loss of memory for the normal state, and the recollection of what transpired during the preceding attacks, and loss of memory for all that happened during the attacks in the normal state, so that the subject may actually live two lives. Analogous to these are the states of ambulatory automatism, in which, as a result of an irresistible impulse, the subjects may wander considerable distances from home, appearing more or less normal during the journey, but preserving an imperfect recollection of what has taken place. Somewhat similar attacks occur as substitutes for the epileptic attack.

(b) **The Digestive System.**—Among the usual clinical manifestations of this group may be mentioned *anorexia* (which may be complete), a strange and persistent perversion of taste, occasional uncontrollable vomiting without nausea (*hysteric vomiting*, *anorexia nervosa*), marked dyspepsia, and at times extreme emaciation with dryness and a parchment-like feel of the skin. Excessive flatulence and the peristaltic unrest of Küssmaul may be marked symptoms, as may also either diarrhea or constipation. *Hysteric hematemesis* is the result of swallowing blood; this is usually drawn from the gums or tonsils, or it may be taken secretly by the patient from other external sources.

(c) **The Respiratory System.**—Difficulty of respiration (*hysteric dyspnea*) is not uncommon, and is characterized by an extreme rapidity and shallowness of the respiratory movements. These are much out of proportion to the heart-beats and are unassociated with cyanosis. In other cases the disturbance assumes the form of uncontrollable yawning, sneezing, or hiccuping, due probably to a spasmodic action of the involuntary muscles of the bronchial tubes and diaphragm. *Hysteric cough* is a troublesome and very often a stubborn symptom, occurring especially in young females. It is dry and barking, and, as a rule, unaccompanied by expectoration. At times it may be followed by *hysteric hemoptysis*, in which there is an escape of light red fluid from the pharyngeal mucosa. *Hysteric aphonia* is also frequently noted; in this condition the patient speaks in a scarcely audible whisper. In such cases restoration of the voice is of as sudden occurrence as is its loss. In one of my own cases aphonia manifested almost true intermittence for a period of five years, while during the last two years or over it has stubbornly persisted even without remission (p. 1045).

(d) **The Vascular System.**—*Hysteric tachycardia* is often noted, and much less frequently *hysteric bradycardia* appears. A variety of *pseudo-angina* is not

of rare occurrence (*vide* Angina Pectoris, p. 666). Very frequently the patient exhibits a localized flushing of the skin (*hysteric erythema*), and especially of the face and neck, or, as has already been noted, there may be an apparent bloodlessness of a part. Profuse general or localized sweating is not uncommon, and may at times be bloody.

Hysteric fever may be mentioned here as a rare manifestation, the bodily temperature usually being normal in hysteria. The elevation of temperature may be moderate or there may be an extreme hyperpyrexia (110° to 120° F.— 43.3° – 48.8° C.), without grave results. If this be associated with localized neuralgia, it becomes a difficult matter to diagnose between the neurotic condition and organic disease of the apparently affected part.

(e) **The Urinary System.**—An excessive flow of urine (*hysteric polyuria*) is of very common occurrence, while the opposite condition (*anuria*) is much rarer.

The **diagnosis** of hysteria depends entirely upon the discovery and recognition of the hysteric stigmata; for one or more of them is always present. Of these, the most frequent are areas of anesthesia, concentric narrowing of the visual field and inversion of the color fields, and hysteric aphonia, although any of the others that have been described may occur. If, in addition, hysteric crises are present or have been observed, the diagnosis becomes certain. A valuable feature is the inability to explain the symptoms by reference to the anatomy of the nervous system. It must not be forgotten that hysteria and organic disease may coexist.

Differential Diagnosis.—Very important is it to distinguish between hysteric and true paralyses, and between hysteric and organic abdominal tumors. In the following tables the most striking points of difference between these conditions have been set down:

HYSTERIC PALSIES	ORGANIC PALSIES
Occur without a previous history of organic disease, but with a neurotic history. Traumatism may be the cause.	Are always secondary to organic disease of the neuromuscular system.
Are accompanied by other hysteric stigmata or perversions of sensation.	Hysteric stigmata are absent.
Are not accompanied by wasting of the muscles involved.	If due to a lesion of the peripheral neuron, atrophy is present. In central neuron lesions it is usually not marked.
Reactions of degeneration are absent.	Reactions of degeneration are more or less marked in peripheral palsies. In central, the electric reactions are normal.
The power of motion returns before sensation.	Sensation if absent first reappears.
In hysteric hemiplegia the facial muscles are not involved.	The facial muscles of the same or opposite side are often involved in true hemiplegia.
Anesthesia generally causes relaxation of hysteric contractions.	Organic paralytic contractions are not affected by anesthesia.
The sphincters are never involved.	Often are in paraplegias.
Babinski reflex not present.	In central palsies (pyramidal tract) it is present.
HYSTERIC ABDOMINAL TUMORS (PSEUDOCYESIS)	ORGANIC ABDOMINAL TUMORS
Almost invariably occur in neurotic women near the menopause.	Occur irrespective of sex.
The percussion-note is invariably tympanitic.	The percussion-note over the swelling is dull, or a dull tympany.
Anesthesia causes a disappearance of the tumor.	Anesthesia has no effect upon the tumor.
Is variable as to size and tonicity.	Slowly but steadily progresses in size.
Is accompanied by tympany and flatulence.	The bowels are not always distended by gas.

Hysteric hemianesthesia differs from that due to organic disease in that the special senses and mucous membranes are affected. The line of demarcation is sharp and in the middle line. Tickling the anesthetic mucous membrane of the nose will cause tears to flow, which will not happen if of organic origin, and lateral homonymous hemianopsia is never present. If either the segmented form or scattered areas of sensory paralysis are present, they often have no connection with any known area of nerve distribution. They all may be transient, reappearing and disappearing, and changing their location.

The differential diagnosis between hysteria and true neurasthenia, psychasthenia, and epilepsy will be found in the discussion of these affections.

Prognosis.—As regards death, the prognosis in hysteria is good; true hysteric patients never die of the disease, nor does the hysteric spasm ever result fatally. As to an ultimate cure, however, the prognosis is very doubtful. If the disease occur early in life and if there is a marked congenital neurotic tendency manifested in the patient, there is almost no hope of affecting a permanent cure. In the acquired cases, under proper moral and hygienic control great benefit may be effected or even an absolute cure recorded.

Treatment.—Of the Temperament.—Accurately speaking, the treatment of hysteria should be begun before birth. Neurotic women bearing children should be subjected to a course of rest-cure and mental and moral suasion, and the condition of their nervous systems should receive the careful attention of the attending physician. Neurotic children require the greatest care during the developmental period. A strong physique must be secured by proper attention to out-of-door exercise, and, for the time being, even at the expense of mental culture. Such children should not be subjected to the "cramming" process so common in our modern courses of education, but should be trained, if possible, at home, where the element of competition may be eliminated. Systematic hours of study and of recreation (with absolute rest from study during the summer months), and opportunities of travel and change of air and scene, will work wonders in these hyperesthetic little individuals. Especially at the time of puberty is the greatest of care required in order to avoid an additional strain upon the already seriously taxed nervous system. In addition to the foregoing a strict watch must be kept over the moral nature of the child. The satisfaction of every whim and the lack of moral suasion are the surest ways to develop the hysteric temperament. When possible the child should be taken away from the enervating influences of city life. The diet should be plain, but nutritious, and all overindulgence is to be absolutely prohibited. Frequent bathing and friction of the skin are very beneficial, as well as careful regulation of the emunctories generally.

The Hysteric Convulsion.—As hysteric patients almost never injure themselves during a paroxysm, protective measures are not necessary. Indeed, the attack is usually prolonged by attention and observation. Extreme measures to cut short an attack are only justifiable if the friends and relatives become unduly anxious. Cold plunge-bathing, dashing cold water into the face, or the hypodermic injection of apomorphin, thereby producing a profound mental shock, may have a beneficial effect. Pressure over the ovary or upon one of the large vessels (as the carotid) will sometimes promptly induce a termination of the attack.

Internal Treatment.—In the latent period of the disease it is probable that most can be done to improve the condition of the patient. In addition to the general laws of mental and physical regimen already advanced, she should be taught, so far as possible, the undignified condition into which she is sinking, and advised and encouraged to exert powerful efforts to control her nervous organism. All harsh methods are to be deprecated, nor should she, after the

first admonition, be reminded too constantly of her condition. Full doses of the nerve sedatives and antispasmodics (valerian, asafetida, sumbul, musk, and camphor), together with the general tonics (iron, arsenic, strychnin), are useful. Change of environment, and particularly of associates, is often of the greatest value. I have repeatedly found the rest-cure of Weir Mitchell especially beneficial at this time; it is fully described under Neurasthenia (*vide* p. 1164).

Suggestion and persuasion are valuable means of causing the removal of symptoms.

In the treatment of the organic manifestations, which, it must be remembered, are dependent entirely upon the general nervous condition, the physician is called upon to exercise the greatest amount of tact. As far as is possible the mind of the patient must be directed away from the affected part. The *irritable bladder* must be treated by internal remedies, as atropin, boric or benzoic acid, salol, or the compound infusion of buchu, and not by local irrigation and catheterization.

Hysterical vomiting may not require any special medication. Occasionally, however, it may be relieved by rectal alimentation or gastric lavage. Cocain hydrochlorate in the form of a 10 per cent. solution (3 to 5 drops internally), and the application of mild counterirritation or of a small fly-blister over the epigastrium will be useful. Cannabis indica, acetanilid, phenacetin, and antipyrin, in small doses and only when absolutely needful, will relieve *hysterical neuralgias*, especially the cephalalgia. For the pseudo-angina pectoris, digitalis, strophanthus, caffein, amyl nitrite, or nitroglycerin, or a combination of these drugs in suitable doses, may be exhibited.

For the *pelvic hyperesthesia* of hysterical females local applications (tincture of iodine, croton oil, or a small fly-blister) over the ovarian region may prove very beneficial.

Hysterical palsies, either general or local, and hysterical disturbances of the special senses, must be treated on general principles. As far as is possible the patient's attention must be directed from the affected part or parts, and an occasional local blistering, the use of galvanism and massage, with daily friction, will be of service, especially when they are supplemented by an appropriate course of internal medication.

Electricity is a very valuable adjunct. The static current is most effective, and it may be applied in various forms. Perhaps the most useful of these is the spark, which should be drawn from the anesthetic area or the paralyzed limb, thus producing a profound mental effect.

Analytic or Cathartic Method.—Based upon the theories of Breuer and Freud (p. 1152), this method has been evolved. Briefly, it consists in getting the patient "to tell the story of his life." In other words, while in a relaxed condition (reclining on a couch) he is encouraged to make a confession of all the disagreeable happenings of his life. This may require some time and a number of sésances. Clues to these may be obtained from the description of the patient's dreams. Gaps may have to be filled in by the physician by some method of psycho-analysis. After the so-called mental catharsis has occurred, the cause of the trouble being so determined, the patient usually recovers.¹

¹ *Psychoanalysis*, Brill, W. B. Saunders Co.

NEURASTHENIA

Definition.—Functional exhaustion and irritability of the nerve-centers. Neurasthenia is the expression of an abnormal sensitiveness (irritability) in response to stimuli, and of weakness of the nerve-centers presiding over the organic functions. Several varieties—cerebral, spinal, cardiac, and gastric—have been distinguished, owing to the fact that the predominating features may be manifested by single organs or systems of the body. That the disease is essentially generalized in all instances, however, I do not doubt.

Pathology.—A variable degree of weakness of the sympathetic centers, permitting congestions on trivial provocation, is obvious, but there are no discoverable lesions (coarse) in the nerve-centers that are peculiar to the affection. C. Y. Hodge¹ has invited attention to certain changes in nerve-cells during the active exercise of their function, and something of pathologic importance has been added to our previous knowledge by his observations. There are many causes and associated affections that present a variety of morbid lesions, but they are purely incidental. It should be pointed out here that neurasthenia is often found in association with other functional nervous disorders—a fact that has not only caused mental confusion among certain authors, but has also led to the belief among others that as a distinct affection it does not exist. Glénard in 1888 called attention to the frequent association of profound neurasthenic symptoms with splanchnoptosis.

Etiology.—The causes are divisible into: (1) predisposing; and (2) exciting. Among the **former** (*a*) *heredity* heads the list. A clear history of nervousness or morbid irritability in one or both parents (oftener the father) is at times obtainable. Ancestors that were sufferers from gout, rheumatism, syphilis, tuberculosis, and chronic alcoholism, all diseases that exhaust vitality, may have transmitted to their offspring a strong neurasthenic disposition. The latter have inherited a small stock of nervous energy with which to begin life's unceasing struggle.

Other predisposing factors are—(*b*) improper training, mental and physical, (*c*) the character of the mental pursuits, those entailing strains being especially deleterious. (*d*) *Age* and *sex* are not without appreciable effect, most cases occurring between the twentieth and fiftieth years, when the work and worry of life are maximal; they are more frequent in men than in women, and (*e*) disturbances of metabolism accompanied by an abnormally low output of endogenous uric acid (Peck and Thompson).

Exciting Causes.—*Traumatism* has an active potency, though it is probably not the most frequent cause. *Overwork*, at least in America, is responsible for a greater number of cases than any other single factor, and in estimating its effects the relativity of individual nerve capital must be carefully considered. Associated causes are to be observed in unpleasurable emotional excitement, mental worriment, particularly if dependent upon love affairs and sexual excesses. *Abuse of the sexual organs*, excessive venery, masturbation, coitus interruptus, and the like are powerful in producing neurasthenia. Finally, as stated under Pathology, the condition may be induced by other functional and organic affections (symptomatic neurasthenia). (Also see Vagotomy, p. 1046).

Symptoms.—The subjective symptoms are protean and varied, and are usually described with great detail, for the patients are, as a rule, exceedingly voluble. Among the more prominent features entering into the symptom-complex of neurasthenia are great *irritability*, *physical fatigue* without adequate reason, even to a feeling of utter exhaustion on rising in the morning, *disturbed sleep*, *headache*, with a sense of weight and constriction, *impairment of memory*,

¹ *Jour. of Morphol.*, vol. v., No. 11, p. 95.

anorexia, and *constipation*; the patient is very irritable, dispirited, is fearful, and frequently sinks into a state of absolute dejection. Female sufferers—and less frequently males also—may manifest strong emotions, and in such cases the condition presents many points of resemblance to the milder forms of hysteria. The external appearances may be indicative of sound, vigorous health; oftener, however, the physiognomy is worn and anxious.

The **motor phenomena** include, besides readily oncoming exhaustion of the muscular strength under exercise, a variable condition of the tendon reactions. On the whole, however, they are increased. Muscular *tremors* (fine) are sometimes present when neurasthenia is the result of trauma or fright (Dercum), and spasmodic contractions of small isolated groups of muscular fibers of the face, trunk, or extremities are observed.

The **sensory** disturbances are varied and sometimes striking. The patient makes constant complaint of feeling "tired" or "never rested," and indeed sometimes betakes himself to bed for this reason. As a rule he feels more tired in the mornings after rising than upon retiring at night. A feeling of "lightness," giddiness, and even true vertigo, may occur and recur, and rarely the latter symptom is wellnigh continuous. The *headache* (previously mentioned) is often wholly dependent upon mental work, since it disappears with the cessation of the latter. Another form of *pain* is a dull aching that may be generalized, though more commonly it is confined to the small of the back and limbs. *Spinal tenderness*, when sought for, may often be elicited over certain circumscribed areas or mere points, and it may be combined with deep-seated ache or an exacerbating pain ("spinal irritation"). Cutaneous *hyperesthesia* is common, but anesthesia is not found in uncomplicated neurasthenia. Numbness, either spontaneous or as the result of slight pressure, is a conspicuous feature for a variable period upon or near the nerve-trunks, and linked with it there may be a generalized or localized feeling of coolness of the body surface, or of pricking sensations (formications) and circumscribed subjective sensations of heat and burning.

The *psychic* symptoms grow out of the same fundamental conditions as do the *physical* symptoms—i. e., fatigue of the nerve-centers. As would be expected, then, the capacity for sustained mental work is generally lessened, and the power to concentrate or rivet the attention upon any subject as well. The patient is self-centered, sensitive to a degree, easily angered, and is morbidly suspicious. His emotional nature is unstable, and the mental depression (before mentioned) deepens until it approaches true hypochondria.

Insomnia is one of the most constant and troublesome of all the symptoms of neurasthenia. It occurs in various forms. Usually the patient goes to sleep readily, but awakens in a few hours and remains awake either for the rest of the night or until morning is approaching; sometimes there is difficulty in falling asleep; sometimes rest is frequently disturbed. *Agrypnia*, total inability to sleep, occurs only in the most severe forms of the disease. Disturbances of the organs of special sense are not wanting. The eye presents the most important fatigue symptoms. *Vision* may be imperfect (blurred) and continuous close use of the eyes may be impossible. There is a lack of power of accommodation and retinal hyperesthesia may supervene. The pupils may be unnaturally large. All forms of *tinnitus* constantly arise in neurasthenia, and may lend so vivid a coloring to the clinical picture that the real nature of the attack is liable to be overlooked. I have recently seen a case of the sort occurring in a clergyman in whom aural disease had previously been diagnosticated. This symptom, like all others due to neurasthenia, may, however, be associated with genuine organic diseases of the ear (*otoneurasthenia*). Disturbances of taste sometimes appear, but they are of minor importance.

Vasomotor disorders, such as hot flushes and profuse sweats, commonly arise in consequence of the diminished tone of the arteries; these form quite distressing fatigue symptoms. Visible throbbing of the superficial vessels and of the abdominal aorta, and rarely also of the veins and the capillary pulse, occur. The *urinary phenomena* may excite particular attention owing to their prominence, and this remark applies especially to the frequent combination of neurasthenia and lithemia (*lithemic neurasthenia*). Oxaluria and transient glycosuria and albuminuria may also be present. The daily amount of urine is often small, and less frequently it is large. The sexual apparatus is weak and irritable, as shown by seminal emissions and incomplete erections, and by premature ejaculation. The fear of becoming impotent often renders the mental attitude of those really potent such as to excite the keenest compassion. The orgasm in the female and the emission in the male are followed by a sense of prostration and mental depression.

The somatic disturbances referable to the heart (palpitation, precordial pain) have been considered under Neuroses of the Heart, and the various gastro-intestinal features in the discussion of Neuroses of the Stomach. Reference has already been made to several clinical varieties based upon the predominance of special and localized groups of symptoms—*e. g.*, when the reigning features are spinal the variety is termed *spinal neurasthenia*; when these are presented by the sexual apparatus, *sexual neurasthenia*, and so on. A further subdivision has recently been made in which the predominant symptoms are various morbid fears, imperative ideas, impulsive acts, and the so-called doubting mania. This has been termed *psychasthenia* (p. 1167). The most obstinate type of neurasthenia is that associated with congenital defects of structure, particularly splanchnoptosis, the so-called Glénard's disease. It does not differ essentially from the ordinary forms, but the gastro-intestinal symptoms predominate.

Diagnosis.—That cases of neurasthenia are misdiagnosed as other conditions, and the reverse, I feel convinced. An important matter at the outset is to avoid confounding the neurasthenic symptoms (secondary) of various local and general organic diseases with the primary form by a careful exclusion of the latter. From *hysteria* the diagnosis is as follows:

HYSTERIA

By nature a psychoneurosis.

Occurs in individuals presenting a marked hereditary taint.

The onset is frequently abrupt.

The clinical features are dependent upon an excess of nervous energy.

Presents the characteristic stigmata, as paralysis and anesthesia in most cases.

Is sometimes accompanied by violent convulsive seizures.

Neuralgic attacks infrequent and absent. Insomnia is not marked.

NEURASTHENIA

A neurosis; often with a pronounced psychical element.

Occurs as the result of nerve tire, overwork, and the like in individuals not necessarily presenting hereditary taint.

The onset is always gradual.

Is characterized by a notable lack or insufficiency of nerve force.

These are absent.

Convulsive seizures never occur.

Neuralgic attacks are very common. Insomnia is very common.

Hysteria, it is to be remembered, may be a complication of neurasthenia, and this association must be distinguished from simple hysteria. Neurasthenia must also be distinguished from psychasthenia (p. 1167). It should also be remembered that neurasthenic symptoms may mark the commencement of various grave physical and mental disorders. Tuberculosis, diseases of the blood, dilated stomach, gastric cancer, gastropotosis, movable kidney, focal infections, chronic uterine and ovarian disease, paresis, dementia præcox,

hypochondria, pellagra¹ (p. 433), and melancholia should all be considered before the diagnosis of pure neurasthenia is made.

Prognosis.—Neurasthenia is a curable disease if appropriate treatment be commenced before secondary structural changes set in and render the use of the most approved measures of no avail. In long-standing cases deleterious habits (morphinism, chloralism, alcoholism) are sometimes developed and prevent the possibility of a cure. Hysteria (the complication) tends to delay, but does not preclude, recovery.

Treatment.—The first step should be, after locating the major cause or causes, to remove them, or, if this be impossible, to minimize their baneful influence so far as may be. For example, if the conditions have been induced by overwork of the brain, rest for the organ must be procured; if sexual excesses have been the obvious responsible factor, rest for the sexual apparatus is imperatively demanded. In the next place, the mental and moral environment must be conducive to contentment and to wholesome forms of exercise of the mind. In this way the exhausted stock of nervous energy can often be increased by the natural recuperative forces alone. Indeed, successful removal of the essential etiologic influences is in the milder forms followed by prompt recovery. In not a few instances the symptoms disappear as the result of a prolonged sojourn in a suitable climate or by travel for a considerable period with its ever-accompanying change of scene, though it is well in doing so to avoid the din and excitement of large cities. The compulsory rest and complete isolation, combined with the purity of atmosphere, afforded by a sea-voyage sometimes work admirable results. Being occupied by easy and agreeable employment under supervision, as embroidery, basket-making, etc., has been successful. Unfortunately, many subjects suffering with neurasthenia, and particularly males, are either unable or unwilling to arrest the loss of nervous function by ceasing their excessive activities. In the majority of instances, for the reasons above stated, certain other measures—hygienic and medicinal—are to be advised.

To Dr. Weir Mitchell belongs the credit of having systematized the "rest-cure" in the management of this disease. This mode of treatment involves (1) physical and psychic rest. The former is obtained by strict confinement to bed, the latter by isolation from all business, professional, household, and family affairs; in severe cases, to the complete exclusion of the family. (2) Hypernutrition. This requires the administration of a quantity of food in excess of the amount required merely to maintain life and repair waste, and is usually secured by feeding at frequent intervals and using nutritious food. (3) The stimulation of the metabolic processes. This is accomplished by massage, passive movements, and electricity. (4) The encouragement and education of the patient. This depends largely upon the tact and authority of the physician and nurse, although graduated and increasing voluntary muscular and mental exercises are of some value. In long-standing cases rest should be made absolute if possible, while in the milder forms merely lengthening the hours for sleep or rest in bed often suffices. The amount of rest must be accurately proportioned to the necessity of each case.

The patient is to be put in charge of a properly selected nurse, who will afford agreeable entertainment by suitable conversation and reading under the direction of the physician. In desperate cases the patient should not be allowed to feed himself, must not rise to void the urine or feces, nor even turn in bed without the help of the nurse.

Upon the careful regulation of the *diet* depends, to a large extent, the success of the treatment. This must be modified to suit each individual pa-

¹ Tucker, *Amer. Jour. Med. Sci.*, March, 1912, p. 332.

tient, and, when it is possible, it is desirable first to make a careful quantitative and qualitative examination of the stomach contents.

The two commonest derangements are excess of hydrochloric acid, with retention of stomach contents and anacidity.

In the former condition the diet must consist of the lighter meats, the more readily digested vegetables, particularly the legumes, the cereals, light desserts, toasted bread, crackers, etc., a liberal amount of fat and milk, and eggs in moderation. I have rarely found it necessary to commence with a very restricted diet of, say milk, but, as a rule, the patient can begin on three full meals a day, with a luncheon consisting of milk and toast or crackers, malted milk, chocolate, or cocoa, etc., in the mid-morning and mid-afternoon, before going to bed, and, in severe cases, also once during the night. These cases are also benefited by the administration of moderate quantities of soda after each meal.

In the achylic form the total quantity in each meal should be somewhat less, but from six to eight meals may be given in the course of twenty-four hours. The diet should consist of meats, eggs, the legumes, the acid vegetables, the cereals, bread, fruit, light desserts, a moderate amount of coffee, and a liberal amount of milk. Hydrochloric acid should be given before each meal. In either case the caloric value of the diet should exceed 3000 in the course of twenty-four hours.

In cases in which the gastric analysis is not possible, it is of advantage to commence with small quantities of food, and to increase them rapidly until a very liberal diet is being taken. As a general rule the red meats should not be given too frequently, the coarser vegetables should be excluded entirely, and sweet food should be taken sparingly. Most cases do well on cream taken in quantities of 4 to 8 ounces at a time, sipped slowly, while, at the same time, crackers or toast are eaten.

It is, of course, understood that the patient should never be consulted about the diet. The nurse brings the food at the proper time, served in the most attractive manner possible, and at meal-time always in courses, so that only moderate amounts of food are placed before the patient at one time. The patient should lie perfectly flat for at least an hour after eating.

Passive exercise, massage, and electricity form an essential part of the "rest-cure." Massage should not be commenced until the second or third day. At first it should be continued for a few minutes only, and consist of gentle rubbing or light strokes. As tolerance becomes established, it should be practised for a longer period (about an hour). Deeper rolling, kneading, and spiral manipulations are then allowable. The direction of the venous blood-current—toward the center of the body from the periphery—is to be borne in mind, and all massage motions are to be made in the same direction. This measure is to be carried out by the nurse, who should be a well-trained masseuse and thoroughly acquainted with the details of her work. Electricity, like massage, compensates for the lack of exercise. The slowly interrupted faradic current is to be selected, and the aim should always be to induce satisfactory contractions with the least amount of pain. The current should be applied to the individual muscles, one of the extremities being selected, and the poles applied over the motor points, passing from muscle to muscle until all have been faradized. The time of each sitting should not exceed half an hour. The entire body should also receive the faradic current (rapidly interrupted). A large sponge moistened with salt water is applied at the nape of the neck, and another to the soles of the feet, and the strongest current tolerable is thus used. This process should be continued from fifteen to twenty minutes, and, like the faradization of the single muscles, it is to be repeated at intervals of twenty-four hours. Passive movements should be employed systematically,

slowly increasing in duration and extent. They promote circulation and nutrition and are soothing.

Hydrotherapy may be employed in the form of the shower, spray, bath, or pack, and is most efficacious when quickly applied for a few moments and followed by vigorous toweling to reinforce the action of the cold. In insomnia with difficulty in going to sleep, the dry cold pack applied to the spine for an hour is often of benefit. Extreme caution is necessary at the beginning of the application of cold to the surface, since there are neurasthenic subjects who not only fail to receive benefit, but are rendered worse in consequence of a highly sensitive organization.

Although the administration of *drugs* plays a minor part in the management of the rest-cure, in certain cases they are essential, and must not be excluded. Alkalies or acids are indicated, according to the condition of the stomach contents. If there is excess of acid, the alkalies may be taken after meals; if there is a deficiency of acid, hydrochloric acid should always be given before meals, and in ample doses—from 10 to 20 minims of the dilute acid.

The most important drugs are the laxatives. In the beginning calomel and the salines are often of great value in flushing out the intestines, but during the course of the disease it is the invariable rule never to purge. Of the vegetable laxatives cascara is probably the most useful, but aloin and rhubarb are often of service. Of the saline laxatives the most efficient are certain forms of magnesia and phosphate of soda. In cases where there is considerable alkalinity from 5 to 10 grains of oxid of magnesia in powder form may advantageously replace the soda after meals. Or 1 or 2 drams of the milk of magnesia may be given in milk, two or three times a day. Small doses of phosphate of soda in hot water should be given just before breakfast in the morning, being carefully regulated so that only a laxative effect is produced.

If there is pronounced anemia, moderate doses of iron, perhaps combined with arsenic and the bichlorid of mercury, are often of service, but must be discontinued if they interfere with the appetite. There is considerable dispute regarding the value of phosphoric acid, or its salts. According to my experience, it is of comparatively little value.

The rest-cure in all of its details should be continued for a period ranging from four to eight weeks. The patient should leave his bed in the most gradual manner, and should sit up for a few minutes only at first, the time being gradually lengthened; soon exercise may be commenced in a like manner and be cautiously increased. During this period of convalescence it is my custom to omit the electric treatment, while the massage is continued at intervals of two or three days for some weeks. After the patient has made some improvement, as evidenced by a large appetite, the disappearance of the most pronounced subjective symptoms, and especially by a substantial gain of weight (20 to 25 pounds—11.3 kgms.), he should be advised to make a change of residence, preferably to the country, the mountains, or the seashore, being guided by the season and the wishes of the patient.

We must increase the activity of the metabolic processes in cases in which the endogenous uric acid output is lowered (400 gr. or less daily). Peck and Thompson¹ advocate the use of the electric-light baths. Cases which are not able to undergo these methods (they being somewhat expensive) must be treated symptomatically, small doses of the bromids, combined with arsenic, if irritability is excessive. Cold douches or baths, with vigorous rubbing in the mornings; tonics, as the glycerophosphates, iron, etc., attention to the gastrointestinal tract, encouragement, regulation of the employment, as much fresh air as possible, electricity in the form of high-frequency currents, etc.

¹ *Jour. Amer. Med. Assoc.*, February 29, 1908.

TRAUMATIC NEUROSES

Owing to the marked influence of trauma in causing both neurasthenia and hysteria, such cases are often specially classified under the above title. The symptoms are, however, essentially those of either hysteria or neurasthenia, or both combined. The general rules of diagnosis and prognosis in these conditions here apply. It should be remembered that the strain incident to litigation, to which these cases are often subjected, may retard recovery.

PSYCHASTHENIA

A group of symptoms, until recently classified under neurasthenia, has been given the above title. They consist of obsessions, fears, doubts, undue anxiety, uncontrollable movements, deficient will-power, combined with more or less of the physical symptoms of neurasthenia. As examples of these mental symptoms may be mentioned dread of impending danger, either to family or self, fear of open spaces (agoraphobia), fear of closed places (claustrophobia), of being alone (monophobia), fear of crowds, abnormal fear of storms, of wind, etc.; fear of personal defilement (mysophobia); the doubting mania, in which the patient is never certain that he has performed an action correctly; irresistible impulse to touch certain objects (*delire du toucher*); irresistible tendencies to repeat continually certain words (onomatomania), to count a certain number of times before performing an action (arithmomania), etc. The patient is conscious of the absurdity of these actions and feelings, but cannot resist them. Epileptiform convulsions may also occur. The prognosis is doubtful, but treatment similar to that recommended for hysteria may achieve good results.

OCCUPATION-NEUROSES

Definition.—Conditions in which the performance of certain habitual co-ordinated movements is prevented by the development of cramp, tremor, paralysis, or pain.

The **pathology** of this condition is unknown. It is probably purely functional, and the discovery of appreciable lesions is not to be expected, though nodular thickening of the peripheral nerves has been described in a few cases.

The **etiology** is various. Those following any occupation requiring the continuous repetition of fine, co-ordinated, muscular movements, as sewing, type-writing, playing musical instruments, telegraphing, and writing, may be affected. Writing is the most common cause, and is known as scrivener's palsy or writer's cramp. It is the form here particularly described, although the symptoms due to other causes are similar. Males are far more frequently affected than females, the condition usually occurring in early adult life, although children are not exempt. Gowers lays great stress upon improper methods of holding the pen, particularly those in which most of the writing is done from the wrist; that is, with the muscles of the forearm and hand. As scrivener's palsy occurs sometimes in those that write properly, and as a similar condition is not uncommon in other occupations, it seems unlikely that this is the most important cause. A person with a neurotic temperament is far more apt to be affected by the disease than one with a normal nervous system;

we, therefore, frequently find it associated with hysteria, neurasthenia, or great bashfulness, and not infrequently it is possible to elicit a neuropathic heredity in the family history. It is also met with in certain other nervous diseases (epilepsy, locomotor ataxia—in the early stage). Often the patients admit that at the time the disease developed they were suffering from severe anxiety.

Symptoms.—Motor.—When the patient attempts the particular movements involved there is usually a cramp of the flexor muscles of the forearm, so that in writing, for instance, the pen is held more or less rigidly, and it is almost impossible to control its motions. Less frequently there is a cramp of the extensor muscles, so that the fingers are spread and it is impossible to hold the pen at all. Sometimes there is a sudden twitching, and the pen may be thrown altogether out of the hand. The spasm is nearly always tonic in character, but often it is associated with a fine tremor, and at times there are clonic movements. In some cases, and particularly those occurring in patients showing hysteric stigmata, there is a coarse, irregular tremor, most marked when the patient is under observation. Paresis is frequently associated with the cramp, so that the arm soon becomes tired and it is almost impossible to write. This fatigue may in a few moments progress to almost complete paralysis of the arm, but, curiously enough, both fatigue and paralysis disappear as soon as some co-ordinated movement other than writing is undertaken.

Sensory.—Pain is very common, and is neuralgic or cramp-like in character, being referred either to the muscles, bones, or joints. In intensity it varies from a dull ache to the most excruciating burning, and may form the only symptom, the muscles performing their work perfectly. At times it is sharply localized to one particular joint, affecting either the metacarpal bones or the fingers. Quite often the patient complains of a tingling or burning sensation in the limb, or it may be numb and the hand feels, when writing, as if a heavy weight were attached to it. Often there is tenderness either of the muscles or the nerves, which may be localized in certain points. In very severe cases *vasomotor disturbances* occasionally occur. The disease ordinarily commences slowly. At first the subject notices that the handwriting is not quite as perfect as before, a stroke occasionally going astray; later distinct spasms appear, and these are finally associated with pain.

The **diagnosis** is usually easy. Care must, however, be taken not to call every disturbance of writing writer's cramp; thus in paralysis agitans, in slowly developing hemiplegia, in multiple sclerosis, and paresis disturbances of writing frequently—in fact, almost invariably—occur. Moreover, those cases in which hysteria or neurasthenia seems to be at the bottom of the trouble should be carefully differentiated from those that are apparently idiopathic.

The **prognosis** is rather unfavorable, though complete cure is sometimes attained.

The **treatment** consists first in a total cessation of the particular movements; if this is impossible, various mechanical devices may be employed to use another set of muscles or the old ones rather differently, such as a thick penholder or one constructed with supports for the fingers. Local treatment of the arm in the form of electricity should be advised; the anode of a constant galvanic current of medium intensity should be placed over the sensitive points on the nerves and over the bodies of the muscles. The wire brush employed, with the rapidly interrupted faradic current, to stroke the painful nerves and muscles, affords great relief. Massage, and particularly careful and systematic exercises, are also of great value. At the same time, the general condition of the patient must not be neglected. In those associated with neurasthenia a treatment appropriate to this condition should be employed.

ACROMEGALY

(Giantism)

Definition.—A disease first recognized and described by Marie, and characterized by a progressive and peculiar enlargement of the face and extremities.

Pathology.—Those cases that have been examined *postmortem* have shown, as the most constant change, an enlargement of the pituitary body, with a corresponding dilatation of the sella turcica, and a persistence of the thymus gland. Alterations may be found in other ductless glands, especially the thyroid, which may be either goitrous or atrophied. In some cases the pituitary may not be enlarged macroscopically. The lips, tongue, and trachea are usually considerably enlarged, and the sexual organs may either be hypertrophied or atrophied, the latter condition being more common in the uterus and testicles. The bones of the extremities and face are thickened, apparently chiefly as a result of hyperplasia of the spongy portion, and Klebs has shown that the peripheral vessels, particularly those in the affected bones, are also larger. Occasionally there are hypertrophy of the heart and enlargement of the spleen and liver.

Acromegaly is due to an increased activity of the anterior lobes of the pituitary body occurring after epiphyseal union has taken place. If it occurs before this (in childhood) *gigantism* is the result. In this changes in the pituitary will be found similar to those occurring in acromegaly. Of 183 cases of pituitary disease in which the urinary findings were given, 88, or 42.6 per cent., showed acromegaly.¹

Cushing² has described cases in which with overgrowth are associated symptoms of posterior lobe insufficiency, *i. e.*, adiposis, increased sugar tolerance, polyuria, polydipsia, subnormal temperature, dry skin, loss of hair, epileptiform disturbances, etc. He believes such cases are due to anterior lobe hyperplasia associated with posterior lobe hypoplasia.

Both sexes are about equally affected, and the disease ordinarily commences in adolescence.

The earliest **symptom** is usually an increase in the thickness of the fingers and toes, so that rings, gloves, and shoes are too small and can no longer be worn. This *enlargement* is chiefly in thickness, although there is also a certain amount of increase in length. Both the soft and hard parts are affected. The nails are flattened, longitudinally ridged, and more friable (*spade-like hand*). The *face* becomes considerably enlarged; the supra-orbital ridges project, giving rise to a rather simian aspect; the nose becomes broader and longer; the cheek bones project; but the most positive characteristic is the enormous enlargement of the lower jaw, so that it becomes broader and prognathous, and the lower teeth can no longer be brought in apposition with the upper. The *spinal column* is ordinarily kyphotic, the change affecting the upper dorsal and cervical regions. Frequently there is also an associated scoliosis. The rest of the skeleton remains unaffected for a long time; finally, changes may be observed in the clavicles, sternum, ribs, pelvis, and particularly in the patellæ. The *skin* sometimes shows slight pigmentation; the hair is rough and may become thinner; the *muscles* occasionally exhibit increased electric excitability, and less frequently there is muscular atrophy with reactions of degeneration. The lips, tongue, and tonsils are usually enlarged, and the larynx is increased in dimensions, so that the *voice* becomes deep and rough;

¹ "Relation of Glycosuria to Pituitary Disease," by J. M. Anders and H. L. Jameson, *Amer. Jour. Med. Sci.*, September, 1914, p. 313.

² *Amer. Jour. Med. Sci.*, March, 1913, p. 313.

this is a very characteristic symptom in women. Ordinarily, an area of dullness can be detected in the upper part of the sternum that has been ascribed to the persistence of the thymus gland. The *tendon reflexes* may either be normal, diminished, or abolished. They are never exaggerated. The *urine* is increased in amount, and glycosuria is often present. The secretion of *sweat* is also greatly increased. The subjective symptoms consist of severe intermittent or continuous *headache* and of a *diminution of the visual power*. There may be paresis of the third nerve, giving rise to external strabismus, and sometimes to *temporal hemianopsia* as a result of pressure upon the central part of the chiasm by an enlarged pituitary body. Sometimes late in the disease there are occasional momentary general tremors. The patients often present polyphagia and polydipsia. Neuroretinitis and subsequent atrophy of the optic nerve may also occur. The mental condition is affected, and there are usually great apathy and diffidence (perhaps explicable by their changed appearance), loss of memory, and somnolence. Symptoms of either myxedema, exophthalmic goiter, syringomyelia, or epilepsy may coexist.

Diagnosis.—In the later stages the appearance is characteristic, and acromegaly can then hardly be confounded with other diseases. The peculiar enlargement of the extremities, the oval, prognathous, and distorted face, the deep, rough voice, the more or less pronounced pigmentation of the skin, the wasting of the muscles, and the profound cachexia give a perfect clinical picture. In those cases in which the cachexia has become extreme there are from time to time peculiar tremors or spasms of the body.

Differential Diagnosis.—In the earlier stages the disease is most easily confounded with the *hypertrophic pulmonary osteo-arthritis of Marie*. In this both hands and feet are greatly enlarged; but the fingers are club-shaped, the face is not involved, and there usually exists some chronic pulmonary complication. In a case that I observed there were bronchiectasis and bronchorrhea. From *osteitis deformans* it may be distinguished by the fact that in this condition chiefly the long bones of the limbs and the flat bones of the skull are hypertrophied and very painful. *Elephantiasis* may be distinguished by the fact that it attacks the lower limbs, does not involve the bones, and the skin presents a granular or a nodular appearance. From *arthritis deformans* acromegaly may be distinguished by the fact that the disease is painful, and is associated with great deformity of the joints, the face ordinarily escaping. The following table (after Dercum) will serve to distinguish two diseases that are apt to be confounded with one another:

ACROMEGALY	MYXEDEMA
Occurs most commonly in early adult life.	A disease of mature life—forty to fifty years.
In males and females equally.	Five times as frequent in females as in males.
Enlargement of the bones characteristic. Marked prognathism of jaw and flattening of cheeks.	No enlargement of the bones. Face full-moon shaped.
Skin brownish yellow; hair coarse and unwieldy; nails short and striated.	Skin pale, waxy, shiny, and boggy; hair falls out; nails not affected.
Fingers symmetric and sausage shaped.	Fingers clubbed at the end.
Administration of thyroid extract is of the smallest benefit.	Thyroid treatment of the greatest benefit.

A skiagraphic examination is of great value in doubtful cases, as enlargement of the sella turcica will usually be found.

The **prognosis** is hopeless for cure and doubtful for duration. The disease is progressive, although it remains stationary for a longer or shorter

period. Retrogression never occurs. Ordinarily the patient dies of some intercurrent condition, although death may be due to the cachexia of acromegaly itself. Life, however, may last for twenty years after the appearance of the first symptoms.

Medical treatment of the condition has proved unavailing. Extracts of both thyroid and pituitary glands have been used with not encouraging results. Removal of the pituitary gland, if the seat of tumor, has been done with good results in some cases. The cephalalgia can be more or less completely controlled by antipyrin or caffeine. Phosphorus, mercury, the iodids, and arsenic have been useful in some cases.

ADIPOSIS DOLOROSA

This disease was first described by Dercum, of Philadelphia, in 1888. It may be defined as a condition in which masses of fat are deposited irregularly in the subcutaneous tissue of the body, with tenderness and spontaneous pain in these masses, and derangement of the menstrual functions. Several cases, including the one first described by Dercum, have been examined post-mortem, and a variety of changes have been found. The fat is usually denser than ordinary fat, due to the presence of a considerable amount of fibrous connective-tissue trabeculae. The thyroid glands are sometimes small and sclerotic, and, in the case recorded by Burr, there was a tumor of the pituitary body. Many of the symptoms suggest hypopituitarism. The cutaneous nerves show a moderate amount of degeneration, sometimes associated with interstitial neuritis. The main nerve-trunks are usually normal. Hemolymph-glands have been found in the fatty tissue.

The **etiology** of the condition is unknown. It has been ascribed to an early climacteric, and to the changes in the thyroid gland, but it is not understood how either condition could give rise to the clinical feature of adiposis dolorosa. It occurs almost exclusively in women.

Symptomatology.—Some time in adult life the patient begins to grow stout. This condition gradually progresses, and the patient notices that the fat is more or less irregularly distributed, appearing first in one and then in another part of the body, and that in the places in which it appears there are severe pains of a burning, shooting character. Finally, the masses of fat become huge; as a result of their weight they become pendulous; they are elastic, give an indistinct sense of fluctuation, but do not pit on pressure. The skin remains soft and flexible as normal. There are no distinct evidences of muscular degeneration, but the patient becomes weak and indisposed to physical exertion. There is no disturbance of the psychic functions, but the mental processes are sluggish. The cutaneous sensibility may be slightly altered, areas of anesthesia, or particularly of hypesthesia, being found in various parts of the body. The knee-jerks are usually lost, but Romberg's symptom is not present. Death occurs as a result of some intercurrent affection.

The **differential diagnosis** is to be made from simple obesity and from myxedema. From simple obesity it differs by the fact that the fat is firmer; it is irregularly distributed; nodules appear and disappear in the skin; and particularly by the sharp pains in the fatty masses. From myxedema, by the absence of mental changes, and of tetany, and by the presence of the pains in the fatty masses. The distinguishing test is the failure to respond to thyroid medication. (See also pp. 1109 and 1169.)

The **prognosis** is hopeless for cure, but the duration of the disease is often greatly prolonged. Dercum's original case was under observation for eleven years, and then died of fatty degeneration of the heart.

Treatment is unavailing. The administration of thyroid substance appears to be of no benefit. The pains must be controlled with anodynes, employing at first the coal-tar analgesics, particularly phenacetin, which must be used in small doses on account of the chronic nature of the case, and if this is insufficient, morphin must be administered.

AMAUROTIC FAMILY IDIOCY

Tay and Sachs have described, independently, a most extraordinary disease of the central nervous system which is characterized by the occurrence, a few months or a few years after birth, of marked impairment of intelligence, and gradually progressive loss of vision. The pathology of the disease is not known. Degeneration of the cells, perivascular accumulation of round cells, and some degeneration of the fibers in the central nervous system have been found. The etiology of the disease is not understood. It is usually hereditary or familial, that is to say, several children in one family are sure to be affected. As it occurs in early life direct inheritance is, of course, impossible, but children of the ancestors have sometimes suffered from the same condition. It is also racial; all the cases hitherto recorded, with one doubtful exception, having occurred among Jews.

The **symptomatology** is as follows. The child at first develops normally, appears healthy and intelligent. Usually in the latter portion of the first year or in the early part of the second, its mother observes that it does not notice as well as formerly; that it appears to be weaker and less intelligent. It gradually becomes more and more idiotic until it is a complete imbecile, uncleanly in its habits, and at the same time the blindness progressively increases. This blindness appears to be due to a degeneration of the retina, the earliest sign being a bluish discoloration or spot in the region of the macula. The reflexes are usually greatly increased and sensation becomes generally blunted.

The **differential diagnosis** is to be made from other forms of idiocy occurring early in life. The race, the familial type of the disease, and particularly the progressive blindness, with the peculiar changes in the eye-ground, usually suffice to determine the character of the disease. (See also p. 1086.)

The **prognosis** is hopeless. The children die in the course of from three to five years.

Treatment is of no avail. Prophylaxis has been attempted, particularly by keeping the mother in good condition before and during pregnancy, and by careful attention to the health of the child during early infancy. As only a certain number of children in each family are affected, it is impossible to determine how effective these measures are. They should at least be employed in all cases in which one member of the family has had the disease. Antisyphilitic remedies are injurious.

VII. VASOMOTOR AND TROPHIC DISORDERS

ANGIONEUROTIC EDEMA

(*Acute Circumscribed Edema of the Skin; Intermittent Angioneurotic Edema; Giant Urticaria*)

Definition.—A disease characterized by the appearance of an edematous swelling of the skin or mucous membranes. In general, it is not accompanied by constitutional symptoms.

The **pathology** of the disease is obscure. It is supposed to be due either to venous stasis or to some nervous influence upon the lymph-channels, causing them to exude liquid. No lesions have as yet been described. It is a vasomotor neurosis.

Etiology.—Neuropathic heredity appears to have some influence upon the disease, but nervous manifestations in the patient himself are more important. Occasionally the condition follows infectious diseases or severe hemorrhage. The most important exciting causes are cold and emotional disturbances. The disease occurs most frequently in males, and almost exclusively in early adult life.

Symptoms.—The *edema* usually appears suddenly, is sharply circumscribed, and the skin of the affected area is slightly elevated and reddened, or else somewhat paler than the surrounding tissue. It does not pit on pressure. Ordinarily, subjective symptoms are absent; occasionally there are slight *paresthesiæ*. The edema may appear in any part of the body, but usually it is most common on the backs of the hands or legs and in the face, especially the eyelid. Occasionally it may appear upon the mucous membranes either of the lips, tongue, or glottis; in the latter situation it sometimes produces severe dyspnea, and at least in one case it has caused death. Its presence has also been suspected in the mucous membrane of the gastro-intestinal tract. Ordinarily the patient has no symptoms whatever of disease; occasionally, however, there are severe colicky pains and sometimes vomiting. In one case hematuria was observed, and in another hemorrhage from the swollen gums; of course, in the latter case the diagnosis was doubtful. Certain writers have noted eosinophilia, with or without leukocytosis. The patient may exhibit a certain degree of anxiety during the attack. Ordinarily the swelling persists a few days, and then disappears, but relapses are exceedingly common, and may recur very frequently for many years.

The **differential diagnosis** has to be made from urticaria, to which it bears a great similarity. According to Osler, giant urticaria is the same disease.

The **prognosis** is, of course, favorable for life unless edema of the glottis occurs; for cure it is more doubtful, as the disease is sometimes exceedingly obstinate.

The **treatment** consists of rest, the use of tonics particularly directed to the nervous system, and the correction of any gastro-intestinal disorder. Strychnin has proved very valuable. Atropin during the attack is also of service. If the larynx is affected, scarification of the edematous areas and even tracheotomy may be required.

RAYNAUD'S DISEASE

(Symmetric Gangrene)

Definition.—A condition apparently of vasomotor nature, affecting symmetric parts of the body, and chiefly the tips of the extremities.

Pathology.—Clinical and pathologic studies seem to show that this condition, as well as others to be mentioned under diagnosis and which are closely related, are dependent upon disease of the peripheral blood-vessels, causing deficiency of the blood-supply. This may be a vasomotor spasm or some form of endarteritis. They may also be associated with organic disease of the spinal cord, especially tabes dorsalis and peripheral neuritis.¹

The **etiology** of the condition is obscure and complex, largely, no doubt, because a number of different conditions have been confounded under this designation. The disease occurs in children and in neurotic women, less often in men. A neuropathic heredity seems to predispose to it, and occasionally it exists in connection with other nervous diseases, as epilepsy, migraine, hysteria, and mental disorders. The occurrence of paroxysmal hemoglobinuria has led to the suspicion that malaria is an etiologic factor. I am not aware, however, that plasmodia have been found in any case, and the asserted good results following the administration of quinin are insufficient to establish the contention. Syphilis and various other infectious diseases have also been mentioned as etiologic factors. The most important exciting cause is exposure to cold, although attacks may also be brought on by severe emotional disturbances.

Symptoms.—The attacks at first are paroxysmal, a typical one consisting of: first, anemia or local syncope; second, cyanosis or local asphyxia; and third, either local hyperemia or, if this does not occur and asphyxia continue, local gangrene. *Local syncope* consists in a vasomotor spasm in one or more extremities, the fingers being most frequently affected, and rarely more than one at a time. They become white, almost waxy in appearance, cold, and hard to the touch, and they may be either dry or covered with a cold perspiration. The finger is perfectly numb, but severe neuralgic pains may be felt in the arm; if the skin be pricked with a pin, no blood flows. Ordinarily this syncope disappears gradually, the reaction being accompanied by tingling and formication in the affected digit, which ultimately returns to a normal condition. *Local asphyxia* is a further stage of this condition: in this the finger is blue and swollen, and there is a sense of discomfort that is apparently due to the stretching produced by the engorged veins. The cyanotic condition may also affect the ears, toes, and the tip of the nose, and, like the preceding stage, it may disappear without leaving any trace of its existence. Patients that have reached this stage seem to be more liable to a recurrence upon slight exposure than those who only present local syncope. The attacks are more likely to recur constantly in the same digit, and not to appear first in one and then in another. During the existence of this stage a not infrequent associated symptom is *hemoglobinuria*; this is especially apt to occur in children, and has led to the suspicion of malarial influence. In some cases, when hemoglobinuria is not found, the urine contains an excess of urates. If hyperemia occurs the affected parts become bright red, which finally disappears and the normal appearance develops. If the attack lasts for several days, *trophic changes* take place in the finger-nail, giving rise to a transverse ridge, which persists until that portion of the nail has grown beyond the end of the finger. If local cyanosis, however, continues sufficiently long, *gangrenous* changes take place. These appear first as small black spots or vesicles filled with serum upon the end of the

¹ Barker and Sladen, *Jour. Nerv. and Ment. Dis.*, December, 1907, p. 745; Sachs, *Amer. Jour. Med. Sci.*, October, 1908, p. 560.

fingers or about the root of the nail; these gradually slough off, leaving a small ulcer that may slowly cicatrize. Often patients subject to recurrences of the disease show a number of cicatrices on the ends of the fingers, or if the ears are affected there may be slight shriveling of their edges. The gangrene, however, may be more severe, in which case the distal phalanges of the affected fingers may become black or dark red, covered with blebs, and finally mummified. The line of demarcation then forms, and ultimately the gangrenous portion falls off, leaving an ulcerated stump that slowly cicatrizes. This form may not be limited exclusively to the hands and feet or ears, but symmetric patches sometimes appear in the skin of the breast. During the time that the gangrene is present the patients suffer from excruciating *pains* in the limbs that interfere with sleep, often causing transient melancholia, and seeming, more than the gangrene itself, to depress the general condition. Fever is rarely present; sugar is sometimes found in the urine, but not constantly.

Diagnosis must be made from erythromelalgia; acroparesthesia (p. 1176); acrocyanosis, in which condition we have cyanosis of the extremities, often associated with gangrene and ulceration, but which differs from Raynaud's disease in not being paroxysmal; and intermittent claudication, which is characterized by muscular cramps, numbness, and transient loss of motor power dependent upon exertion (p. 1084). As has been said, all of these symptom groups are closely related, and a sharp line of demarcation cannot always be maintained. The condition of the posterior tibial and dorsalis pedis arteries should always be determined, an absent or diminished pulsation being frequently found. Cases of this type are especially prevalent among the Russian Jews, and the feet are mostly affected. They are characterized by more or less constant pain, constant coldness of the feet with local syncope, tenderness of the calves, diminution of sensibility in the feet, followed by local asphyxia and gangrene. The pain is usually relieved by allowing the feet to hang down. Buerger has applied the name thrombo-angiitis obliterans to them.¹ Diabetic gangrene with neuritis may be confounded, but examination of the urine should make the diagnosis clear.

Senile gangrene differs in its mode of onset and by its occurring in old age. Tabes dorsalis, in which these symptoms may occur, can be distinguished by the occurrence of other characteristic symptoms of that disease. The same may be said of syringomyelia. Peripheral neuritis may be sometimes difficult to exclude, especially the form known as senile neuritis, due to arteriosclerosis. If tenderness over the nerve-trunks and muscular weakness and atrophy are present, neuritis undoubtedly exists.

Leprosy may also have to be considered. Scleroderma (p. 1178) is also related to the vasomotor neuroses above mentioned, and may be mistaken for them.

The **prognosis** is favorable unless there is some arterial disease. Ordinarily they become in time less frequent and ultimately disappear, but in a few cases the tendency to recurrence is obstinate.

The **treatment** consists of improvement in the general condition during the intervals. During the attack the most effectual measures are a mild massage, the use of local lukewarm baths, and electricity very cautiously applied either by the application of the anode to the spine and the cathode placed in a vessel containing water into which the affected part is put or the high-frequency current. Nitroglycerin is sometimes beneficial. For the relief of the local syncope Cushing has devised a plan of treatment which has been successful. It consists in applying an elastic bandage to the limb tight enough to stop the arterial circulation for several minutes; it is then loosened, when

¹ *Amer. Jour. Med. Sci.*, January, 1910, p. 105.

the circulation will usually return. In obstinate cases it may have to be repeated. Pilocarpin also has been employed with good results. If the pains are very severe, they must be combated by morphin—although gangrene may occur at the site of the injection—administered hypodermically, if necessary. Sleep should be obtained by means of narcotics. The gangrenous parts should always be carefully protected by a local dressing, and surgical intervention in the form of amputation may be required. If so, it must be done high or a return of symptoms may occur.

ERYTHROMELALGIA (*Weir Mitchell*)

(*Paralytic Vasomotor Neurosis of the Extremities*)

Definition.—A disease characterized by paresthesia, redness of the skin, and by pain, usually in the toes and heels, associated with more or less severe general disturbances.

The **pathology** is doubtful—arteriosclerosis of the blood-vessels in the affected limb has been found, but the disease appears to be due to some disturbance of the vasomotor centers or nerves.

Etiology.—It may occur in association with various forms of spinal cord disease (see Raynaud's Disease).

Symptoms.—The earliest symptom, as a rule, is the occurrence of severe *pains in the feet*. Objectively, there are swelling and reddening of the skin, and the sensitiveness is so severe that the patient is unable to walk. The attacks occur more frequently during the summer months, and are always aggravated by exposure to heat or a vertical position of the limbs. Ulceration may occur.

The **diagnosis** is often difficult, the condition being confused with inflammation of the foot. Operations have frequently been performed upon these cases. A characteristic feature of the condition is that the redness and pain are excited by allowing the feet to hang down, and disappear when they are elevated (see also Raynaud's Disease). It may occur in the course of hemiplegia and in some organic diseases of the spine, and these should be excluded.

The **prognosis** as to relief is bad; often the disease will recur at irregular periods for a number of years. The attack can usually be cut short by plunging the limb into ice-cold water.

Treatment.—This should always be tonic, and employed during the intervals; massage, hot and cold douches, and the faradic current may be used upon the affected extremities. The pain may call for anodynes. Resection of the long saphenous and musculocutaneous nerves and stretching of the plantar nerves have been done with success. It has also caused gangrene.

ACROPARESTHESIA

(*Spastic Vasomotor Neurosis of the Extremities; Waking Numbness*)

Definition.—A disease characterized by abnormal sensations in the hands, slight vasomotor disturbances, and slight stiffness of the fingers.

The **pathology** and **etiology** are not understood. Those of a neurotic temperament are more liable. It is also in some cases associated with the gouty diathesis or other metabolic disturbances. It is probably a neurosis,

although in some cases there may be a neuritis. It occasionally occurs after injury or as a result of prolonged exposure to cold, hence is common among laundresses. It is more frequent among women than men, and usually develops in middle life.

The **symptoms** consist in the more or less sudden development of *formication* and *tingling* or *numbness* in the fingers and finger-tips, usually bilateral, but sometimes occurring only on one side. Less frequently the toes are affected. These pains are more severe in the night and early morning, frequently arousing the patient from sleep. The vasomotor disturbances are variable. Sometimes nothing can be observed, and sometimes the extremities are bluish and cold, sometimes pink and warm. Sensibility is rarely affected. In some cases, however, there is considerable hyperesthesia; in others moderate anesthesia. In a few cases there is stiffness of the hands. Slight *trophic disturbances* have been reported in a few cases. The attacks may last from a few minutes to several hours, and may recur frequently or only at considerable intervals. Usually during the attack the abnormal sensations are continuous, but occasionally they are intermittent in character. The condition known as *tender toes*, that occasionally occurs after an attack of typhoid fever, is probably a form of this disease. It is ascribed to the Brand treatment, but incorrectly.

The **diagnosis** is usually easy. Care should be taken, however, not to confuse these cases with commencing locomotor ataxia, subacute combined sclerosis, tetany, or hysteria. In Raynaud's disease cold increases the intensity of the symptoms.

The **prognosis** is, in general, favorable, the disease usually disappearing after some months; sometimes, however, the condition is obstinate.

The **treatment** is rather unsatisfactory. Laundresses should be advised to adopt some other vocation. Local stimulation with the faradic brush has sometimes been of value, and hydrotherapy, to exercise the vasomotor system, may also be employed. At the same time the patient should be given tonics, particularly if anemia is present, or eliminative treatment if indicated. Salicylates seem to be of service in some cases. Large doses of quinin at bedtime are sometimes useful, as is also the causing of congestion in the fingers by constriction of the arm for two or three minutes three times daily with an elastic band or Esmarch bandage. Alkaline washes are almost a specific for the tender toes. Saturated solutions of sodium bicarbonate should be employed.

MERALGIA PARÆSTHETICA

(Bernhardt's Disturbance of Sensation)

Definition.—A disease characterized by paresthesia and disturbance of sensation on the outer side of the thigh, in the region supplied by the external cutaneous nerve.

Pathology.—Nawretsky has examined one case, and found chronic interstitial neuritis. There is reason to believe that this is not always present.

Etiology.—This is very various; some of the cases have been preceded by injury, excessive exercise, or infectious disease. Alcoholism, constipation, and pregnancy are also common predisposing causes; cold douches have been blamed in several instances. Sometimes the disease is hereditary. The exposed situation of the nerve to pressure is supposed to render it more liable to this peculiar disturbance.

Symptoms.—These are of two varieties: First, the *paresthesiæ*. There may be burning, tingling, or stabbing pains that are severe enough to disable

the patient; or there may be only a feeling of cold or numbness. Second, the *sensory disturbances*. These vary from slight hyperesthesia to total anesthesia. The different senses are not always equally involved; pain, temperature, and electrocutaneous sensibility being usually more profoundly affected than the others. Frequently both thighs are affected. There is often a tender point just inside the anterior superior spine of the ilium.

The **diagnosis** is easy.

The **prognosis** is doubtful. Some of the cases recover rapidly, but the majority become chronic.

Treatment.—But little can be done. Locally, the dry brush seems to do good in some cases; the high frequency current is worth a trial. The general health should be improved if possible. In aggravated cases a portion of the nerve may be excised.

SCLERODERMA DIFFUSUM

Definition.—A peculiar hardening of the skin, with areas of pigmentation and depigmentation, associated in the more advanced stages with trophic lesions, muscular atrophies, and affections of the bones.

Pathology.—The affected skin is characterized by an increase of the connective tissue and of the elastic fibers, and by a narrowing of the vessels as a result of perivascular infiltration.

The **etiology** is not clear. Some of the cases are associated with joint affections that resemble those of chronic rheumatism; others follow exposure to a very low temperature. The presence of trophic lesions in the skin and the development of myopathies lead to the supposition that it is properly classed with the trophoneuroses. The disease usually occurs in middle life, although cases have been observed among children. Women are more frequently affected than men.

Symptoms.—Three stages are recognized: *First*, a rather dense edema. *Second*, a true sclerosis, in which the skin appears thicker, with an absence of the normal folds; it becomes firm and hard, so that it cannot be pinched between the fingers and lifted from the flesh. Moreover, there are always *pigmentary changes*, certain parts being darker than normal, while others become a dead white, appearing almost as if composed of alabaster. The disease, as a rule, attacks first the upper portion of the body—*i. e.*, the face, neck, hands, and arms, or the surface of the thorax—and is most pronounced in those regions where the bones are subcutaneous. The *diminished elasticity* considerably interferes with the movements of the body. If the neck is affected, it is difficult to turn the head; if the skin over the joints is involved, their normal flexion and extension cannot be perfectly performed. The subjective sensations are those of tension, the patient complaining that the skin has become “too small” for him. If any forcible action is attempted, there is severe pain, accompanied by slight tears in the skin. The skin is paler and cooler than normal, and the slightest exposure to cold causes great discomfort and cyanosis. The secretion of sweat may be normal, but is usually diminished. Tactile sensibility is unimpaired. The *third stage* is that of atrophy; the skin becomes thin as paper; the other symptoms, however, remain as before, except that the secretion of sweat is abolished and *ulcerations* appear that either heal slowly or not at all. In addition, there are muscular atrophies associated with contractures. Often there is considerable *atrophy of the bones*, or there may be a development of exostoses from the periosteum (sclerodactylia). Occasionally

the end-phalanges of the fingers undergo a process of gangrene that is similar, in some respects, to that of Raynaud's disease. *Chronic joint affections* may also be observed in this stage, particularly of the fingers (see Morphea).

The **course** of the disease is variable. Usually it develops slowly and lasts for many years.

The **diagnosis** is usually easy, though occasionally it has been confused with *Addison's disease* on account of the excessive pigmentation. There is, of course, some resemblance to *Raynaud's disease*, although the condition of the skin itself is very different. In the atrophic stages it may be confounded with xeroderma pigmentosum.

The **prognosis** is always doubtful. In the later stages the patients become emaciated, and pass into a cachectic state, in which death may occur. Pulmonary complications may develop. Complete cure may, however, occur, and particularly in cases that have a rapid course.

The **treatment** is unsatisfactory. The unpleasant tension of the skin may be somewhat diminished by ointments and massage; warm water or steam baths may also give considerable relief. The most important thing is to maintain the general condition of the patient by tonics and a change of climate. Sodium salicylate has been recommended, but is probably valueless. Thiosinamin hypodermically may prove to be of service.

MORPHEA

(*Scleroderma Circumscriptum*)

This disease consists of the development of *small areas of sclerosis* of the skin that are distinctly related to the distribution of the nerves. These areas are round or oval, brownish or violet in color, and as they increase in size there develops in their centers more or less sclerosis. In these sclerotic areas there are often punctiform collections of pigment, the hairs fall out, and superficial ulcerations may be present. Occasionally they may go on to atrophy of the skin. There are no constitutional symptoms.

The **diagnosis** is usually easy.

The **prognosis** as regards life is favorable; as regards cure it is doubtful.

The local **treatment** is the same as for the diffuse form of scleroderma.

AINHUM

This is a disease characterized by an enlargement of the little toe and the formation of a line of demarcation at its base.

The **pathology** is not known, but it appears from a roentgen-ray picture that the bones are absorbed. There is some dispute as to whether it is one of the manifestations of leprosy or not. At any rate, it does not appear that typical lepra bacilli have been found.

Etiology.—The disease may occur in childhood or early adult life, and is most common in negroes. It occurs almost exclusively in tropical regions—*e. g.*, Brazil and Syria.

The **symptoms** of the condition consist in the formation of a *furrow* at the base of the little toe of one of the feet. This grows deeper and deeper until spontaneous amputation has occurred. Rarely the other toes on the same foot become progressively involved. Certain *vasomotor disturbances* may be ob-

served; the foot is usually swollen, bluish red, and cold; sometimes the other foot may exhibit similar changes without the formation of furrows at the base of the toes. There is some *diminution of sensation* to touch, temperature, and electricity, and ordinarily the patient complains of vague pains in the limbs.

The **diagnosis** is to be made from leprosy, with which, indeed, it may be identical, and congenital amputation; the latter only occasions difficulty when the disease commences in early life.

The **prognosis** is favorable to life, but the disease is usually slowly progressive.

No effective **treatment** has been discovered but the parts should be protected against injury, and the patients may be given tonics and anodynes as required.

PROGRESSIVE HEMIATROPHY OF THE FACE

(*Progressive Facial Atrophy*)

Definition.—A rare disease, characterized, as its name would indicate, by a progressive atrophy of one-half of the face, stopping sharply at the middle line, and in the severer forms involving the skin, muscles, and bones.

The **pathology** of the condition is unknown. Rarely symptoms indicating inflammation of the cervical sympathetic, such as dilatation of the pupil or flushing, have been present, and symptoms indicating inflammation of the trigeminus have been equally infrequent. Mendel, however, has reported a case in which he found chronic interstitial neuritis of the branches of the trifacial, and other cases have been reported in which the gasserian ganglion was diseased. Microscopic examination has shown a disappearance of the subcutaneous fatty tissue and a general atrophy of the elements of the skin itself, often associated with the presence of an abnormal quantity of pigment. As a rule, the vessels are relatively enlarged.

The **etiology** is unknown. The condition usually commences early in life and shows no predilection for either sex. An hereditary tendency does not appear to exist, but the disease occurs frequently as a complication of, or rather in connection with, other neurotic conditions. Of these the most frequent are neuralgia, migraine, epilepsy, and mental disorders; less frequently, tic convulsif and chorea, particularly if the latter affects the muscles of the jaw and tongue. Occasionally it has been recorded as occurring in patients suffering from syringomyelia, locomotor ataxia, or multiple sclerosis. It does not appear, however, that progressive facial atrophy has any anatomic connection with these conditions. In a few cases the disease has been preceded by an injury to the skull or face, and in others it has followed an acute infectious disease. Ordinarily it occurs in early life—*i. e.*, between the tenth and fifteenth years—and in these cases it usually progresses to the most severe type.

The earliest **symptom** is a flattening of the skin on the affected side, constituting the lightest form of the disease, which may remain stationary at this point; if, however, it progresses, the muscles and bones also become involved, so that the affected half of the face is distinctly smaller than the healthy side. The objective changes that take place in the skin are the development of *white spots* in which the pigment has disappeared, and which have the appearance almost of scar-tissue, or, what is more commonly the case, of an increase in *pigmentation* with a formation of yellowish or brownish blotches, the skin being depressed in these areas, which usually lie along the course of the nerve-trunks, especially the infraorbital. The *hair* becomes thinner, dryer, and often falls out. The secretion of the sebaceous glands is diminished and the skin dryer.

Rarer phenomena are the *disturbance of blushing*, so that the affected side of the face remains unchanged in color when, as a result of some emotional disturbance, the other is distinctly reddened. Disturbances of sensation are not common. In some cases electric and tactile sensibility have been diminished; in others the patients have complained of slight paresthesiæ. The special senses remain unaffected, and even when the atrophy extends to the tongue, taste remains perfect on the affected side. In one case there were a slight disturbance of hearing and occasional tinnitus.

The **diagnosis** of the condition is easy both when it is suspected and when it is far advanced. The only condition with which it could be confounded is congenital facial asymmetry. In facial hemiatrophy, however, the skin is shrunk and wrinkled, and the hair is dryer and thinner, contrasting markedly with the healthy side, and there is usually a history of commencement some years after birth. In congenital asymmetry the difference between the two sides is slight, and the skin over the smaller side is normal in every respect. Commonly in this condition we also find differences in the development of the extremities. In a case that I recently observed with marked facial asymmetry, the left side being smaller, the hand and foot on the same side were distinctly smaller than the corresponding members.

The **prognosis** is unfavorable as regards cure. The disease itself is not in the least dangerous, and cases have been recorded that have been under observation for thirty years or more.

Treatment is unsatisfactory. The prolonged use of electricity has been said to arrest the process, and sometimes this arrest occurs spontaneously; it is not certain that the treatment is of any use.

An allied condition is **hemihypertrophy of the face**. This is an exceedingly rare condition, and is apparently always congenital. It involves chiefly the soft parts, the ear, skin, tongue, and tonsils being all enlarged. There is an increased secretion from the sebaceous glands, which may appear as small elevations upon the skin. Usually, as in congenital asymmetry, there is enlargement of the extremities on the same side. The only case that has come to autopsy presented no lesions.

Treatment is, of course, unavailing.

PART XI

DISEASES OF THE MUSCLES

MYOSITIS

RHEUMATIC myositis and the suppurative form observed in pyemia, and rarely in other acute infectious diseases, have been appropriately described in connection with the diseases to which they are secondary manifestations. There remain to be discussed two rare forms of the disorder.

INFECTIOUS MYOSITIS

(*Acute Polymyositis*)

Definition.—A primary acute or a subacute inflammation of the voluntary muscles due to an unknown microbial agent.

Pathology.—The disease is a true inflammation of all the voluntary muscles, involving chiefly the muscular fibers, and to some extent, also, the interstitial connective tissue. Beginning with marked hyperemia, there next occurs an exudation of leukocytes. The muscles are hard, fragile, and later undergo fatty degeneration. Serous infiltration occurs and there is a slight hyperplasia of the intermuscular connective tissues. Hueppe records a case that showed nothing definite beyond a hyaline degeneration of the muscular fasciculi.

Etiology.—We are no less ignorant of the predisposing influences than of the specific exciting agency, though, perhaps, young males are most often the victims of this malady.

Symptoms.—As a rule, first the muscles of the extremities, and later of the trunk also, become swollen, firmer than normally, and stiff, rendering locomotion somewhat difficult and painful.

The involved parts may also be tender to the pressing finger, and a slight edema may be noticed that is at first more or less localized, but finally becomes generalized, and extends even to the face. An erythematous eruption then appears, which is irregularly disseminated over the skin surface, and may tend to more or less pigmentation. Moderate pyrexia and splenic enlargement are among the early and constant symptoms. In the advanced stage the muscles of deglutition and of respiration become involved, rendering the act of swallowing difficult, and inducing marked dyspnea.

Among the *complications* may be enumerated bronchitis and bronchopneumonia, the latter often being a terminal condition.

Diagnosis.—Taken in the aggregate, the symptoms are of little diagnostic importance and the previous history is invariably negative. *Trichiniasis* must be discriminated, since this disease produces an identical clinical picture. The distinction may rest upon the examination of an excised piece of affected muscle, which will not only discover the trichinæ, if present, but also enable the microscopist to detect the positive evidences of polymyositis. *Multiple neuritis* presents neither swelling nor edema.

Course and Prognosis.—The course of the disease may either be comparatively rapid (two or three months), or it may be slow (chronic) and

continue over two or three years. It usually terminates in death, which is caused, in the immense majority of cases, by paralysis of respiration. Occasionally, since the heart muscle has been sometimes found to be implicated, the end may be preceded by cardiac failure.

The **treatment** is simply palliative and supportive.

PROGRESSIVE OSSIFYING MYOSITIS

Definition.—Myositis, either general or local, in which the affected muscles undergo progressive ossification.

Pathology.—Following the changes that ordinarily characterize myositis (swelling, leukocytic exudation, etc.), a calcification that is often complete takes place. The process may extend to and involve the heart.

The **etiology** is obscure, though males are especially the subjects of the complaint, which usually begins about the time of puberty.

Diagnosis.—The muscles are represented by plates of bony hardness, leading to more or less complete ankylosis of the joints and vertebræ.

The **course** of myositis ossificans is very slow, and **treatment** has afforded only negative results.

MUSCULAR DYSTROPHIES

Definition.—These are hereditary affections characterized by progressive muscular wasting beginning in certain groups of muscles, which is sometimes preceded by or associated with apparent hypertrophy of other muscles, without fibrillary tremors and marked change in the electric reactions. They are also known as myopathies.

Etiology.—The only factor known is the influence of heredity, the disease running through a number of generations. It usually appears before puberty, but may develop later.

Morbid Anatomy.—In the early stages true hypertrophy of muscle-fibers may be found. Later, proliferation of the muscle nuclei and longitudinal splitting of the fibers, with an increase of connective tissue which takes the place of the degenerated muscle-fibers. A marked deposit of fat is present in the pseudohypertrophic type. The nervous system is normal.

Symptoms.—A number of clinical types have been described, depending upon the muscles first affected, occurrence or not of apparent muscular hypertrophy, and the age at onset. They may all more or less overlap. They are:

1. Pseudomuscular hypertrophy of Duchenne.

- (a) Leyden-Moebius or hereditary type.

2. Erb's juvenile or scapulohumeral type.

3. Landouzy-Déjérine type, or infantile progressive muscular atrophy of Duchenne or the facioscapulohumeral type.

PSEUDOHYPERTROPHIC MUSCULAR PARALYSIS

Symptoms.—This form usually appears under the age of ten. The enlargement, as a rule, affects the muscles of the calves of the legs, although various muscles in other parts of the body may be involved, as the infraspinatus and masseter, or the muscles of the arms and thighs, giving the patient the appearance of an unequally developed athlete. With this may be associated atrophy of the latissimus dorsi, lower part of the pectorals, and muscles of the upper arm and thigh. The electric reactions show no qualitative alteration, but are quantitatively diminished in proportion to the loss of power. This loss of power is manifested first in the gait, which is uncertain and wad-

dling; next, by the difficulty the patient has in arising from the ground. He first gets on his hands and knees, then lifts his knees from the floor and, placing his hands first on his ankles, climbs up his legs until he assumes a more or less upright position (Fig. 79). In the later stages of the disease the volume of the muscles becomes less than normal. At this period contractures may occur leading to the development of club-foot or of lateral deviation of the spine. Lordosis may also be produced by weakness of the muscles of the back, and the spinal column, being no longer properly supported, may topple to one side or the other. Ultimately the patient may lose all power in the affected limbs and pass into a cachectic state, in which he dies. Few ever reach adult life. Some of the cases, however, seem to be milder in character, and may amount to nothing more than a slight weakness, which persists throughout life, but does not seriously inconvenience the patient. Often signs of intellectual disturbance are present, the patient learning more slowly and showing an impaired intellectual co-ordination. At other times epilepsy may be present. A peculiar

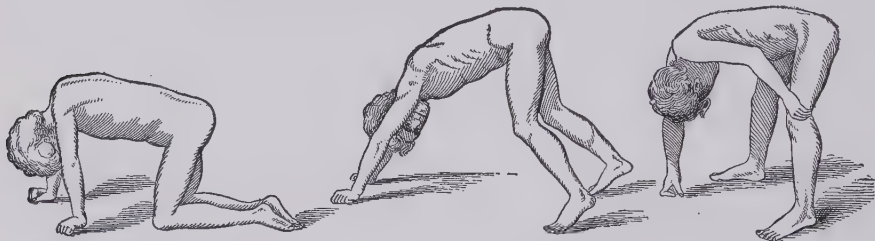

Fig. 79.—Mode of rising from the ground in pseudohypertrophic paralysis (Gowers).

variety is known by the French as *forme fruste*; this is characterized by a rapid atrophy of the hypertrophied muscles, and consequently the course of the disease is more severe.

HEREDITARY MUSCULAR PARALYSIS (*Leyden-Moebius*)

This commences in children, and usually between eight and ten years of age. It affects the muscles very much as they are affected in the pseudohypertrophic form, except that there is no increase in size. The disease is markedly hereditary in type.

SCAPULOHUMERAL OR JUVENILE TYPE (*Erb*)

Symptoms.—This type may appear as late as twenty years of age. The muscles first affected are usually the pectorals and the latissimus dorsi. From these the process rapidly extends to the muscles in the neighborhood—*i. e.*, the serrati and the muscles of the back. The muscles of the upper arm and thigh are usually most involved. Those that are most likely to escape are the sternomastoid, the spinati, deltoid, and those of the forearm and leg below the knee. The extensors of the wrist and fingers and the tibialis anticus and peroneal group may, however, eventually become affected. The muscles gradually waste, and the wasting is accompanied by a corresponding loss of power, a diminution in the reflexes, and of the electric reactions. Reactions of degeneration are not present. Certain peculiar appearances are produced by the atrophy of certain of the groups of muscles. As the shoulder-blades are no longer supported, they stand out from the back, giving rise to the so-called “winged” appearance, and as the result of the weakness of the muscles of the back lordosis is exceedingly common. Weakness of the muscles of the back, and particularly of the glutei, causes the patient, when he rises from the stooping posture, to go through the same actions that are carried out by children

suffering from pseudomuscular hypertrophy—*i. e.*, climbing up his own legs. Motion is affected proportionately with the degree of atrophy. The gait is disturbed and becomes waddling, due to the alternate lifting of the sides of the pelvis in order to clear the foot of the ground. Sensation is never disturbed. The sphincters are not involved and bulbar symptoms do not appear, even late in the disease.

FACIOSCAPULOHUMERAL TYPE (*Déjérine-Landouzy*)

Symptoms.—This type usually develops about the third or fourth year. The disease usually begins in the muscles of the face. Of these, the muscles about the angle of the mouth first undergo degeneration, giving rise to a peculiar expression, caused by the lips protruding (tapir mouth); the under lip drops forward and downward; the upper lip is wasted and expressionless; all wrinkles disappear, and the patient has a peculiar and strikingly stupid expression. The ordinary movements of the face are considerably affected. Whistling cannot be accomplished and speech is imperfect. Otherwise the course of the disease is that of the scapulohumeral type.

The **diagnosis** is to be made from the *spinal* and *neural forms* of muscular atrophy and from the *congenital absence* of certain groups of muscles. From the two first-mentioned forms it can readily be distinguished by the fact that the hand becomes involved, if at all, in the last stages of the disease; also by the absence of the reactions of degeneration and of muscular twitching. It is also diagnosed from the neural type by the absence of disturbances of sensation. From the congenital absence of certain groups of muscles the diagnosis is sometimes difficult, for, curiously enough, the groups of muscles affected are usually the same as those affected by the myopathy. A distinction can be made partly by the history, partly by the more efficient and perfect compensatory hypertrophy of the muscles that remain.

The **course** of the disease is slowly progressive, only occasionally exhibiting a temporary arrest.

The **duration** is variable, but patients may live thirty or forty years after the first symptoms appear.

The **prognosis** is, of course, hopeless as regards cure or improvement. As regards existence, however, it is the most favorable of all the forms of progressive muscular atrophy—a fact that is probably due to the ability of the patients to walk until the very last stages of the disease, so that they are able to maintain a better physical condition.

The **treatment** is the same as that for other forms, and consists of electricity, massage, and especially of systematic gymnastics. Children born of dystrophic parents should be guarded carefully, their nutrition being maintained at the highest possible point and physical strain avoided. Mothers so affected should not suckle their children.

MYOTONIA ATROPHICA

This rare condition is characterized by weakness and atrophy of the facial muscles resembling that found in the facioscapulohumeral type of dystrophy. The sternomastoids, vasti of the thighs, and dorsal flexors of the feet are also usually affected, as may also other muscles. With this there is a slow relaxation of certain muscles after contraction, the stronger the contraction the slower being the relaxation. In some instances cataract developing early in life has been a symptom. It may be a familial disease.

ARTHRITIC MUSCULAR ATROPHY

Pathology.—It has frequently been observed that after inflammation of a joint the muscles that move it have undergone a certain degree of atrophy. This usually occurs in the extensors, and is severe in proportion to the duration of the inflammation. Microscopic examination of the muscles shows a rather uniform diminution in the breadth of the fibers, as well as a slight proliferation of the nuclei and occasionally an indistinctness of the striation. The nerve-trunks and cord have been reported to be normal.

The **etiology** of the condition is not clearly determined. It has been supposed to be due to disuse, but if such were the case all the muscles moving the joint would be equally affected. Moreover, it sometimes occurs too rapidly to render this explanation acceptable. It has also been supposed to be due to the extension of the inflammation either to the nerves or directly to the muscles, but the other symptoms of neuritis are rarely present. Finally, Vulpian has suggested that it is of reflex origin, and this hypothesis is most generally accepted.

Symptoms.—The wasting usually occurs very rapidly after the onset of the joint affection. The muscles show a diminished contractility to faradism. and galvanism, but the reactions of degeneration do not occur. Occasionally there is fibrillary twitching. The mechanical irritability of the muscles is greatly increased, and the reflexes show a corresponding exaggeration, ankle-clonus being frequently observed when the knee- or ankle-joints are affected.

The **diagnosis** may be readily made upon the existence of the joint affection, the local character of the muscular atrophy, and the absence of degenerative reactions with increased mechanical irritability.

Prognosis.—Ordinarily, as soon as the joint has recovered, improvement commences in the muscles and progresses rapidly to complete restoration of function. In some cases, however, atrophy persists, and in a few instances secondary contractures take place.

The **treatment** consists, first, in the removal of the cause by the cure of the articular condition; second, in gentle massage and electric stimulation of the muscles. As a rule this should not be commenced until the joint is well.

MUSCULAR ATROPHIES

These may also occur as a result of other conditions, such as direct injury, fracture of the bones, or prolonged work with a single group of muscles, but they scarcely demand separate description. On the other hand, *muscular hypertrophy* may occur, though rarely.

THOMSEN'S DISEASE

(*Myotonia Congenita*)

Definition.—An hereditary disease of the muscles in which the groups that have been contracted by a voluntary influence remain for a short time in a state of contraction, and then relax slowly.

Pathology.—Certain authors have described alterations in the terminal nerve-plates in the muscles, but it is difficult to determine whether these alterations are artificial or an actual part of the disease. The peripheral nerves are normal. The muscles themselves exhibit the following alterations: The muscle-fibers are, on the average, of an increased transverse diameter—*i. e.*, the smallest are the size of ordinary muscle-fibers, and the largest about twice

the size. There is also a distinct and considerable increase in the number of nuclei. The protoplasm is not so clear as in normal muscles, but shows a fine granular cloudiness, rendering the striation less distinct. Occasionally the muscle-fibers are vacuolated. The connective tissue between the muscle-fibers is normal.

Etiology.—Hereditary influence is the most important factor in the causation of the disease. Thomsen, who was himself a victim, has been able to trace the disease for five generations in his own family. Occasionally a generation is skipped. Other factors that have been supposed to act as predisposing or exciting causes are prolonged exertion (a case having developed in a man without myotonic antecedents after two years of severe exertion) and emotional disturbance of the mother during pregnancy. Exposure to cold, and fright, and a neurotic temperament have also been accused of exerting a predisposing or exciting influence. The disease is somewhat more frequent in males than in females, usually develops in early life, is often associated with manifestations of mental disturbance, and occasionally occurs in those whose ancestors have exhibited lesions of the nervous system other than myotonia.

Symptoms.—The chief symptom of the disease is the so-called myotonic contraction. If the patient, after a period of rest, attempts to set a certain group of muscles in action, the first contraction is made, but is not followed by relaxation for a considerable interval—sometimes as much as half a minute; during this period the muscles remain in a state of tonic contraction. Thus, if the patient attempts to shake hands, he clasps the other hand strongly, and the clasp persists. When he lets go, it is seen that a slight degree of tonic contraction still exists, for it is impossible for him to straighten out his fingers immediately. Upon a repetition of the movement the tonic contraction recurs, but not so strongly, and if the repetition is continued, it disappears entirely, so that the muscular system of the patient behaves in all respects like that of a normal person, and long walks or other severe muscular exertion may be undertaken. In some cases practically the whole muscular system is affected, although, excepting the muscles of mastication, the muscles of the face usually escape. In others the disease is limited perhaps to the upper, perhaps to the lower, extremities. In the former condition the patient may, upon an attempt to make a vigorous motion after resting, suddenly become rigid and fall to the earth with considerable force, often injuring himself severely. He will then lie upon the ground perfectly conscious, but incapable of relaxing his muscles. When the disease, as is more frequently the case, is limited to the lower extremities, the chief disturbances observed are in walking. The first step is accomplished, whereupon the patient halts, both legs having become fixed; after a time they relax and another step is taken. The period of delay is now much shorter, and after a few more steps disappears entirely. The severity of the contraction is diminished by moderate exercise, heat, and tranquillity of the spirits, and is increased by excitement, cold, and fatigue. The muscles of deglutition and the sphincters and the muscles belonging to the non-striated muscular system are never involved. Pain is not present, except perhaps a slight sensation of cramp, nor are there disturbances of sensation. Mental disturbances are frequent, and have been ascribed to the anxiety occasioned the patient by the disease. They consist of irritability, the avoidance of society, and sometimes of melancholia. The reflexes show various modifications; the knee-jerks may be either normal, increased, diminished, or absent. The most important pathognomonic symptoms are the alterations in the electric reactions of the muscles. The changes are as follows: Mechanical irritability of the motor nerves is normal or diminished; but of the muscles it is increased, and so modified that the contraction instead of being sudden is

slow, with a long tonic after-contraction. The fardiac irritability of the nerves is normal, and faradic excitation of the muscles produces a tonic contraction of long duration. The galvanic irritability is quantitatively increased and qualitatively altered; that is to say, ACC is equal to and sometimes even greater than KCC. All the contractions are slow, tonic, and of long duration. Finally, the application of the constant galvanic stream gives rise to rhythmic contractions that pass along the body of the muscles in slowly moving waves at the rate of about one to three per second. Occasionally qualitative galvanic alterations have been observed in the nerves. Finally, the appearance of the patient is of some value. The muscles are developed almost as much as those of an athlete, without a corresponding increase of power.

The **diagnosis** is usually easy, and particularly if it be possible to examine the electric reactions. The condition might possibly be confounded with *pseudohypertrophic muscular paralysis*, in which the muscles are also considerably developed; but instead of being normal they manifest greatly diminished power and fail to give a myotonic reaction. From *tetany* the condition may be distinguished by the absence of Trousseau's sign, by a briefer period of tonic contracture, and an absence of severe pains. From *spastic paraplegia* and *Little's disease* it may be distinguished by the fact that in these diseases the spastic conditions are permanent and do not disappear after exercise. From *occupation-neuroses* it may be distinguished by the fact that the cramps only appear upon the performance of a certain peculiarly co-ordinated movement. From *hysteria* it is differentiated by the absence of stigmata and the care a hysteric patient exhibits to avoid injury to himself, and by the peculiar electric reaction. Myotonia atrophica resembles it (p. 1185).

The **prognosis** is hopeless. The disease commences in early life and continues until death, with more or less frequent remissions and exacerbations. It is possible that these remissions may be permanent, and one case has been reported of a young woman whom marriage greatly benefited. The disease is rarely dangerous to life, except in so far that those who suffer from it are much more liable to injury.

Treatment is exceedingly unsatisfactory. Practically nothing can be done, although in a few cases systematic stimulation of the muscles has produced some mitigation. The patients often learn methods by which they can at least diminish the unpleasant symptoms. Certain movements seem to prevent or shorten the period of tonic contraction. Of course exposure to cold or emotional disturbance should be avoided as far as possible.

MYATONIA CONGENITA

(*Amyotonia Congenita*)

This disease, first described by Oppenheim in 1900, occurs in early childhood, and is characterized by a more or less general hypotonia of the muscles. There is flaccidity of the limbs, especially the lower, and all of the joints are abnormally movable. Muscular power is much diminished. The deep reflexes are either diminished or lost. The electric reactions are either quantitatively diminished or lost. The mental faculties are not impaired. The fact that it is a congenital but not a hereditary disease distinguishes it from the dystrophies. It differs from amaurotic family idiocy in the absence of blindness and mental impairment. In Spiller's¹ case disease of the muscles was found,

¹ *Univ. of. Penna. Bull. Med.*, January, 1905.

and there was also a lesion of the thymus gland. Oppenheim believed it to be due to an arrested development of the muscle.

The disease is not necessarily fatal, and measures to improve the nutrition of the muscles (massage, electricity, etc.) may be of service.

MYASTHENIA GRAVIS

(*Asthenic Bulbar Paralysis*)

The exact classification of this disease is still a matter of dispute. The only definite changes that have been found are the electric reactions in the muscles. It is characterized by progressive weakness in the muscles, an increased susceptibility to fatigue, and the occurrence of the myasthenic reaction. The **etiology** is unknown. Possibly infectious processes may have something to do with it; but it bears no definite relation to syphilis. Pathologic changes have not been found. Pemberton has suggested that it is a derangement of metabolism evidenced by an increased calcium and reduced creatinin output. The muscles of deglutition, mastication, and speech, and the group of muscles controlling the eyes are particularly affected; sometimes one group, sometimes another being first involved. The muscles of the body also become weaker. There may be dyspnea, and even difficulty in walking. The most peculiar feature is the rapidly developing fatigue in the muscles when they have been used. Thus, if the patient attempts to lift the arm a number of times, each successive motion will be weaker than the previous, until finally complete paralysis ensues. If the eyes have been held open for any length of time the upper lid will droop until there is a transient but complete ptosis. The muscles also exhibit the so-called *myasthenic reaction*. Upon repeated application of the faradic current the muscles contract less and less vigorously, until finally the capacity for contraction appears to be exhausted, to return after a period of rest.

The **course** of the disease is variable. There are remissions more or less complete and prolonged, but ultimately the patient dies of progressive exhaustion or of increasing dyspnea. Occasionally patients have strangled while attempting to swallow. It has been noticed in women that the symptoms are always increased during menstruation.

The **diagnosis** is to be made from bulbar paralysis. The symptoms resemble each other very closely. In bulbar paralysis there is usually complete reaction of degeneration in the affected muscles. The myasthenic reaction is absent, and in the unaffected muscles the susceptibility to fatigue is not particularly increased. If the patient has been observed for any length of time, the remissions in the course are in favor of myasthenia. In poliomyelitis superior or acute lesion of the oculomotor nuclei, the sudden onset and permanent weakness also serve to make the distinction.

Treatment appears to be entirely without avail. Strychnin hypodermically appears to be useless; electricity is harmful. Full doses of calcium salts may be tried. The patient should be put absolutely at rest, and all sources of worry should be avoided. If there is difficulty in swallowing, the stomach-tube may be employed with advantage.

PART XII

THE INTOXICATIONS; OBESITY; HEAT-STROKE

THE INTOXICATIONS

ALCOHOLISM

(*Alcoholic Inebriety*)

Definition.—An acute or chronic intoxication due to the abuse of alcohol. It is a general degenerative condition, particularly of the brain and nervous system, characterized by a moderate (often progressively increasing) or excessive, continuous or periodic, craving for alcohol, leading to drunkenness. Alcoholism is often simply a variety of *inebriety* or *narcomania*, a congenital or acquired brain and nervous disease, characterized by a resistless, permanent desire for alcohol (*alcoholic inebriety*). *Mania-a-potu*, or “crazy drunkenness,” is an acute maniacal condition occurring in an alcoholic drinker of a neurotic constitution. *Delirium tremens* is a hallucinatory manifestation that occurs in habitual drinkers of alcohol, either as the direct consequence of the long-continued action of alcohol on the brain, or because of its sudden withdrawal in an inebriate. *Dipsomania* is an alcoholic insanity in which an intense maniacal “drink-impulse” occurs in a periodic drinker (usually of spirits).

Pathology.—In cases of death from **acute alcoholism** the brain and kidneys are found to be greatly engorged with blood. The gastroduodenal mucous membrane is also markedly congested, injected, and covered with a thick, sticky, blood-tinged mucus.

Chronic Alcoholism.—Since alcohol is physiologically a poison, and not a food, and essentially a drug, and not a drink, the effects of its habitual ingestion are directly to produce degeneration of nearly all of the bodily tissues, and indirectly to increase the liability to many diseases by lessening the systemic powers of resistance, thus favoring fatality from such disease. The degree of pathologic change depends upon the innate vigor of the tissues, the age at which indulgence in alcohol is commenced, and upon the kind, degree of concentration, and the quantity of alcohol habitually taken. Ethylic alcohol is less deleterious than the “fusel oil” that is sometimes used as an adulterant in spirits.

The chief effects of chronic alcohol-poisoning are seen in the nervous and digestive systems, and in the kidneys. Fatty changes are prominent in the malt-liquor intemperates, while a connective-tissue overgrowth predominates in spirit-drinkers. The mucosa of the stomach presents the appearance of chronic gastric catarrh. Dilatation of the stomach is common in free drinkers of beer, ale, and porter. The liver shows the changes of chronic congestion, of fatty infiltration or degeneration, or of cirrhosis and contraction. The renal changes are analogous to those of the liver, the chronic congested (“pig-

backed") and fatty kidneys occurring mostly in cases due to malt liquors, while the sclerosed and fibrous kidneys are seen in spirit habitués. The heart is often loaded with fat, and the muscular structure may reveal fatty degeneration, being pale, flabby, friable, and dilated. The blood-vessels are atheromatous, thickened, tortuous, and sometimes varicose, and sudden death has been caused in inebriates by the rupture of small aneurysms of the middle cerebral artery. In the brain the various stages of sclerosis, with shrunken, narrow, and flattened convolutions often appear. Chronic pachymeningitis, with slight hemorrhages, is not infrequent. The pia-arachnoid membrane also may be opaque and thickened, and serous effusions into the subarachnoid space and into the ventricles have been noted. The nerve-cells, nerve-centers, and nerve-fibers show degeneration, hardening, and atrophy. Alcoholic neuritis is especially prominent in many cases.

Etiology.—An impaired personal health and vigor, as well as the "personal equation" and a deficiency of will-power, self-control, conscience, and conviction, are *predisposing causes*. Drunken or inebriate parents frequently transmit to their offspring a morbid desire for alcohol, and an environment of depraved morality and of depressing and corrupting social influences are usually potent disposing influences, particularly in those who are ill prepared, by heredity or training, to resist the temptation and insidious activities of such evil surroundings. Some assert that poverty predisposes to intemperance: it is more likely to be the cause rather than the consequence of poverty. The *exciting cause* is the persistent misuse of alcohol as a beverage in the form of distilled liquors or spirits, wines, and fermented or malt liquors. "In this country there is a little appreciated but not uncommon cause of alcoholism in the use of patent medicines and nostrums as tonics and cure-alls" (Lambert).

The **symptoms** of acute alcoholism range from mild intoxication to an acute delirium or a profound stupor and coma. It begins with the stage of *vascular relaxation* and of feelings of warmth and exhilaration, due to the depressing and paralyzing effects of the alcohol upon the vasomotor tone. The second stage is one of *partial functional paralysis of the nerve-centers*, marked disturbance of the faculties, muscular inco-ordination, and delirious speech. In the third stage, of "dead-drunkenness," there are acute coma, stertorous breathing, a bloated and congested face, a slow and full, but weak, pulse, a cold and clammy skin, a heavy alcoholic odor of the breath, and, sometimes, incontinence of urine and feces. It frequently happens that unconsciousness is not so profound but that the patient may be aroused, though replies to questioning are stupid and incoherent. Ordinary acute alcoholism seldom passes beyond a stage of exhilaration, ending in mild narcosis. Sometimes, however, the irritant action of the alcohol predominates over its narcotic action, giving rise to acute alcoholic gastritis or nephritis.

Acute mental disorders (*acute alcoholic insanity*) are not infrequently met with. *Mania-a-potu* may come on quite suddenly in debauchees, or in those who have drunk hard during a short time, as in a night's carousal. The mental excitability increases until a violent maniacal storm not unlike the mania of epilepsy possesses the drinker. While in this state of infuriated delirium homicide may be committed. Tremors are absent. *Acute alcoholic melancholia* develops suddenly in some cases, with a suicidal tendency. *Delirium tremens* is more common in alcoholic inebriates, and is also seen at times in those who drink greatly to excess, but are not habitués. Convulsive seizures have been noted in some cases, interrupting the coma ("acute alcoholic epilepsy"); these may or may not be accompanied by mania. An *acute alcoholic paralysis* from multiple neuritis (occasionally with ataxic symptoms) may attack hard drinkers, and may last for several weeks or months.

Chronic alcoholism (alcoholic inebriety) I consider a true disease. While acute alcoholism may also be an occasional manifestation of the chronic affection, it is often a vice which, if indulged in to an excessive degree, or if too frequently repeated, becomes a disease, though it is difficult to determine at what point the transition occurs. Again, it is not always easy to learn whether the early acute alcoholic excesses are really vices or morbid, diseased cravings for alcohol in hereditary narcomaniacs. The disease of inebriety (alcoholic) is a condition in which, as some one has said, it is not whether one "cannot" or "will not," but in which one "cannot will" to resist the desire for alcohol.

The steady, so-called "moderate drinker" who saturates his blood and tissues every day for years is much more apt to suffer from chronic alcoholic poisoning with its attendant degenerations than one who goes on a "spree" once a month for a day or two, and during the intervals is free from the toxic influence of alcohol. The *symptoms* develop very gradually, and are usually marked for some time by the deceptive sensation of stimulation, warmth, and well-being, due to the vasomotor paresis and the anesthetic effects of the alcohol. Impairment of digestion is early noted. There are a coated tongue, foul breath, vomiting before breakfast, and gastric distress after eating. Gastritis and achylia, caused not only by the alcohol but also the irregular meals and habits of life of the addicts, are present as a rule. Constipation alternating with diarrhea is common. Muscular tremors gradually develop and often progress into an ataxic gait. Insomnia, mental impairment, and blunting of the moral sense come on. "Alcohol dims the perception, confuses the judgment, paralyzes the will, and deadens the conscience" (Kerr). In his distress and degradation the inebriate seeks to relieve himself by taking more of the alcohol, only to find, on awakening from his narcosis, that body, intellect, will, and emotion are still more depraved. In fact, the brain and nerve disorders are more grave, permanent, and extensive in the majority of instances than those of the viscera. This is owing to the delicacy of the nervous mechanism and to the ready degeneration under the influence of the altered blood, and the consequent impaired cellular nutrition, directly due to the toxic action and deficient normal pabulum, and indirectly to the lessened elimination of waste products.

Dementia is often the terminal state of the chronic inebriate. Delusions of persecution are frequent, especially those of marital infidelity, in alcoholic insanity. The depurative organs manifest various symptoms due to the long-continued irritating action of alcohol. The liver is either fatty and enlarged, or cirrhotic and contracted, and jaundice, dropsy, and hemorrhoids, along with physical hepatic signs, are correspondingly observed. The watery eye, the injected conjunctivæ, the swollen eyelids, the bloated and flabby or pallid and shrunken face, the dilated capillaries of the nose (*acne rosacea*) and cheeks, may now be seen. The urinary examination will show in many cases the deranged function of the kidneys and point to the nature of structural impairment. On account of the weak and flabby heart there are palpitations, dyspnea, and precordial distress, and occasionally sharp pains. Chronic valvular endocarditis may be discovered. The pulse is soft and weak in beginning fatty degeneration of the vessels. Thickened arteries are common in old cases, and the pulsations are often increased in tension and usually rapid. Muscular capacity and endurance are greatly diminished.

Delirium tremens occurs in the majority of cases in inebriates or chronic drinkers during or after a debauch, and particularly from the use of spirituous liquors. It may occur, also, during abstinence from alcohol, on account of some mental perturbation, or fright, accidental shock, or acute inflammatory illness. It may either come on suddenly, or be preceded (often for a day) by some slight

premonitory symptom, as anorexia, restlessness, or depression of spirits. The patient usually awakens at night with a tremor, becomes sleepless, wants to get out of bed to do some imaginary thing, talks constantly and incoherently, looks about uneasily and fearfully, and breaks gradually into a cool perspiration. Hallucinations of sight, hearing, and smell develop. The patient sees terrifying and loathsome reptiles, and tries to escape from them, or to clutch them in order to cast them away. The "horrors" may become so great that suicide may be attempted, as by falling out of the window. Auditory hallucinations may take the form of enemies, policemen, or the roar of wild animals. The muscular tremors increase, the pulse becomes frequent and weak, and the tongue coated with a thick white fur. There is moderate fever, which, if the delirium is prolonged, takes on a typhoid character, the tongue becoming tremulous, dry, brown, and fissured, with the onset of subsultus tendinum, carphologia, coma-vigil, and muttering delirium. In favorable cases improvement begins on the third or fourth day, from which time the symptoms gradually subside. Convalescence may be said to be established when restful sleep can be obtained; this is followed by a desire for food. In unfavorable cases the patient may pass from a typhoid state into exhaustion and death, or may die suddenly either during a paroxysm of cardiac failure or from some complication, as cerebral hemorrhage or pneumonia.

Kosakow's psychosis, or the mental symptoms that may occur in connection with alcoholic neuritis, is described on page 1022.

Diagnosis.—The condition of persons found dead-drunk is seldom mistaken for any other. The reverse more often happens, and in this way *apoplectic* and *uremic comas* may be diagnosed as alcoholic coma. Cases picked up in the street in a state of apparent unconsciousness should be carefully tested in this regard. Instances in which, as the *postmortem* examination subsequently has shown, cerebral hemorrhage has followed a drinking-bout, render the diagnosis more difficult; in such the patient should be given the benefit of the doubt and handled as though the case were one of apoplexy. An important early step is to ascertain whether the coma is complete, or whether the patient can be roused by shouting in the ear, by applying ammonia to the nostrils, or, better still, by pressing, with gradually increasing firmness, over a sensitive spot, as the supraorbital notch; if the unconsciousness is alcoholic, he will come to his senses, if only for a moment. Abstemious apoplectics have been known to stagger and talk thickly, like drunken men (Kerr), and have been arrested and taken to a police station instead of to a hospital. *Congestion and lobar pneumonia* affecting the bases of the lungs should be looked for, as they are common causes of death in drunkards. A table giving the principal points in the differential diagnosis will be found under Uremia (*vide* p. 942).

The diagnosis of chronic alcoholism is made from the history, and from the muscular tremors (worse in the morning), vomiting, mental restlessness, "mendacity," and involuntary "lying" (Kerr). The condition may resemble general paralysis, and if the habits of the patient are kept secret it may be very difficult to differentiate these affections. A prominence of disorder of the digestive tract usually points to alcoholism. Nervous excitement, tremors, fear, wakefulness, and the distinctive physiognomy are more evident in chronic alcoholism, even when general paralysis has been caused by alcohol, which is apparently the case. *Paralysis agitans*, *locomotor ataxia*, *epilepsy*, and *nervous dyspepsia* may also be mistaken for chronic alcoholism by the unwary.

Delirium tremens is distinguished by the history, by the restlessness, delirium, hallucinations, tremors, and terrors. *Mania-a-potu* differs from the preceding mainly in its usual association with acute alcoholism in neurotics, in the muscular contractions, the furious mania, and convulsive movements.

The delirium of *apical pneumonia* that obtains in some cases (as well as in meningitis) must be thought of in the diagnosis of delirium tremens. The diagnosis of *alcoholic neuritis* from other conditions simulating it will be found elsewhere (*vide* p. 1022).

Prognosis.—In acute alcoholism the prognosis is favorable in private, manageable cases. Many of the cases brought into hospitals are affected also with pneumonia, and usually die. The tissue changes in chronic alcoholism are so profound, and they affect such delicate and vital tissues, that when the alcohol habit thus becomes fixed permanent recovery never takes place. The treatment appropriate for the inebriate and forced abstinence from alcohol relieve many of the symptoms and some of the debility, but relapses are all too common and are almost certain to occur. Insanity and paresis are not infrequent terminations of chronic alcoholism. Many complications are apt to supervene, as Bright's disease, epilepsy, melancholia, fatty heart, pneumonia, and thrombosis. Alcoholic neuritis often clears up upon withholding alcohol and stimulating the peripheral nerves both by appropriate drugs and external remedial measures. Recovery from delirium tremens is dubious in cases of severe injury, inflammatory troubles, or infections.

Treatment.—In cases of acute drunkenness, which are only too commonly met with, nothing special is required except to prevent the ingestion of any more alcohol and to allow the patient to sleep until the elimination of the poison is more or less complete. The effects of the intoxication, in the general depression, headache, anxious and irritable stomach, and various functional visceral and nervous disorders, may need careful corrective and sustaining treatment for a week or more. The diet should be light and nutritious. Aperient waters, hot baths, with liquor ammonii acetatis frequently repeated, and a combination of dilute mineral acid and bitter tonics (nux vomica, gentian), are also indicated.

In profound cases of alcoholic coma, convulsions, or mania-a-potu no alcohol should be given. Trite though this injunction may seem, it is important to emphasize this statement, so that the physician may be sure to counteract a popular impression that the giving of more alcohol will cause a mania to subside *permanently*, and to guard against the smuggling of liquor to the patient by his misguided friends. It is often necessary to empty the stomach at once when collapse is imminent by the use of the stomach-tube or pump, washing out the organ with hot water, to which ginger or cinnamon has been added. To this end emetics may be used—viz., ipecac or apomorphin, hypodermically (gr. $\frac{1}{8}$ to $\frac{1}{6}$ —0.008–0.01). The external application of warmth, friction, artificial respiration, faradism to the phrenic nerve, ammonia or amyl nitrite inhalations, and hypodermics of atropin, strychnin, and digitalis, may all be tried. Hot rectal enemata or a calomel purge, if the stomach will tolerate the drug, should be used early. The maniacal attacks may be treated by hypodermics of morphin and hyoscin, and by such sedatives as chloral, bromids in large (3j–4.0) doses, and rarely such hypnotics as paraldehyd, trional, chloralamid, and the like. Indeed, it is very important to secure sleep as soon as possible. As soon as some quietude and sleep have been obtained, it is in order to administer concentrated food in an easily assimilable form.

The treatment of *chronic alcoholism* is more often best conducted in "homes" for inebriates, in hospitals, and similar institutions. A. Lambert believes that the majority of periodic drinkers who are endeavoring hopelessly to cease their periodic sprees are really cases of chronic tobacco poisoning (*e. g.*, incessant cigarette smokers). At the outset there must be an "unconditional surrender" in the use of alcohol. Its withdrawal should be enforced at once in many cases, and very rapidly in all others, according to the judgment of the

physician as to the psychic and physical condition of the patient. Substitutes for alcohol are the strong fruit-juices, as hot lemonade or hot ginger, capsicum infusion, and cardamom tea often is useful. Coffee, milk, cocoa, and hot broths are also to be recommended. The diet should be carefully increased in nutritive strength as the gastric irritability diminishes. Sometimes such sedatives to the stomach as the bismuth preparations, effervescent alkaline drinks, and lime-water may be indicated. Peptonized food is often well borne at first in cases in which gastric distress is marked. Nutrient enemata are seldom required, but should be resorted to in the gravest cases, particularly during the states of alcoholic dementia. The general health must be looked after by placing the patient in the best of fresh air, exercise, cold and warm bathing, by mental and social occupation, and by diversion. When the craving for alcohol is hereditary and intense, seclusion in an inebriate-house or some similar institution is often necessary for a long time to lessen the danger of lapsing into the former drink habit.

The insomnia of chronic alcoholism may be met temporarily by the use of large doses of bromids, chloral, or hyoscin. Morphin may be indicated at times, but should be used with great caution in order to avoid adding the morphin habit to that of alcohol. Perhaps the best single agent to use in counteracting the symptoms of chronic alcoholism is strychnin, either as the nitrate or sulphate, hypodermically and by the mouth; iron, arsenic, dilute phosphoric acid, quinin, and the like are often useful adjuvants in the tonic treatment. Atropin, hypodermically, may also be recommended when vascular dilatation and weakness are prominent. Sweating and purging the patient, and the administration of bromids, chloral, and gelsemium for a day or two in advance may avert a "drink-storm" or the periodic cravings for alcohol that may be expected by prodromal manifestations. Sometimes, however, as in the sudden outbursts of dipsomaniacs, there is no time to institute their treatment. It is claimed that hypnotic suggestion will abolish effectually the ardent desire for alcohol in a certain number of neurotic cases of alcoholic inebriety. Temperance revivals may be said to do permanent good only in those similar neurotic cases that are fortunately impressionable to appeals by total abstinence orators, but, in order to maintain the reformed drunkard's pledge, it is often necessary that interested persons continue to watch, guide, and inspire him, in order that a weakened will may not precipitate a cyclic lapse into his old habits.

All the influence of culture, music, and the fine arts, of high-toned morality and pure, undefiled religion, should be enlisted to strengthen self-respect and to fortify volition and inhibition. Moral regeneration may thus in certain cases check the physical and mental degeneration, but it cannot efface the consequences of the alcoholic poisoning which it represents.

McBride recommends the following method of treatment: Hypodermic injections of strychnin three times daily, at first $\frac{1}{60}$ grain, increased to $\frac{1}{30}$ gr. by the end of the first week, and at the same time hypodermic injections of atropin are given, which are rapidly increased until the patient's tongue is made dry and the pupils dilated. A bitter mixture containing cinchona, gentian, rheum, capsicum, and more atropin and strychnin is also given six times a day. During the first week, usually during the first days, all taste for alcohol is lost. During the second week this treatment is continued, but during the third the injections of atropin are gradually diminished, and, finally, stopped, and the capsicum is withdrawn from the mixture taken by the mouth. Thus modified, the treatment is continued during the fourth week. At the end of that time the atropin is withdrawn from the mixture and the latter is given four instead of six times daily. During the sixth week the injections

of strychnin are reduced and stopped. At the beginning of the week the cinchona is also withdrawn. The author necessarily varies this treatment with the requirements of individuals. The Towns-Lambert method of treatment enjoys an enviable reputation at present writing. In treating an alcoholic, however, the details differ from those suitable in morphinism, as shown by Lambert.¹

Delirium tremens requires firm but tactful isolation and vigilant nursing. All alcohol should be withheld. If stimulation is needed, aromatic spirits of ammonia; strychnin, and atropin, with bland hot drinks and broths, may be administered. Easily digested and nutritious food should be given to support the strength. Sleep must be procured by such means as are mentioned above in the treatment for *mania-a-potu*. The dosage required, however, is usually not as great, but must be kept up longer than in the maniacal condition. Cardiac weakness may need such stimulants as digitalis and strophanthus. Steinebach² has found the symptoms to be relieved by lumbar puncture. Leonard corroborates this experience. After removing spinal fluid (10 to 40 c.c.), a cubic centimeter for every 25 pounds of body weight of a 25 per cent. solution of magnesium sulphate, at a temperature ranging between 95° and 100° F., was introduced by means of a cubic centimeter syringe, through the lumbar puncture needle, in the sitting posture. No patient received a second treatment. The delirium and restlessness rapidly subsided, with restoration to the normal within twenty-four hours. Out of 12 patients treated, 10 recovered. Based on the theory that the severer types are caused by an acid intoxication, Hogan attempts to dilute and neutralize the effects of this intoxication and favor its rapid elimination. Two solutions, one composed of sodium bicarbonate and sodium bromid, the other of glucose, are both given intravenously for the purpose.³ After the attack subsides, tonic doses of strychnin, gentian, asafetida, and iron, together with graduated exercise out-of doors, are to be employed. Turkish baths, industrial occupations, and the like are indicated to fortify the patient against yielding to a morbid appetite.

GINGER AND COLOGNE-WATER INEBRIETY

Habitual drinkers of alcoholic ginger, capsicum, and lavender preparations, and eau-de-Cologne are practically alcohol habitués or inebriates. They drink these liquids for the alcohol that is in them. The so-called essence of ginger (Jamaica ginger), which contains considerable alcohol in some of its preparations, is often used primarily for relieving an attack of "cramps" or "colic," and if frequently repeated, can readily induce a morbid habit of "ginger-drinking." In other cases the craving for alcoholic indulgence (often hereditary), may have been aroused by a social glass of wine, but, from a sense of shame the desire has been kept secret, and gratified by drinking eau-de-Cologne, lavender essence, or even tincture of capsicum. Perhaps many more such cases exist, and especially among neurotic women in good circumstances, than are usually recognized.

OPIUM-POISONING

Definition.—A chronic intoxication due to the habitual use of opium (*opiumism*) or its alkaloids.

Pathology.—In cases of death from acute or chronic opium- or morphin-poisoning there is nothing distinctive in the pathologic appearances. In acute

¹ *Jour. Amer. Med. Assoc.*, February, 18, 1911, p. 503.

² *Deutsch. Med. Woch.*, 1915, xli, 369.

³ For further details, *vide Jour. Amer. Med. Assoc.*, December 16, 1916, p. 1826.

cases vascular congestion of the brain and membranes has been noted; but even in chronic cases the tissue degeneration and fatty and connective-tissue proliferations that are characteristic of alcoholism, are practically absent. Decided lesions are usually traceable to associated affections. The principal anatomic changes are those due simply to malnutrition. Thus, we have the emaciation and the shrunken appearance of cerebral anemia, and pallor and atrophy of the cardiac muscle and of the vascular walls. The dried and wasted structures, due to tissue starvation, are quite a contrast to the fat-infiltrated or degenerated, cirrhotic, and inflamed tissue of alcoholic inebriety. Direct destruction of parenchymatous cells is more evident in the latter.

Etiology.—The climate, country, and nationality have a certain disposing influence in the development of opiumism and morphinism. In the opium-growing parts of Asia, as in China, India, and Persia, where the climate is warm, enervating, and conducive to physical and moral abandonment during the greater part of the year, and in Turkey also, opium-eating and -smoking habitués are as numerous as alcohol habitués are in Europe and America among the Caucasians.

Women are more commonly the victims of morphinism than men, except physicians and druggists as a class.

Ennui and an idle spirit of irritation and adventure among the sensation-loving and luxurious sometimes sow the seeds of an indulgence in narcotics that bring forth fruitage in the form of a fixed habit.

The incautious prescribing of morphin and the too ready hypodermic use of the alkaloid by physicians in treating various cases of pain are not infrequently the cause of morphinism. Overwork of the brain, great business or social strains, prolonged worry and anxiety either with or without work, insomnia, remorse, idleness, and secret vices, are the most common predisposing agents of the morphin habit.

Paregoric, laudanum, chlorodyne, and "soothing-syrup" are drunk to a frightful extent in large cities among the poor and miserable, and cause great disturbance of the health of the habitués. Heroin is being used to an alarming extent in spite of all efforts to limit its sale.

Symptoms.—These may be in abeyance for some time, while the habit is forming and the doses are still slight. As the craving increases, the dose and its frequency increase to keep pace with the desire. Anemia gradually develops, with sallowness of the skin, wasting of the features and body, languor, weakness, functional deterioration, mental depression, anorexia, restlessness, insomnia, tremors, irritability, shyness, dilatation of the pupils (except when under the influence of the drug), and a characteristic propensity to lying. Cardialgia is often complained of by those who use opium pretty constantly. The associated vices of opiumism are less violent and inflammatory than those of alcoholism, and more secretive and speculative, such as gambling and sexual perversions. Itching is frequent, and especially after taking the opium or morphin. Attacks of chills, followed by pyrexia, with delirium and transient albuminuria (renal congestion) occur in some cases. Diarrhea and dysentery have been observed in some instances. There may be also disturbances of the visual muscular apparatus. Sufferers from painful carcinoma in whom opium or morphin is required for steady use do not become, except in rare cases, true morphinomaniacs.

The *course* of morphinism is that of a progressive asthenia, in which cardiac palpitation, dyspnea, abdominal and muscular cramps, trembling, fear, sleeplessness, mental confusion, melancholy, slovenliness, and moral obtuseness come on. Some women, known to be kleptomaniacs, have been found to be secret opiumists. Sexual impotence in the male, and amenorrhea and abortion

in the female, are common results. The skin is wrinkled, dry, and harsh, and may show numerous needle-scars and abscesses in those addicted to the hypodermic use of the drug. The *termination* is the direct result of the extreme debility or marasmus or of some intercurrent affection.

The **diagnosis** must be made from the history. When the latter is wanting because of a lack of veracity or deception, *chronic alcoholism* may have to be differentiated from opiumism. The more open and often periodic habits of the alcoholic habitu  , and the general aspect of the physical and mental and complicating conditions, usually show marked differences between the two drug intoxications.

Prognosis.—The likelihood of a cure is exceedingly remote. On the other hand, under proper conditions much relief may be given and life prolonged for years. Opium smoking produces less injurious consequences, and is more readily cured than other forms of the addiction.

The **treatment** is manifestly difficult and unpromising. Institutional isolation, rest, diversion, watchful care, regular and studied feeding, baths, and graduated exercise in the open air as far as possible, but under surveillance in order to prevent the smuggling of opium, morphin, heroin, or compound preparations containing them, are the most efficient measures. As to the manner of withdrawing the narcotic, much care, judgment, and tact form a *sine qu   non* in the treatment. A sudden and absolute stoppage of the use of the drug sometimes leads to great distress, and even to collapse ("abstinence phenomena"); it is, therefore, not to be recommended, as in chronic alcoholism. On the other hand, the too gradual withdrawal is torturing. A middle course, the "rapid-gradual method" of Erlenmeyer, is usually resorted to, in which the reduction of the quantity of morphin or opium to nothing occupies but a week or ten days. Various substitutes have been recommended that generally prove not to be substitutes at all, but simply act in a symptomatic way, and may lead to another habit as bad if not worse. Such drugs as cocain, hyoscyamus, bromids, and chloral have thus been used. Hare and others have reported good results from the method of treatment suggested by Lott, namely, by the use of hyoscin hypodermically in large doses (gr. $\frac{1}{100}$ —0.0006 every two hours) until the patient is rendered calm or even unconscious, after which this state is to be maintained for several days and then the dose is to be gradually diminished so as to permit a return to the normal condition. Cardiac stimulants may be needed. The Towns-Lambert method of treatment is now widely adopted, and the results which have been recorded in literature are most promising.¹

In the symptomatic treatment of the morphin habit moderate doses of bromids, with cannabis indica and some such vegetable bitter as gentian, may prove useful in allaying the nervous irritability and restlessness at night. Cathartics, stomach sedatives alternating with tonics, concentrated foods, massage, hot and cold bathing, electricity (general galvanization), and "complete control over the patient" are usually indispensable adjuncts in the treatment after the withdrawal of the opium or morphin. Cardiac stimulants, strychnin and physostigmin salicylate (gr. $\frac{1}{100}$ —0.0006) hypodermically, have been recommended recently as important in counteracting the functional depression of these habitu  s. Industrial activity, and mental and social diversion aid in maintaining any improvement made and in rendering the patient less liable to a relapse.

¹ For details, see *The Jour. Amer. Med. Assoc.*, February 18, 1911, p. 503.

PLUMBISM

(Chronic Lead-poisoning; Saturnism)

Definition.—A chronic intoxication due to the slow absorption of lead, either industrially or accidentally.

Pathology.—The principal lesions are found in the muscles, peripheral nerves, liver, kidneys, and mucous membranes. The affected muscles are wasted, pale-yellow in color, and, in advanced cases, show a marked fibroid growth. The vessels in the muscles also reveal arteriosclerosis. The peripheral nerves are affected with a parenchymatous neuritis, and are especially involved, with degenerative changes in the nerve-endings in the muscles. The nearer we approach the spinal cord along the course of an affected motor nerve, the less marked are the changes, although in some cases a very slight involvement of the anterior nerve-root cells has been noted. The cord is usually normal.

In the brain, slight meningitis and arteriosclerosis of the cerebral blood-vessels here and there, with a corresponding connective-tissue growth and capillary hemorrhages. The liver and kidneys show parenchymatous atrophy and cirrhosis.

Etiology.—(a) *Personal susceptibility* to lead-poisoning is greater in some people than in others, all other things being equal. (b) Plumbism is more common in *adults* than in *children*, because of greater exposure. (c) *Sex.*—Women are more susceptible than men. (d) *Occupation* is the most frequent cause of lead-intoxication. Workers in white lead (plumbic carbonate), red lead, and litharge, all of which substances are used as paints, are especially to be mentioned as liable to saturnism. Among the most common industrial causes are the following: painting, plumbing, lead-mining, rolling sheet-lead, pottery glazing, type-founding and setting, shot-making, dressmaking (in which lead-dyed silk thread is used and the ends bitten off), lace-making, glass-grinding, and calico-printing. (e) Accidental contamination of food and drink. Men employed in the manufacture of white lead and eating lunches in dusty work-rooms suffer from plumbism. Drinking-water stored in lead-lined cisterns, and passed through lead pipes is frequently contaminated, especially if the water contains a slight amount of acid. Flour, bread, biscuit, candy, butter, and milk may cause poisoning by adulteration with lead chromate, used to give a rich, yellow tint to these articles; and tobacco wrapped in lead-foil has resulted in saturnism. (f) Workers in lead suffer more frequently during the warm season. (g) Previous attacks greatly increase susceptibility.

The *absorption* of the lead takes place mainly through the gastro-intestinal tract, including its inhalation as dust, followed by swallowing, and absorption from the skin or an abraded surface. It may be deposited in most of the soft tissues and viscera, but especially in the nerves, muscles, and liver. *Elimination* takes place through the kidneys, and probably, though in very slight quantities, with the bile and saliva, and through the skin.

Symptoms.—Depending upon individual susceptibility, it may be months or years before the first manifestations appear. *Anemia* is an early and marked symptom. The red cells and hemoglobin are reduced correlatively. Boston, in the study of 24 cases, found the leukocytes to number between 10,000 to 23,000 per cubic millimeter; an average of 12,600. The erythrocytes are pale, distorted, and show evidence of punctate basophilic degeneration. Grawitz and Frey regard polychromatophilia as an important blood finding (Need). The general nutrition is poor.

The characteristic *blue line* at the borders of the gums is rarely absent, especially in those who are not scrupulous in their attention to the teeth.

It is, as a rule, most distinct at the roots of the lower canines and incisors, and is formed by a deposition of lead sulphid. Bluish patches may also be met with. Gowers points out that this line is black instead of blue, and is present only when the gums are slightly separated from the teeth. Slight jaundice may at times be noted.

Colic is very common and is also characteristic. The pains center around the navel, and are quite severe and griping. They are associated with retraction and rigidity of the abdominal walls, and with obstinate constipation. The pains are paroxysmal, may be referred at times to the epigastrium, and may be accompanied by vomiting. Between the paroxysms a dull pain usually exists over the whole abdomen. During the attacks the pulse-tension is increased and cardiac action lessened. The stomach contents show no HCl as a rule.

Exaggerated tendon reflexes may be present early. *Paralyses* are common symptoms, and may either be acute, subacute, or chronic in nature. Although usually localized, palsies are sometimes generalized. The most characteristic lead-palsy is that known as *wrist-drop* (see also Multiple Neuritis, p. 1022). Both fine and coarse *tremors* occur. They usually begin in the hands and arms, are rather constant, and are aggravated by *voluntary effort* and emotional excitement.

Cramps in the affected muscles and about the joints (*lead-arthralgia*) are occasionally noted. Slight anesthesia, especially in cases of wrist-drop, is sometimes detected here and there, but may in certain instances be due to saturnine hysteria.

The *cerebral symptoms* are important. The phrase "lead encephalopathy" includes such manifestations as delirium and coma, neuroretinitis, aphasia, convulsions, hemiplegia, amaurosis, hysteria, and insanity. The delirium and coma are the commonest brain symptoms, and may come on suddenly with tremors and hallucination. Epileptic convulsions are often severe. Hemianopsia has been observed. Mania and melancholia occur in cases of mental unbalancing, and hysteric outbreaks are seen in girls. Intense headache is not uncommon. "Saturnine gout," so called, is described as a result of chronic plumbism. The kidneys are contracted, the heart is hypertrophied, and arteriosclerosis is marked, with a diminution in the excretion of urea and uric acid. The pulse-tension is increased. These evidences show a similarity to gout, and favor the development of uratic deposits in the joints. Lead may be discovered in the urine by laying a strip of magnesium in it and noting the deposit of metallic lead if present (Von Jaksch). Abram asserts that the addition of a solution of ammonium oxalate (1 gm. to 150 c.c. of water) facilitates the test. Hematoporphyrin may be found in the urine.

Diagnosis.—The history of exposure to lead-poisoning is usually clear in those working the metal in its various forms. *Accidental origins* of saturnism are often obscure and very difficult to trace, although if the characteristic wrist-drop, the gingival line, colic, and cachexia be present, the diagnosis is readily made.

Alcoholic paralysis of the lower extremities may be differentiated by the history, the greater prominence of sensory symptoms, and by the absence of the blue line on the gums, and of punctate basophilia.

Prognosis.—In the absence of the graver nervous, arterial, and renal symptoms, the prognosis is good. When there is paralysis, with reactions of degeneration, and especially in primary atrophy of the muscles, the prognosis is generally bad. In encephalopathic forms, and in cases in which arteriosclerosis and renal cirrhosis are manifested, the prognosis is unfavorable, but

depends upon the extent of damage done. Pulmonary tuberculosis often complicates lead intoxication.

Treatment.—The prevention of plumbism is difficult in lead-working establishments, owing to the carelessness and indifference of both employers and employees, and to the lack of any adequate antidote during exposure. Rigid cleanliness is absolutely necessary, especially of the hands and nails and before eating. Means to allay dust should be regularly and constantly employed. Milk and sulphuric acid lemonade have been recommended for use by workers in lead, for their supposed antidotal effects. As perfect ventilation as possible should be secured, and respirators are in use in some lead-works, being worn as “snouts.” Potassium iodid should be given in chronic plumbism, beginning with small doses (gr. iii to v—0.2–0.3), given preferably in milk, after meals.

In *lead-colic* hot applications to the abdomen and hypodermic injections of morphin and atropin are often indicated. Efficient doses of Epsom or Glauber’s salts are used to combat the constipation. Given in combination with dilute sulphuric acid (in order to form an insoluble lead sulphate) and with belladonna, the best and speediest benefits may be obtained thereby.

Iron for the anemia, strychnin and galvanism for the paralysis, mild diuretics for the renal deterioration, and nitroglycerin or sodium nitrite for the arteriosclerosis (enough to relieve increasing tension) are the symptomatic items of treatment that are usually indicated. Rarely, hopeless cases of saturnine encephalopathy need to be sent to asylums for the insane.

ARSENICISM

(*Chronic Arsenic-poisoning*)

Definition.—A chronic intoxication resulting from the gradual absorption of arsenic.

Pathology.—The peripheral nerves show a degenerative neuritis, and the anterior horns of the spinal cord may be similarly affected.

Etiology.—The causes of arsenicism may be habitual, industrial, medicinal or accidental, and individual predisposition varies. A neurotic diathesis usually underlies the habit of “arsenic-eating” in those who crave the drug. Not a few women suffer from chronic arsenicism as the result of the ingestion of arsenic “to improve the complexion and brilliancy of the eye.” Men employed in arsenic works of various kinds often suffer from the chronic poisoning. For example, miners and smelters of arsenic pyrites, dyers and wall-paper workers using Scheele’s or Schweinfurth’s green, artificial-flower makers, shot-makers, glass-workers, and taxidermists, are all liable on account of their occupations. The medicinal use of arsenic, even for a short time, may in very susceptible persons induce arsenical paralysis (Putnam, Osler). Again, “cancer cures” containing arsenic may cause poisonous effects. Accidental arsenicism may come from living in rooms where wall-paper, carpets, colored paper ornaments, toys, or curtains are contaminated with arsenic anilin dyes. Drinkers of beer may suffer, the arsenic being derived from the sulphuric acid used in manufacturing the glucose that is employed in its manufacture.

Symptoms.—There are anemia, loss of flesh and strength, dryness and irritation of the mucosæ, of the eyes, nose, throat, and upper respiratory tract. Anorexia, nausea, and diarrhea indicate the presence of a gastrointestinal catarrh. In some cases, milder than others, the fat is well preserved. Slight puffiness of the eyelids or eyebrows may occur, and some epigastric distress may be complained of. Marked conjunctivitis, occasional dysenteric attacks, loss of the hair, and numbness and tingling in the extremities form a

commonly observed symptom group. Cutaneous symptoms may appear, as pigmentation ("arsenic bronzing"), keratosis, and eczematous, herpetic, urticarial, and pemphigoid manifestations. Albuminuria with casts and blood mark the renal irritation that sometimes occurs. A high blood-pressure is frequently seen.

The most characteristic evidence of chronic arsenic-poisoning is seen in the gradual increasing diffuse or multiple neuritis. Differing from lead-palsy, the leg-extensors and the peroneal group of muscles are involved first, although the arms may also become affected later (*vide* Multiple Neuritis, p. 1022). Contractions in the lower and a finer tremor of the upper extremities are apt to occur. Arsenic-poisoning may also cause headache, vertigo, melancholia, and hysteria. The drug is eliminated by the kidneys and may be found in the urine. Sometimes a great toleration of arsenic is observed in workmen and habitués, the only evidences being a clear, sallow, waxy complexion, a gloomy expression, and some dyspepsia, perhaps, as in the well-known Styrians.

Diagnosis.—This is not difficult when once the source of the poisoning is determined. The clinical appearances are distinct from *lead-intoxication*, especially in the mode of progress of the paralysis, and in the more marked sensory symptoms combined with the motor disturbances of arsenicism. Arsenic should be sought for in the urine.

The **prognosis** is favorable in most cases in which removal from the exposure to the influence of arsenic is possible. A few cases die from the great general debility.

Treatment.—Abstention from the use of arsenic for cosmetic purposes, avoidance of its influence in the arts, care in its medicinal administration, and prophylaxis as regards the possible or discovered sources of contamination, form the first considerations in the treatment. Elimination of the arsenic may be promoted by the use of potassium iodid and purgatives. Gastro-intestinal and other irritations must be met by appropriate sedative remedies. The neuritis and palsies require—as soon as the tenderness and pain subside—massage and electricity. Judicious and wholesome alimentation and tonics are indicated.

MERCURIALISM

(*Chronic Mercurial Poisoning*)

Definition.—A chronic intoxication caused by the habitual ingestion or combined industrial absorption of mercury in susceptible individuals.

Pathology.—No marked pathologic changes have been noted in human beings aside from the evidences of oral, gastro-intestinal, and renal irritation and inflammation. It is not improbable that the cerebral cortical areas suffer more from metallic irritation than do the spinal or peripheral nerve tissues.

Etiology.—Some persons are much more easily mercurialized than others. (a) *Salivation and stomatitis* from the therapeutic use of mercury form a variety that is less frequent than formerly. (b) *Industrial origin.* The chief cause of chronic mercurialism is the inhalation of the vapor of the metal by artisans in the industries in which it is used. Thus miners and smelters and those engaged in making mirrors, barometers, thermometers, amalgams, felt hats, vermilion pigment, and artificial teeth sometimes suffer from chronic mercurial poisoning. It should be pointed out here that mercury is volatile at ordinary temperatures, and is absorbed into the blood through the lungs, digestive tract, and skin. Calomel vapor-baths have caused poisoning in a few cases. (c) Purely *accidental* mercurialization also occurs. (d) Women and children are

more susceptible to the action of mercury than men. In all cases the mercury exists in the tissues as an albuminate.

Symptoms.—There are anemia, emaciation, gastro-intestinal disorders, stomatitis, salivation, maxillary necrosis, ulceration of the gums, loosening of the teeth, fetor of the breath, marked tremors, and paralysis. The oral symptoms are not as prominent, however, as in acute mercurial poisoning. The hair falls out, the nails become brittle, and pigmentation of the skin is seen.

The *tremor* is characteristic. It is first felt or noticed in the tongue and lips, is usually fine, later coarse and choreiform, and spreads gradually throughout the muscular system. It is aggravated by voluntary effort, and may cease during sleep in mild cases. Speech is altered. Hysteric tremors may also exist. Great irritability and restlessness are common. Aphasia, hemiplegia, hemianesthesia, and peripheral neuritis with palsies, occur. There is no atrophy, nor are the reactions of degeneration present in the paralyzed muscles. Severe pains may be present in the extremities, including the joints, and grave cerebral symptoms occasionally develop (stupidity, headache, loss of memory, insomnia, hallucinations, delirium, coma, convulsions, and confusional insanity). Albuminuria with anasarca may occur. The effects of chronic hydrargyria in women upon their offspring are also important, the children being rachitic, weak, sickly, and prone to tuberculosis.

Diagnosis.—The history, the characteristic tremors, paresis, and mental irritability are significant. In the absence of a history of exposure to mercury, the differentiation from *progressive general paresis*, *disseminated sclerosis*, or *paralysis agitans* may be more or less difficult.

Prognosis.—Recovery is common upon the removal of the source or on removing the patient from the source of the poisoning. Fatal terminations rarely ensue, and then in cases of mercurial encephalopathy of a grave type and with a tendency to idiocy.

Treatment.—Prevention of further poisoning is imperative, and elimination is to be promoted. Potassium chlorate, with the tincture of myrrh, and astringents are useful for the occasional stomatitis and salivation. Potassium iodid and also sulphur baths may be used to aid in the elimination of the mercury. Iron, cod-liver oil, good food and fresh air, and a free activity, of the emunctories are useful. For the marked tremor, sedatives (*e. g.*, codein, chloral, bromids, belladonna) are recommended. Electricity may be resorted to for the paresis.

FOOD INFECTION AND PTOMAIN-POISONING

In recent years there have been reported an increasing number of cases of serious illness that have been traced to infected and contaminated food. Undoubtedly many such instances are now brought to notice that in former times were attributed to other causes, or that were not diagnosticated because of a lack of knowledge. On the other hand, the increased consumption of canned and preserved meats has certainly augmented the liability to poisoning from these products, as the reports of cases show. Lack of care in the inspection and selection of the meats, uncleanness, and sometimes unscrupulousness in their handling and preparation, must result in infection, putrefaction, and toxicity. The infection of the food may be due to (1) disease of the animal or plant from which the food is derived; (2) microbial inoculation of the food after derivation and before ingestion by human beings; (3) infection by toxicogenic bacteria, and the presence of ptomains or toxalbumoses. The transmission to man of such affections in animals as tuberculosis, anthrax, glanders, and pleuropneumonia, by eating the infected meat, has been suf-

ficiently proved. Again, meat and milk may become infected before being ingested by the patient, by pathogenic micro-organisms, as of typhoid fever and diphtheria, or from the production of toxins owing to the action of non-pathogenic putrefactive micro-organisms. A great many instances of food infection, particularly of meat and milk, have been shown to be due to the presence of saprophytic germs, this happening even when the articles of food have been obtained from healthy stock and have been kept free from specific pathogenic bacteria. It is not, however, the saprophytes themselves in all cases, but the poison developed in the food before it is eaten or formed in the body afterward, that produce the symptoms and sometimes death. According to Novy, some of the saprophytic bacteria with which food is infected outside of the body, under certain conditions, are capable of living in the body as parasites, especially on dead matter, and there become toxicogenic.

The chronic poisons or ptomains resulting from the action of the saprophytes in foods are called "putrefactive alkaloids"; those bacterial products of a protein nature are called "toxalbumins" or "toxalbumoses." The latter, according to Vaughn, are more frequently present in infected foods. They are all absorbed from the digestive canal.

Poisoning by Infected Milk and Milk-products.—It is now well known that the cause of the high mortality rate among infants in hot weather is traceable directly or indirectly to the "summer diarrheas" in children fed artificially, wholly or partially, with milk infected by numerous varieties of saprophytic germs and thus poisoned by ptomains, such as tyrotoxinon. This special chemical poison has been isolated by Vaughan, and discovered by him in cheese. It has also been found in ice-cream, frozen custards, and cream-puffs, and has caused poisoning symptoms mainly of acute gastro-intestinal inflammation, "constriction of the fauces," nausea and vomiting, sharp, griping intestinal pains, headache, thoracic oppression, chilliness, dizziness, and sometimes purging, followed by relief in mild cases. In the severe and long-continued forms, however, exhaustion may supervene, with subnormal temperature, coma, collapse, and death in the graver cases. No chemical or physiologic antidote is known. Elimination may be assisted, and stimulation is needed. Irrigation may be employed for the former in both stomach and bowels. Strychnin, nitroglycerin, atropin, and the aromatic spirits of ammonia are most effective as stimulants.

Meat-poisoning.—Various tainted meats, as mince-meat "warmed over," veal pie, carelessly kept chicken salad, badly preserved and canned meats, partially decayed sausages (*botulismus*) have caused violent symptoms of poisoning. Diseased raw and partially cooked meat have also been eaten with disastrous results. Prolonged cooking may fail to destroy the toxic action of certain ptomains in infected meats; also, that meat that has been cooked and kept under certain conditions may become infected with bacteria as well as when it is raw. Putrid meat, however, has been known not to cause toxic symptoms. Gärtner's bacillus (*Bacillus enteritidis*) is probably the exciting cause of meat-poisoning. Wilbur and Ophüls¹ met with typical instances of botulism caused by the eating of domestically prepared canned string beans served without preliminary heating.

The symptoms caused by the poisoning are—"(1) those due to a true infection; (2) those due to simple poisoning" (Mann). Cases of the former group run the usual course of an infectious disease, often simulating typhoid fever. Those under the second division manifest the symptoms of a violent gastro-enteritis, with vomiting, intense colicky pains, purging, fever, accelerated pulse, nervous prostration, great muscular weakness, and cramps in the calves

¹ *Arch. Inter. Med.*, October, 1914.

of the legs. Often a subsequent subnormal temperature, extreme depression, convulsive movement, vertigo, dimness of vision, dyspnea, somnolence, great soreness of the mouth, collapse, and sometimes death supervene. The mortality rate varies from 15 to 55 per cent. of all the cases.

Differential Diagnosis.—Arsenic-poisoning may have symptoms similar to those of ptomain-poisoning. But, as Harrington points out, there are three chief points of difference: in arsenic-poisoning there is swallowing because of pain; in ptomain-poisoning the pupils are usually dilated and the muscular prostration is almost as extreme as a palsy.

The *treatment* is largely eliminative, symptomatic, and supportive. The prophylactic measures, private and public, are generally obvious.

Poisoning by Fish (*Ichthyismus*) and Shellfish.—Many instances of this serious form of intoxication have been produced. The fish may contain certain poison glands, ovaries, etc. Especially is this true of certain species known in Japan, one of which is believed to cause the disease called "kakke," which prevails during the summer months in Tokio. A certain species of fish (*Clupea venenosa*) inhabiting the West Indian waters is supposed to be always poisonous, although the source or true character of the poison is doubtful. In Russia many cases of ichthyismus have resulted from eating both the fresh and preserved sturgeon and salmon meat that are affected with an infectious disease peculiar to the fish. In Germany and others parts of middle Europe a severe form of gastritis called "Barbencholera" follows the eating of sick barbels.

The use of tainted preserved and canned fish, eels, oysters, mussels, crabs, lobsters, and the like, is more frequently the cause of symptoms of poisoning, however. Brieger's *mytilotoxin*, the active poison formed in some mussels, and the eating of which at Wilhelmshaven caused several epidemics, is probably developed only under certain favorable conditions of saprophytic infection. Deviled crabs, lobsters, and salad have also caused severe gastro-enteritis because of contamination with germs producing ptomains. Oysters have been known to convey typhoid infection (*vide* p. 25). The *symptoms* of fish and shellfish-poisoning are variable. Sometimes marked cerebrospinal manifestations predominate, with convulsions and paralysis. Dryness and constriction of the throat, dizziness, labored respiration, disturbed vision, jerky speech or aphonia, perhaps rapid pulse, loss of co-ordination, numbness, coldness of the extremities, dilated pupils, paresis, collapse, and death within a few hours, may ensue.

Other cases have a pronounced gastro-intestinal or choleraic group of symptoms, with nausea and vomiting, pain, tenesmus, and mucous and bloody stools. In some of them marked cutaneous irritation is shown by erythema, great heat and itching, urticaria, and swelling. Dyspnea, lividity, and sometimes delirium have also been noted. The *prognosis* is grave in many instances. The *treatment* is similar to the above—namely, emetics, purgatives, enemata, and lavage. The indications are to be provided for as they arise.

GRAIN- AND VEGETABLE-POISONING

Ergotismus.—Epidemics of ergotism have resulted from the continued use of meal made from contaminated grains grown on virgin soil. The parasite (*Claviceps purpurea*) is a fungus that infests rye and other grains; it does not, however, grow readily where the soil is well cultivated, and epidemics of ergot-poisoning are much less frequent than formerly, if we except certain places in Spain and Russia. According to Kobert, three poisonous substances are found in the ergot: ergotinic acid, sphacelinic acid, and cornutin. The first of these is not poisonous when taken into the stomach; the second is supposed to cause

gangrene; and the last produces grave effects on the nervous system, and is found only in fresh ergot, hence the greater prevalence of nervous manifestations in sickness that breaks out soon after harvest.

The nervous symptoms are remarkable for their convulsive characteristics (*ergotismus convulsivus*). Prodromes of weakness, tingling in the extremities, and headache may exist for several weeks before the spasms come on. The formication increases, and cramps and contractures, with flexed wrists and extended feet and toes, seize the patient. In severe cases epileptoid convulsions occur and may prove fatal. Delirium and, in very chronic cases, dementia may supervene. Recovery is slow, and the contractures may persist for some time, with muscular atrophy and anesthesia. In some interesting instances there may appear nervous symptoms resembling locomotor ataxia ("ergot tabs"), owing to posterior spinal sclerosis. Abortion results in pregnant women.

Gangrenous ergotism (*ergotismus gangrænosus*) is characterized by dry gangrene of the hands and feet, usually of the fingers and toes. Before the gradual blackening appears, there may be formication, pain, spasm, numbness, and coldness. As mortification and the line of demarcation progress, the parts drop off bit by bit, and fever may attend the sphacelation. Pneumonia (septic) may sometimes complicate this malady. The fatality has been considerable in some epidemics. The treatment of ergotism is entirely symptomatic.

Lathyrismus is an intoxication caused by the seed (used in the form of meal) of three varieties of vetch or chicken-pea, viz., *Lathyrus cicera*, *Lathyrus sativus*, and *Lathyrus clymenum*, or, respectively, red, German, and Spanish vetch. The meal is generally mixed with that obtained from other cereals. Its use for several hundred years has been observed to cause leg stiffness, passing into a transverse myelitis, with sensory and motor paraplegia. Spasticity and exaggerated tendon reflexes may remain for some time after the paralysis subsides. Slight fatty degeneration was noted by Cautain in excised bits of muscle. Very chronic cases may die in paralysis from the toxic effects of the poison, which, thus far, has not been separated.

Mushroom-poisoning.—Though not so common as formerly, poisoning from eating non-edible mushrooms occurs now and then, owing to ignorance or carelessness in gathering, keeping, and cooking them. *Fresh morels* are poisonous, while those that have been dried and boiled are not so, because of evaporation or solution of the contained poison.

The *red agaric* (*Amanita muscaria*), on account of the poisonous alkaloid muscarin that it contains, may cause very severe symptoms. These are nausea, vomiting, diarrhea, hemoglobinemia, hemoglobinuria, and jaundice (probably *hepatogenous*) in the case of fresh morel-poisoning (Strümpell). Tetanic and epileptiform convulsions give a slow pulse, dilated pupil, disturbed vision, salivation, coma, and death in the gravest cases of red agaric intoxication, in addition to the symptoms of gastro-intestinal irritation.

The treatment is symptomatic. Emetics, purgatives, stimulants, and, in red agaric poisoning, atropin, for its physiologic antidotal effect, are usually indicated.

ANAPHYLAXIS OR FOOD INTOXICATION

By anaphylaxis is meant an increased susceptibility, a hypersensitiveness, to a foreign protein introduced into the body. In susceptible individuals the reaction that occurs is known as anaphylactic shock. The pathogenesis of anaphylaxis depends upon the sensitization of the individual, usually in some unknown manner, by a foreign protein, the anaphylactogen. After a definite interval the reintroduction of the protein will cause certain symptoms as a re-

sult of the action of the toxic substance, the anaphylatoxin, elaborated at the time of reintroduction of the protein. The foreign protein that may produce injury may be, for example, blood-serum, producing the well-known serum sickness following injection of diphtheria antitoxin; it may be a plant pollen, the inhalation of which causes hay-fever or asthma; but in the present discussion we are concerned only with the hypersensitiveness produced by foods. This hypersensitiveness may be produced by any of the proteins of the usual food-stuff which under ordinary circumstances in non-sensitized individuals may be taken with impunity. Certain foods are more likely to cause anaphylaxis than others, thus egg, milk, fish, especially shell-fish, pork, mushrooms, strawberries, buckwheat, and cheese have been found to cause hypersensitiveness in many instances. The hypersensitiveness may be inherited, or acquired in some unknown manner. In the acquired forms of food susceptibility it is to be presumed that the gastro-intestinal mucous membrane is abnormal, as, for example, the seat of a chronic catarrh.

The **symptoms** may vary from a mild attack of indigestion to severe prostration with a diarrhea, abdominal pain, vomiting, subnormal temperature, and a cold clammy skin. In addition to the general and gastro-intestinal symptoms, other symptoms may arise alone or in combination with the former. Thus, asthmatic symptoms are frequently directly dependent upon food intoxication, and certain vasomotor and skin lesions are common, among which may be cited urticaria, angioneurotic edema, erythema multiforme, and so on.

Auer and Robinson have shown that alterations in the heart rhythm and partial or complete heart-block may arise in acute shock. Besides the acute manifestations of anaphylaxis certain chronic conditions are apparently attributable to chronic poisoning, notably eczema and asthma. Longcope has shown that repeated injections of foreign protein in animals previously sensitized produces extensive focal degeneration of the heart muscle cells as well as those of the kidney and liver. It is thus fair to presume that repeated protein poisoning may be one of the causes of chronic degenerative disorders.

Diagnosis.—Frequently the patient learns to recognize that certain articles of the diet may cause a severe upset. In other cases the diagnosis may be made upon the symptoms, the correlation of gastro-intestinal manifestations, urticaria, and respiratory symptoms indicating the nature of the disorder. If anaphylactic poisoning is suspected the nature of the offending protein may be determined by skin reactions. These tests are performed as is the von Pirquet tuberculin test and a positive reaction is much the same—a whitish wheal surrounded by a well-marked erythema appearing within several hours. An aqueous solution of the suspected food may be rubbed into the skin abrasion, or the pure protein, which may be purchased in the open market, may be employed.

Treatment.—The acute attacks are handled by the ordinary measures to control shock, viz.: stimulation, heat, and so on. It is advisable to empty the intestinal tract by an active purge. Atropin has been shown to control anaphylactic shock in animals, as has adrenalin. They should be given hypodermically, gr. $\frac{1}{100}$ (0.00065 gm.) of the former, 10 to 15 minims (0.6–1.0 c.c.) of the latter in a 1 : 1000 solution. Calcium chlorid may be given by the mouth.

The cure of hypersensitiveness is only possible when the offending protein is known. It should be given in very small, gradually increasing doses, until immunity is secured. For example, Talbot, in treatment of children sensitive to egg albumin, gives minute doses in capsules, gradually increasing the dose every couple of days until the child can take whole eggs without any disturbance.

OBESITY

(Polysarcia Adiposa; Lipomatosis Universalis)

Definition.—Corpulence, or the presence of an excessive amount of bodily fat, may be said to begin to take the form of a metabolic disorder when it becomes an inconvenience or impairs the bodily functions. Many recent writers regard obesity as being symptomatic of a variety of underlying pathologic conditions (*e. g.*, pituitary disease) rather than a disease.

Pathology.—The chief alteration is the marked and, in some instances, colossal increase in the fat deposit throughout the body. Not only is the adipose tissue greatly increased in localities where it is normally found, but the various internal organs and tissues that are normally quite or nearly free from fat may in obesity show a decided fatty infiltration. The round fat face, "double chin," broad and deep chest, large waist, thick and prominent, sometimes overhanging, abdominal *panniculus adiposus*, and bulky, cylindric, and apparently shortened extremities, are familiar appearances *postmortem* as well as *antemortem*.

There may be differences in the number and size of the fat-glubules in the histologic elements. Thus, in the plethoric form of obesity the cellular fat-globules are larger than those of the anemic or hydremic form. The heart is overlaid with fat. Hypertrophic dilatation is often present.

The arteries may show fatty changes and chronic endarteritis with sclerosis. The veins are often affected with varicosities. In plethoric obesity the blood shows an increase in specific gravity (1.062–1.070). The erythrocyte count may rise to 6,000,000 per cubic millimeter. Passive congestion and edema of the lungs, secondary to the cardiac weakness, are common. The liver, lungs, and kidneys may be enlarged, owing to fatty infiltration. Chronic interstitial nephritis may form a complication.

The stomach may be dilated, and often shows a catarrh of the mucosa.

Pathogenesis.—Obesity is probably dependent on a disturbance of cell activity, and this disturbance of metabolism may be transmitted through heredity (*vide infra*). The overuse of carbohydrates leads directly to fat increase. The consumption of proteins may also result in a fat-forming non-nitrogenous residue, which if not oxidized may produce fatness (see also Etiology).

Etiology.—Among the chief *predisposing* conditions are heredity, climate, habit, occupation, temperament, age, and sex. Among 543 of my cases, in which the family history was noted, heredity was distinctly traceable in 60.7 per cent. Gout was either in association or occurred among the antecedents in 43.2 per cent. of these cases and the same was true of "rheumatism" in 35.5 per cent. The condition of 10 dates from longer or shorter periods of enforced rest, *e. g.*, following accidents and infective diseases, as typhoid fever (in 4.7 per cent. of 543 cases). The disease dated from child-birth in 16.2 per cent. of the cases and from marriage (apart from child-birth) in 4.8 per cent. among 437 females. The menopause has little if any influence. Corpulence is much more frequent among the inhabitants of hot, moist climates, and of low countries of the temperate and arctic regions. Thus it is commonly observed among Orientals, Dutchmen, South Pacific Islanders, Southern Italians, and certain African races. Sedentary habits and occupations form common predisposing factors. The sluggish, luxury- and rest-loving, phlegmatic temperament also favors an abnormal fat deposition. As regards the age, polysarcia generally makes its appearance in persons of advanced middle life, between forty and fifty years, while hereditary obesity dates from infancy and early childhood; in women, it may appear at puberty and between thirty and

forty years of age. Women, and especially Jewesses, seem to be more subject to corpulence than men. Congenital anomalies and monstrosities (idiots, cretins, acephali), also anemics and hemiplegics, are often excessively fat.

The *exciting* causes of obesity are especially the ingestion of too much fat-making food, the intemperate use of alcoholic beverages, especially beer, ale, and porter, with or without deficient exercise. The fat may be derived from an excess of albumin, fat, or carbohydrates. An excessive diet of starches and sugars acts indirectly as a fat-producer by lessening the oxidation of the ingested fat and of the fat formed from proteins, because the carbohydrates themselves are so readily oxidized.

Symptoms.—Obesity is not accompanied by any bodily symptoms at first. Except some inconvenience, and a sense of burdensomeness during walking or working, nothing may be complained of for years. With the progressive development of the disease, however, and particularly with the involvement of the viscera, subjective manifestations increase in number and intensity. Usually the earliest troublesome symptom is *breathlessness* on exertion, due to a weak heart and to the hampering of respiration by heavy chest walls and the upward crowded diaphragm. In *plethoric* individuals the face is red and congested, as are also the mucous membranes (conjunctivæ, labiæ). In *anemic* subjects (usually women) the skin is pale, the muscles are flabby and weak; the pulse is small and compressible, and dyspnea, palpitation, inclination to rest often and sleep much, and dizziness (symptoms of anemia and chlorosis) are manifested. On the other hand, in *plethoric*, corpulent subjects (usually men) the muscles are firm and strong, and the pulse and heart-beats vigorous; later, however, the latter becomes weak and irregular. Brachycardia is not infrequent. The signs of fatty heart (*vide* p. 647) are obtained on physical examination. Muscular power may diminish and irregular fat masses (in the anemic variety) in subcutaneous tissue, are obtained on physical examination. Muscular power may diminish rapidly. Intercurrent acute infections (typhoid fever, pneumonia) are badly borne, and hyperpyrexia is usually associated with them. In the anemic form the blood changes are of the chlorotic type, while in the plethoric both the hemoglobin percentage and erythrocytes are increased.

The *liver* may show enlargement. The passive congestion of the *respiratory mucous membrane* is often signaled by cough and distressing dyspnea and attacks of asthma. Profuse sweating is common. There may be *polyuria* or *oliguria*, according to the activity of the skin and kidneys, at the same time. Uric acid and the urates are usually found to be increased.

Symptoms of *gastric catarrh* and *gastrectasia* may occur. Great thirst and bulimia are noted in some instances. Constipation may be followed by chronic diarrhea. Sexual desire is often abated, and azoöpermia is not rare. Corpulent women often suffer from uterine displacement and prolapse. Amenorrhea, sterility, endometritis (congestive), leukorrhea, and an aggravated climacteric are seen in obese women also. The skin is often irritated (intertrigo) by the excessive sweating, and by the friction of cutaneous surfaces in the folds of fat, as under the breast, at the abdominal and inguinal folds, and around the scrotum and labia. This may be followed by eczema. Painful excoriations, pruritus, acne rosacea, and alopecia are also not uncommon.

Complications.—Hernia, cardiac asthma, bronchitis, pulmonary congestion, edema, arteriosclerosis, albuminuria, glycosuria, anginal attacks, Cheyne-Stokes respiration, cerebral hemorrhage, and coma may manifest themselves as the precursors of the final stage.

Diagnosis.—This is not difficult in most cases. Care should be exercised in detecting complications and sequelæ. In myxedema the skin is thick and

inelastic, and the physiognomy much altered, while the lips, tongue, nostrils, and mouth are all thickened by infiltration.

The **prognosis** will depend upon the peculiar features of each individual case, the cause and its removability, and upon the variety, degree, symptoms, and prevailing complications.

Treatment.—**Prophylaxis** is important in the earlier years of those showing an hereditary predisposition to corpulence. The fat-forming (farinaceous) substances must be diminished in the dietary. The proportions of fat and protein in the food must be regulated according to the amount of muscular activity, and the latter should be encouraged in fresh air, along with cool bathing. In those predisposed to polysarcia, all imprudences in eating and drinking should be cautioned against, and the quantities of various articles of food and the time of eating regulated. Outdoor sports and gymnastics should be also gaged accordingly.

The **dietetic** treatment of confirmed obesity is all important. Inseparable from this is the stimulation of the bodily forces that oxidize and destroy the fat. These two means are utilized in the principal methods of treating obesity, and that method must be selected which invigorates, while at the same time it involves no weakening of the patient.

The principal systems of dietary are those known by the names of Banting, Ebstein, and Oertel.

In "Bantingism," sugars, fats, and starches are greatly reduced in the diet-list; water, however, is not restricted, and vinous and spirituous liquors are permitted. In those of a rheumatic or gouty diathesis Banting's heavy protein and alcohol dietary is not to be recommended. It is best, I think, to exclude alcohol in most cases, owing to its effect in diminishing tissue oxidation and in retarding cell metabolism. This method fails to secure elimination of waste products.

In Ebstein's diet-list more than double the amount of fat and carbohydrates is permitted as compared with Banting's list, while the albuminous substances are diminished. Fat is freely allowed, as this does not increase stored fat (?), but tends to impair the appetite, while sugar and potatoes only are strictly forbidden.

Oertel allows more fat than Banting, but less fat and more (about double the quantity) proteins and carbohydrates than Ebstein. The amount of *free* water permitted daily is only 1 pint; about 1 pint additional in other food is allowable. This method is adapted to cases of obesity with feeble hearts and of the anemic form.

Oertel¹ writes: "The body stores up fat if more than 118 grams of albumin and 259 grams of fat, a total of 277 grams (2894 calories), are taken in. On the other hand, 110 grams of albumin and 600 grams of starch, a total of 710 grams (2944 calories), may be given without producing a deposit of fat. With a mixed diet the limit lies near 118 grams of albumin, 100 grams of fat, and 368 grams of starch, a total of 586 grams (2923 calories)." His diet-table for obesity is appended:

	Albumin.	Fat.	Carbohydrates.	Calories.
Minimum.....	156	25	75	1180
Maximum.....	170	45	120	1608

Oertel gives a special diet-list in circulatory disturbances.

On the basis of Voit's laws, Strümpell recommends in the average cases 125 gm. (4 oz.) or more of albumin, 40 gm. (1½ oz.) of fat, and 150 gm. (462 oz.) of starch. Schwenniger's rule differs from Oertel's merely in the forbidding of

¹ *Twentieth Cent. Prac. of Med.*, vol. ii, pp. 698, 699.

liquids with the meals and in permitting their use only after two hours have elapsed. Yeo's diet-list is also a useful guide. In plethoric obesity (usually associated with or dependent on gout) a judicious rearrangement of the food (some increase of the albuminoid substances), coupled with sufficient muscular exercise (walking, horseback-riding, bicycling, rowing, swimming, gymnastics), accomplish successful reduction, as a rule. Moritz¹ has found an exclusive milk diet extremely effectual.

Increasing weakness of the heart with an impeded circulation naturally diminishes the excretion of water by the cutaneous and renal routes. In such cases the circulatory system must receive careful attention and the consumption of fluid must be limited. If evidences of anemia be present, the amount of liquid may be much restricted, the total per diem not exceeding 1 liter (quart) and the fat-forming dishes rigidly excluded. "The hydremic form must be opposed by the ingestion of an abundance of albuminoid material, of fat-producing substance, and the hydrocarbons" (Oertel). Cases of obesity in which diabetes or hyperglycemia is associated should receive an antidiabetic diet. Sabbe and Furet² recommend a regimen from which salt is entirely eliminated, in connection with the ingestion of fluids in abundance, which carries off excrementitious products. There are cases in which a large part of the excess of weight is due to retention of water; in such, a salt-poor diet may be employed with marked success. Under any system of dietetic treatment the patient should be weighed accurately and frequently, and the food limit be diminished or modified according to the results. The food may be weighed and measured at first, but the patient soon learns to estimate by bulk the requisite quantity of each substance.

The following dietary illustrates what may be ordered in many cases:

Breakfast.—Fruit, as an orange or 2 peaches or half a grapefruit (without sugar), or a sour apple; fine wheat bread, $1\frac{1}{4}$ ounces (0.4 gm.); a soft-boiled egg; milk, 1 ounce (30 c.c.); saccharin, $\frac{1}{2}$ gr. (0.03 gm.); coffee, $4\frac{1}{4}$ ounces (127 c.c.).

Luncheon.—Caviar, 2 drams (8 gm.); lamb chops, sweet breads, boiled ham (cold), or fowl or game in season, 3 to 4 ounces (90–120 gm.); salad, 1 ounce (30 gm.) (with a small amount of French dressing); cheese, 1 dram (4 gm.); bread, rye or bran, $\frac{1}{2}$ ounce (15 gm.); fruit (except strawberries and bananas), or instead of the latter, 4 ounces water (120 c.c.).

Dinner.—Soup (clear), 3 ounces (90 c.c.); fish, 2 ounces (60 gm.); roast or broiled beef, lamb, veal, or game or poultry, 4 to 5 ounces (120 to 150 gm.); one or two of the following green vegetables: spinach, string beans, green peas, celery (stewed), asparagus, raw sliced tomatoes, Brussels sprouts, $1\frac{1}{2}$ ounces (45 gm.). For dessert the patient may take plain rice pudding, junket, cup custards (all slightly sweetened), or fruit (except strawberries and bananas), either raw or cooked, 4 to 5 ounces (120 to 150 gm.). The patients may take 4 to 5 ounces (120 to 150 c.c.) of water when fruit is not used.

Additionally, a glass of water on rising and three hours after each meal is to be taken, and during the warm season from 1 to 3 glasses over this amount.

Galisch recommends the simple measure of reducing the amount of food taken after midday, so as to lessen nourishment at night, out of which to build fat. Folin and Denis³ suggest as a perfectly safe, rapid, and effective method of reducing the body weight of very obese persons, repeated fasts of increasing duration, the ammonia or beta-oxybutyric acid determination being used as a guide to the length of each fast.

The **mechanical treatment** (to increase oxidation), by exercise, is to be used in conjunction with the dietetic. The form of the exercise, and also the time

¹ *Munch. Med. Woch.*, 1908, xxx, 569.

² *Rev. de méd.*, 1905, No. 9, p. 674.

³ *Jour. Biol. Chem.*, 1915, xxi, 183.

and frequency, must be adjudged for each case (*vide supra*). When cardiac dilatation and myocardial degeneration (fatty) are the cause of symptoms of precordial distress, dyspnea, and palpitation, resort may be had to Oertel's system of graduated walking on the level or climbing along "health paths" (*vide Fatty Overgrowth*, p. 647). Or the well-known Nauheim or Schott treatment may be used. Great care must be exercised in prescribing the mechanical treatment in obese persons who have atheromatous vessels.

Allard¹ recommends the employment of a vibrating ball controlled by an electric motor in circumscribed obesity. Chatillon lauds the Bergonié electric apparatus.

The **medicinal** treatment is neither satisfactory nor successful. Causative or associated conditions—*e. g.*, gout—may present special therapeutic indications. The juice of the phytolacca berry may reduce the weight, but is harmful.

Recently the use of thyroid extract has come into favor. Leichtenstern, Wendelstadt, Ewald, and others have reported success in a number of cases, especially in those exhibiting the anemic, flabby, "myxedematoid" form of obesity. The loss of weight was from 2 to 3 pounds (1-1.5 kgms.) in one week, and as high as 20 pounds in two to four weeks. In 2 of my own cases belonging to this category the use of thyroid extract (desiccated) in small doses (gr. j—0.065, t. i. d.) caused a progressive loss of weight at the rate of 4 to 6 pounds per week respectively, without injury to the general health. In cases in which dietetic measures with exercise fail, thyroid insufficiency should be suspected, and thyroid treatment instituted. Jump states that in the constitutional or thyrogenous type, in which a small or inactive thyroid and poor catabolism are associated, thyroid extract may be given with care. Thyroidin, the active principle of the thyroid gland, as shown by Baumann and Ross, and iodothyryn give results that are perhaps as good as those of thyroid feeding. The dried extract should be employed and the commencing dose small (gr. ss to j—0.03-0.06), to be gradually increased, and symptoms of thyroidism are the signal for a reduction in the dosage (*vide Myxedema*, p. 484). Hematicinics are indicated in the anemic variety of obesity. Arsenic also promotes metabolism of albumin. Finally, the treatment must be adapted to the special case, and also varied from time to time to meet indications and complications as they arise.

HYPOPHYSEAL OBESITY

In 1901 Fröhlich first described this condition; it is characterized by a tumor (adenoma, carcinoma, etc.) of the hypophysis accompanied by monstrous general obesity and atrophy, or delayed development, of the genital organs. These subjects have a high tolerance to carbohydrates. The syndrome being due to hypopituitarism, they are naturally benefited by the use of extracts of hypophysis. Other glands with an internal secretion may, when their function is disturbed, produce pathologic obesity (pineal gland, suprarenals).

ADIPOSIS TUBEROSA SIMPLEX

The writer has described a condition which resembles adiposis dolorosa (Dercum's disease) clinically, but differs from the latter in that it is dependent upon general obesity, and is, therefore, amenable to treatment.

"Circumscribed fat masses appear in the subcutaneous tissues; they form distinct, moderately dense, slightly movable, somewhat flattened tumors, ranging in size from a bean to that of a hen's egg. Their number varies all the way from one-half dozen to two dozen or more. These moderately firm

¹ *Rev. de therap.*, 1905, No. 6, p. 191.

fat-nodules are not distributed over the entire body, but in some cases are confined to the extremities, particularly the lower, and in others to the abdomen. The tumor masses show no tendency to fuse together, and are not elevated above the surrounding surface; they are sensitive to the touch, and may be the seat of pain, which varies in intensity within rather wide extremes, being moderately severe and distressing in rare cases and trivial or even absent in the majority of instances. The lymphatic glands are not involved, and the skin remains soft, flexible, and non-adherent. The mental processes are normally active, and also the muscles; asthenia is not present, and there is no more indisposition to physical exertion than is observed in cases of obesity, as a rule. The knee-jerks are present, and the cutaneous sensibility is unaltered, in some cases at least the mammæ and abdominal panniculus adiposus may be overhanging or pendulous, but not in all cases. It is an uncommon condition, since it was noted in only 4 out of a total of 324 cases" (Anders¹).

HEAT-STROKE

(*Sunstroke; Insolation; Thermic Fever; Heat-exhaustion; Heat-prostration*)

Definition.—A diseased condition the effect of exposure to excessive heat.

Pathology.—*Rigor mortis* is marked and comes on early. The high temperature of the cadaver accelerates the putrefactive changes, which also appear early. There is considerable venous engorgement of the brain and of the cerebral and spinal membranes; also of the lungs, spleen, and conjunctiva. The blood is fluid and dark, and the corpuscles are crenated and do not tend to form rouleaux. Parenchymatous changes in the liver and kidneys may be found. Rigid contraction of the left ventricle is a notable feature, while the right ventricle is usually dilated with blood. Van Gieson's recent report of the cellular pathology of the cerebrospinal system in 3 cases of sunstroke in New York shows an acute parenchymatous degeneration of the neurons of the whole neural axis similar to that of "a species of auto-intoxication."

Etiology.—Anything that lessens bodily resistance to external high heat predisposes to heat-stroke. Thus, privation, unsanitary surroundings, fatigue of body or mind, emotional excitement, worry, and excessive fretfulness, over-eating, indulgence in alcoholics (especially), clothing suitable for cold weather worn on hot days, and previous attacks of sunstroke, are all conducive to heat-stroke on exposure to high temperature. Males are affected more often than females, and the condition is rare in childhood. The colored race is more resistant than the white to the effect of the direct solar rays.

Sunstroke occurs in persons (on land) working hard under the direct rays of the sun, in an atmosphere that is very hot and humid, still, and sultry. Soldiers on the march and heavily accoutered, masons, bricklayers, hod-carriers, roofers, drivers, farmers, and other out-door laborers are particularly subject to insolation.

Heat-stroke and **thermic fever** are terms more appropriately applied to those similarly affected in midsummer while working in places not exposed to the sun, but yet close, confined and excessively hot, such as glass-works, foundries, ocean steamers, stoke-holes, boiler-rooms, steam laundries, sugar-refineries, kitchens, and the like.

Heat-exhaustion (*prostratio thermica*) is caused under similar conditions as the preceding, but manifests dissimilar effects.

The majority of the cases of sunstroke occur between 2 and 5 P. M., although

¹ *Amer. Jour. Med. Sci.*, March, 1908.

heat-stroke and heat-exhaustion may occur at night as late as 10 or 11 P. M., as among bakers, night engineers, and hotel cooks.

The direct cause of the symptoms of the sunstroke, heat-stroke, or heat-prostration is the action of the excessive heat upon the heat-centers, or upon the vasomotor center or nerves (H. C. Wood), the former of which, if paralyzed, produces *thermic* or *heat-fever*, while the latter, if paralyzed, produced *heat-exhaustion*. Lambert and Van Gieson, after a clinical and pathologic study of 805 cases, hold to the view that the immediate basis of sunstroke is autotoxic, with heat only as a contributing cause. Sambron contends for the infective nature of heat-stroke and thus explains its endemic and epidemic proclivities.

Symptoms.—Two forms of heat- or sunstroke are usually met with: (1) The *asphyxial* or *apoplectic form*; (2) the *hyperpyrexial form*. Flint believes that the majority of the cases of sunstroke are combinations of apoplexy and exhaustion. Vallin puts all cases of insolation into two classes: the first sthenic or asphyxial, corresponding to our hyperpyrexial or congestive variety; the second, asthenic or syncopal, corresponding to our heat-exhaustion. Mixed forms may occur quite frequently, the most prominent symptoms being referable to the organs suffering the most, as the cerebrospinal system, heart, lungs.

Heat-apoplexy (*asphyxial sunstroke*) is probably the least frequent form. There may be sudden premonitions, or dizziness, chromatopsia, throbbing headache, cessation of sweating, or dyspnea. Sometimes the patient, while at work in the sun, suddenly falls unconscious, a few convulsions may occur, and in this state he may die with symptoms of cardiac failure. More often, insensibility is not so profound as complete coma, there is much restlessness, epigastric "cramp" may be complained of, also a sense of thoracic oppression, and occasionally there are nausea and vomiting. The headache may be intense, the face is flushed, the pulse is rapid and full, the temporal and carotid arteries are bounding, the breathing may be labored and stertorous, the pupils are contracted. The skin is hot and dry, and may show petechiæ. The tongue is coated. A wild delirium has been observed in some cases. The temperature may be subnormal, and is not higher than 102° F. (38.8° C.) in many instances. In others, a mild degree of thermic fever may be associated with the apoplectic condition, the thermometer registering 104° to 106° F. (40°–41.1° C.). In fatal cases the coma becomes deeper and deeper, the pulse more rapid and feeble, and Cheyne-Stokes respiration may precede the termination. A "mousey" odor about the body has been noted. In favorable cases the temperature falls to normal by lysis in three or four days, consciousness being rapidly regained at the same time.

The *hyperpyrexial* variety comprises the numerous cases of marked sunstroke that resemble the preceding type, with the addition of an intensely high temperature (*thermic fever*). The patient may suddenly become comatose and die in an asphyxiated condition, with a temperature as high as 110° to 115° F. (43.3°–46.1° C.) or even higher.

Sometimes prodromes, as an anorexia, progressively increasing physical weakness, cramp-like abdominal pains, irritability and restlessness, vertigo, colored and blurred vision, lack of sweating, a "bursting" headache, and an irritable bladder may exist for several days. A subconscious (automatic) state, in which the patient may be unaware of his surroundings, although walking or even working, may be noted for hours before he is stricken down. The onset is marked by hyperpyrexia; the skin is hot, burning, dry, sometimes flushed and red, and sometimes cyanotic and clammy; the eyes are suffused or "staring and filling," with pin-point pupils. There is a full, rapid, and non-

compressible pulse, and coma may be present. Clonic spasms may alternate with either muscular rigidity or flaccidity. Delirium, moaning, jactitation, and explosive expiratory sounds may occur. There is frequently incontinence of both feces and urine. The temperature is very high in most of the cases, varying from 105° to 112° F. (40.5° – 44.4° C.).¹ The pulse-rate varies with the temperature, from 90 to 160 beats per minute. The respirations are also increased to 24 to 50 per minute. Many of the alarming symptoms, including the high fever, unconsciousness, cyanosis, dyspnea, and convulsions, may greatly subside during and after the use of the cold bath. Secondary exacerbations occur for a few days before convalescence is established in the favorable cases (*vide* chart, Fig. 80). Some patients never rally and die in a state of asphyxia.

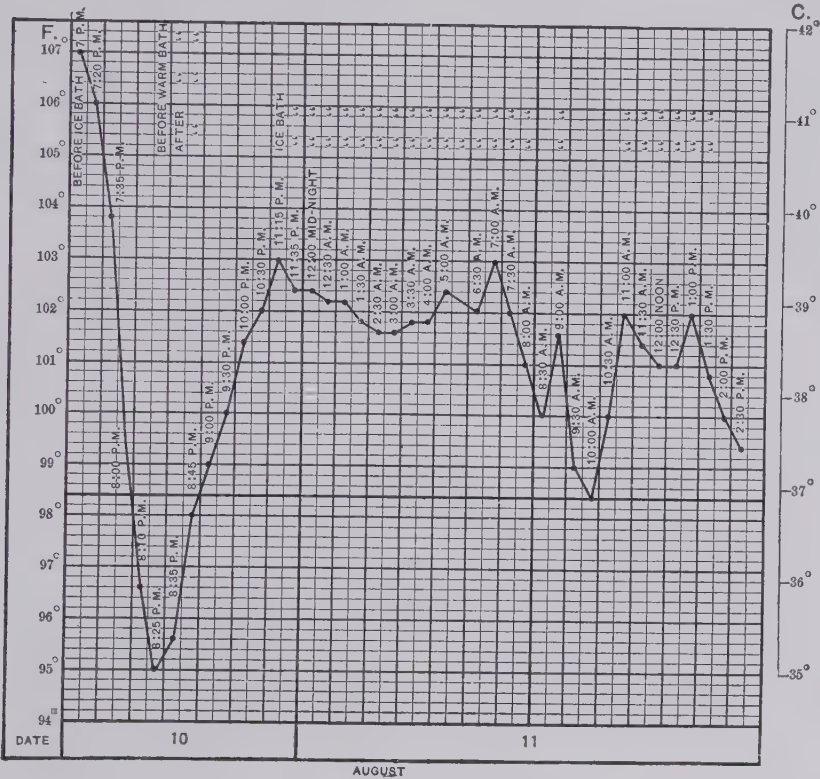

Fig. 80.—Chart of a case of sunstroke. C. B., aged twenty-nine years. Recovery.

Retention of urine (suppression) is observed at times, and particularly in those accustomed to the use of alcohol. Leukocytosis is noted.

Fatal complications of sunstroke are pneumonia, meningitis, uremia, and cardiorespiratory paralysis.

Heat-prostration or heat-exhaustion may come on gradually or suddenly, with prodromal symptoms (dizziness, faintness, headache, nausea, thirst, drowsiness, yawning, epigastric or lumbar pains, numbness, and tingling of the hands and feet). These are followed by coldness, clamminess, and pallor of the surface, marked muscular weakness and prostration, a small, febrile, rapid pulse, sighing breathing, syncope, and collapse in the graver cases.

¹ Lambert reports a case in the New York Hospital of 117.8° F. (47.6° C.).

The temperature at first is subnormal (95° to 97° F.— 35° – 36.1° C.), though mild thermic fever of from 100° to 102.5° F. (37.7° – 39.1° C.) may be present. Consciousness is rarely completely absent. Recovery usually takes place within one or two days, and in milder cases, under prompt and appropriate treatment, within a few hours. In a few cases of extreme prostration in weakly persons death may ensue from cardiac failure.

Sun-traumatism (Manson) describes a condition characterized by sudden death from paralysis of the heart or respiration after exposure to the sun. *Siriasis* occurs only in high temperatures, and is characterized by pulmonary congestion, coma, and hyperpyrexia. *Heat collapse* from exposure to the sun is often seen on hot summer days and is too transient to be called sunstroke. The temperature is normal or slightly elevated, and the respiration shallow and rapid.

The sequelæ of heat-stroke are quite interesting. Osler relates the case of a patient who "was subsequently so sensitive to temperatures in the neighborhood of 75° F. (23.8° C.) that he lived comfortably only in the cellar, and finally sought refuge in Alaska."

Chromatopsia, severe headaches, irritability and ugliness of temper, or delirium may occur in some patients as soon as warm weather sets in, and may be due occasionally to chronic meningitis (Wood).

Heat-cramps may develop among those exposed to high artificial heat while doing muscular work—*e. g.*, stokers on steamships, workers in iron foundries. It is essentially a continuous fibrillary contraction of the muscles, especially those of the calves. The condition is attributable to an acute degenerative process in the muscles (Edsall). Painful, tonic spasms of the muscles, more particularly of the forearms and legs, occur in paroxysms, lasting from one-half to one minute. The duration of an attack of heat-cramps is usually less than twenty-four hours, and it is followed by muscular soreness and slight exhaustion.

Diagnosis.—Bearing in mind the characteristic differences that are outlined above between sunstroke (asphyxial and hyperpyrexial forms) and heat-exhaustion, the diagnosis is not difficult. The history and circumstances attending the seizure are also important factors. From other affections, as *acute alcoholism*, *meningitis*, *uremia*, and *cerebral apoplexy*, the differentiation is readily made by noting the previous history, mode of attack, presence or absence of thermic fever, state of consciousness, urine, skin, pupils, pulse, respiration, and nervomuscular apparatus. *Malaria* can be excluded by a blood examination.

Prognosis.—This is usually favorable in cases of heat-prostration and heat-cramps. It is less so in sunstroke, but in all cases it depends on the severity of the stroke, the previous health and habits of the patient, the complications, and the promptness and facility of the treatment. In general, cases in which unconsciousness lasts from twenty-four to forty-eight hours terminate fatally. The mortality rate during a prolonged period of hot and humid weather may be very high, ranging from 15 to 50 per cent. In New York City, during the week ending August 15, 1896, out of a total number of 1810 deaths, 648 were reported as due to sunstroke (Lambert).

Treatment.—**Prophylaxis.**—This is highly imperative in hot, sultry weather, in which persons must work in the sun or in poorly ventilated and highly heated closed places. Workmen should be taught and warned privately and publicly, as through the medium of the press and Health Board circulars, to take extra precautions during hot weather, to work and sleep in as well-ventilated rooms as possible, and to secure artificial ventilation, if necessary. They should live regular and temperate lives, avoiding alcohol and heavy

eating; oatmeal water should be drunk, light-weight and light-colored clothing should be worn, and the direct rays of the sun should be avoided as much as possible. The condition of the skin should be watched and care taken that sweating continues freely. Shelter or rest should be sought at once if sweating stops. Cool wet cloths or green leaves should be worn inside a light straw hat, and sometimes it may be necessary for employers to shorten the hours of labor during the hottest part of the day.

Treatment of the Attack.—Cases of ordinary *heat-prostration* seldom require much treatment beyond the removal of the patient to the shade of a comparatively cool place, loosening all constricting clothing, spraying with cool water, the use of ammonia or amyl nitrite inhalations, and of the aromatic spirits of ammonia or nitroglycerin by the mouth. If the temperature is subnormal and collapse threatens, a hot bath is advisable. Strychnin and digitalis may be used for a day or two to combat the nervomuscular weakness.

Heat-stroke, especially the hyperpyrexial cases, must be promptly treated by the application of the ice-bath (ice floating in a tub of water), temperature about 40° F. (4.4° C.), or by rubbing, by the cold pack, or by the needle-spray with iced water for the purpose of overcoming the vasomotor depreciation.

In the *asphyxial* cases venesection is frequently indicated. The subcutaneous or intravenous injection of physiologic salt solution (F. A. Packard) may be a valuable procedure in many cases. Wooley advises a solution prepared as follows:

Sodium chlorid,	30 gm.;
Sodium carbonate (crystallized),	20 gm.;
Water,	1000 c.c.

To be given slowly per rectum. For intravenous use the following is recommended:

Sodium chlorid,	14 gm.;
Sodium carbonate (crystallized),	10 gm.;
Water,	1000 c.c.

To aid in the reduction of the cerebral pressure lumbar puncture should be done. External stimulation should be applied to the precordium by mustard and to the feet by hot bottles, and hypodermic injections of nitroglycerin, strychnin, atropin, brandy, camphor, or ether are useful. Ice should be rubbed over the head constantly. Care should, however, be taken to see that the temperature is not reduced too far. A temperature of about 102° F. (38.8° C.) should be the signal for cessation of the ice-bath, and for the removal of the patient to a cot, where he is to be rubbed dry and allowed to rest until an exacerbation of fever indicates the reapplication of the cooling measures. Ice-water enemata, with or without brandy, are often useful adjuvants. The needle-spray of cold water is an excellent nervous stimulant as well as antipyretic. It is given while the patient lies on a Kibbee or netting cot, or on a cot covered with a rubber sheet so arranged as to drain into a pail or trough. Internal antipyretics are seldom well absorbed, and their depressant action is so well known as to discourage their use in place of hydrotherapy. Hutchinson, Coplin, and Bevan recommend highly the use of morphin to control the convulsions of heat-stroke. Chloroform has also been advised. Artificial respiration in the asphyxial cases, kept up until other measures and stimulants have time to act, may be the means of saving life.

After the reduction of the hyperpyrexia the patient should be lightly covered on a cot placed in a cool place. An ice-cap should be applied to his head, and

small pieces of cracked ice may be given to allay gastric irritability, with calomel to open the bowels if necessary. Albumin-water, skimmed milk, buttermilk, unfermented grape-juice, junket, and the like may be given for several days preparatory to the ingestion of heavier food. If, as sometimes happens, free diaphoresis does not come on after the reduction of most of the fever and the stimulating treatment, a hot bath may be given, and perhaps aided by the hypodermic injection of pilocarpin in urgent cases. *Sequelæ* must be treated on general principles.

In *heat-collapse* "treatment consists in removing the patient to a cool or shady place, loosening the clothing, and spraying the face and body with cold water. He should be given a cup of strong tea or coffee. A hypodermic injection of strychnin or camphor may be needed." For the violent muscular spasms (*heat-cramps*—*vide* p. 1216) chloroform by inhalation affords temporary relief, and warm baths are recommended for their relaxing effect. H. M. Welsh¹ has employed apomorphin, in doses varying from gr. $\frac{1}{12}$ to $\frac{1}{20}$, as a relaxant in the severe cases.

The increased susceptibility to repeated attacks of insolation (after the first attack) makes it necessary to avoid exposure to heat ever after, and, if possible, to seek a cooler climate during the hot months.

SAUNDERS' BOOKS

on

**Practice, Pharmacy,
Materia Medica, Thera-
peutics, Pharmacology,
and the Allied Sciences**

W. B. SAUNDERS COMPANY

WEST WASHINGTON SQUARE

PHILADELPHIA

9, HENRIETTA STREET, COVENT GARDEN, LONDON

**Carman & Miller's X-ray
Diagnosis**

Röntgenology of the Gastro-intestinal Tract. By **RUSSELL D. CARMAN**, M. D., Head of Section on Röntgenology, and **ALBERT MILLER**, A. B., M. D., Second Assistant in Section on Röntgenology, Division of Medicine in The Mayo Clinic, Rochester, Minnesota. Octavo of 550 pages, with 504 illustrations.

COMPREHENSIVE IN DETAIL

This work takes up the diagnosis of disease of the alimentary tract, following its course from the esophagus to the rectum. You are told what apparatus is needed, and exactly how to use it, with formulas for the barium meal and enema. You are given the Röntgen appearance of the normal organ under discussion, what appearances signify abnormality, and exactly how to detect abnormality. Then you get the Röntgenologic symptoms of every disease of the organ, followed by several actual examples of each to show individual variations, and an extensive bibliography on every topic. A few of the important topics treated are early cancer, diverticula, gastropnoxis, 'hunger-pain' in duodenal ulcer, Lane's kinks, auto-intoxication, intestinal stasis, cecum mobile, Jackson's membrane, and incompetence of the ileocecal valve.

A NEW CLINICAL PUBLICATION

Medical Clinics of Chicago

Issued serially, one octavo of 200 pages, illustrated, every other month. Sold only by the Clinic Year (July to May), six volumes. Cloth, \$12.00 net.

EXCLUSIVELY INTERNAL MEDICINE

These bi-monthly publications are devoted exclusively to *Clinical Internal Medicine* in all its departments—Diseases of Children, Contagious Diseases, Neurology, Dermatology, General Constitutional and Functional Disorders, Fevers, X-Ray Therapy, etc., etc. They give you the bedside and amphitheater teachings of such leading Chicago internists as Mix, Tivnen, Tice, Case, Portis, Weaver, Friedman, Hamburger, Pusey, Williamson, Edwards, Abt, Preble, Goodkind, Hamill, Strouse, Brophy, Zeisler, representing such large hospitals as Mercy, Cook County, St. Luke's, Michael Reese, and Sarah Morris Memorial for Children, with their wealth and diversity of clinical material. These clinics are stenographically reported by a corps of competent medical stenographers, and thoroughly edited by the clinical teachers themselves.

The widest variety of cases is included, bringing out forcibly every feature of history-taking, diagnosis, treatment, and general management. The cases are illustrated with x-ray pictures, photographs, pulse-tracings, and temperature charts; the technic of all laboratory tests is given in detail, and every aid that can serve to make the diagnosis and treatment of the cases thoroughly clear to the general practitioner is emphasized. These publications are *clinical in the strictest sense*—they are an exposition of diagnosis and treatment as *actually practiced* at the bedside and in the amphitheater.

Goepp's State Board Questions

**Just Issued
New (4th) Edition**

STATE BOARD QUESTIONS AND ANSWERS. By R. MAX GOEPP, M.D., Professor of Clinical Medicine, Philadelphia Polyclinic. Octavo of 723 pages. Cloth, \$4.25 net.

"Nothing has been printed which is so admirably adapted as a guide and self-quiz for those intending to take the State Board Examinations."—*Pennsylvania Medical Journal*.

Sahli's Diagnostic Methods

Second Edition

A TREATISE ON DIAGNOSTIC METHODS OF EXAMINATION. By PROF. DR. H. SAHLI, of Bern. Edited, with additions, by NATH'L BOWDITCH POTTER, M. D., Assistant Professor of Clinical Medicine, Columbia University (College of Physicians and Surgeons), New York. Octavo of 1229 pages, illustrated. Cloth, \$6.50 net; Half Morocco, \$8.00 net.

Cabot's Works on Diagnosis

Differential Diagnosis. Presented through an Analysis of Cases. By RICHARD C. CABOT, M. D., Assistant Professor of Clinical Medicine, Harvard Medical School, Boston. Each volume an octavo of about 750 pages, illustrated. Per volume: Cloth, \$6.00 net.

Dr. Cabot's work takes up diagnosis from the point of view of the *presenting symptom*—the symptom in any disease which holds the foreground in the clinical picture: the principal complaint. It groups diseases under these symptoms, and points the way to proper reasoning in coming to a correct diagnosis. It works backward from each leading symptom to the actual organic cause of the symptom. This the author does by means of *case-teaching*.

The *symptom-groups* considered in Volume I [New (3d) Edition] are: Headache, general abdominal pain, epigastric pain, right hypochondriac pain, left hypochondriac pain, right iliac pain, left iliac pain, axillary pain, pain in arms, pain in legs and feet, fevers, chills, coma, convulsions, weakness, cough, vomiting, hematuria, dyspnea, jaundice, and nervousness—21 symptoms and 385 cases.

Volume II (Just Out): Abdominal and other tumors, vertigo, diarrhea, dyspepsia, hematemesis, enlarged glands, blood in stools, swelling of face, hemoptysis, edema of legs, frequent micturition and polyuria, fainting, hoarseness, pallor, swelling of arm, delirium, palpitation and arrhythmia, tremor, ascites and abdominal enlargement—a total of 19 symptoms and 317 instructive cases.

Morrow's Diagnostic and Therapeutic Technic

Diagnostic and Therapeutic Technic. By ALBERT S. MORROW, M. D., Clinical Professor of Surgery, New York Polyclinic. Octavo of 834 pages, with 860 original line drawings. Cloth, \$5.50 net.

SECOND EDITION

Dr. Morrow's new work is decidedly a work for you—the physician engaged in general practice. It is a work you need because it tells you just how to perform those procedures required of you every day, and it tells you and *shows* you by clear, *new* line-drawings, in a way never before approached. It is not a book on drug therapy; it deals alone with physical or mechanical diagnostic and therapeutic measures. The information it gives is such as you need to know every day—transfusion and infusion, hypodermic medication, Bier's hyperemia, exploratory punctures, aspirations, anesthesia, etc. Then follow descriptions of those measures employed in the diagnosis and treatment of diseases of special regions or organs: proctoclysis, cystoscopy, etc.

Journal American Medical Association

"The procedures described are those which practitioners may at some time be called on to perform."

Musser and Kelly on Treatment

Practical Treatment. By 108 eminent specialists. Volumes I, II, and III, edited by JOHN H. MUSSER, M. D., and A. O. J. KELLY, M. D. Each an octavo of 950 pages, illustrated. Cloth, \$6.00 net; Half Morocco, \$6.50 net. Volume IV, edited by JOHN H. MUSSER, JR., M. D., and THOMAS C. KELLY, M. D. Octavo of 990 pages, illustrated. Cloth, \$7.00 net; Half Morocco, \$8.50 net. *Subscription.*

VOLUME IV—All the New Treatments—JUST OUT

With Musser and Kelly's Treatment within arm's reach you have at your instant command the combined experience and teachings of 108 leading internists and specialists of America and England. In many cases you get the *actual prescriptions* used by these authorities. The past few years have seen radical developments in medicine; it is these new developments that constitute the subject-matter of *Volume IV*. Bacteriology, the endocrine glands, serum therapy, synthetic chemistry, new surgical and non-medical treatments—these are only a few of the subjects covered. Remember, Musser and Kelly's Treatment covers the *entire field*. It is a Treatment that will give you more service—*better service*—than any other.

Thomson's Clinical Medicine

Clinical Medicine. By WILLIAM HANNA THOMSON, M. D., LL. D., formerly Professor of the Practice of Medicine and of Diseases of the Nervous System, New York University Medical College. Octavo of 675 pages. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

TWO PRINTINGS IN FOUR MONTHS

This new work represents over a *half century of active practice and teaching*. It deals with *bedside medicine*—the *application* of medical knowledge for the relief of the sick. First the meaning of common and important symptoms is stated *definitely*; then follows a chapter on the use of remedies and a classification of them; next the section on infections, and last a section on diseases of particular organs and tissues. It is medical knowledge *applied*—from cover to cover. An important chapter is that on the mechanism of surface chill and "catching cold," going very clearly into the etiologic factors, and outlining the treatment. The chapter on remedies takes up non-medicinal and medicinal remedies and *vaccine and serum therapy*. In the chapter on the ductless glands the subject of *internal secretions* is very clearly presented, giving you the latest advances. The infectious diseases are taken up in Part II, while Part III deals with diseases of special organs or tissues, every disease being fully presented from the *clinical side*. Treatment, naturally, is very full.

Ward's Bedside Hematology

Bedside Hematology. By GORDON R. WARD, M.D., Fellow of the Royal Society of Medicine, London, England. Octavo of 394 pages, illustrated. Cloth, \$3.50 net.

INCLUDING VACCINES AND SERUMS

Dr. Ward's work gives you the exact technic for obtaining the blood for examination, the making of smears, the blood-count, finding coagulation time, etc. Then it takes up each disease, giving you the synonyms, definition, nature, general pathology, etiology, bearings of age and sex, the onset, symptomatology (discussing each symptom *in detail*), course of the disease, clinical varieties, complications, diagnosis, and treatment (drug, diet, rest, *vaccines and serums*, etc.).

Faught's Blood-Pressure

Blood-Pressure from the Clinical Standpoint. By FRANCIS A. FAUGHT, M. D., formerly Instructor in Medicine, Medico-Chirurgical College of Philadelphia. Octavo of 475 pages, illustrated. Cloth, \$3.25 net.

NEW (2d) EDITION

Dr. Faught's book is designed for practical help *at the bedside*. Besides the actual technic of using the sphygmomanometer in diagnosing disease, Dr. Faught has included a brief general discussion of the process of circulation. The practical application of sphygmomanometric findings within recent years make it imperative for every medical man to have close at hand an up-to-date work on this subject.

Smith's What to Eat and Why

What to Eat and Why. By G. CARROLL SMITH, M.D., Boston. 12mo of 377 pages. Cloth, \$2.75 net.

NEW (2d) EDITION

With this book you no longer need send your patients to a specialist to be dieted—you will be able to prescribe the suitable diet yourself just as you do other forms of therapy. Dr. Smith gives the "why" of each statement he makes. It is this knowing why which gives you confidence in the book, which makes you feel that Dr. Smith *knows*.

Pennsylvania Medical Journal

"All through this book Dr. Smith has added to his dietetic hints a great many valuable ones of a general nature, which will appeal to the general practitioner."

Kolmer's Specific Therapy

Infection, Immunity, and Specific Therapy. By JOHN A. KOLMER, M. D., DR. P. H., Assistant Professor of Experimental Pathology, University of Pennsylvania. Octavo of 900 pages, with 143 original illustrations, 43 in colors, drawn by Erwin F. Faber. Cloth, \$6.00 net; Half Morocco, \$7.50 net.

ORIGINAL ILLUSTRATIONS

Dr. Kolmer's book gives you a full account of infection and immunity, and *the application of this knowledge* in the specific diagnosis, prevention, and treatment of disease. The section devoted to *immunologic technic* gives you every detail, from the care of the centrifuge and making a simple pipet to the actual production of serums and vaccines. Under *specific therapy* you get methods of making *autogenous vaccines* and their *actual use* in diagnosis and treatment. The directions for injecting vaccines, serums, salvarsan, etc.—with the *exact dosage*—are here given so clearly that you will be able to use these means of treatment in your daily practice. You also get full directions for making the *clinical diagnostic reactions*—the various tuberculin tests, luetin, mallein, and similar reactions, all illustrated with *colored plates*. The final section is devoted to *laboratory experiments*.

Anders & Boston's Medical Diagnosis

A Text-Book of Medical Diagnosis. By JAMES M. ANDERS, M. D., PH. D., LL. D., Professor of Medicine, and L. NAPOLEON BOSTON, M. D., Professor of Physical Diagnosis, Medico-Chirurgical College, Graduate School of Medicine, University of Pennsylvania. Octavo of 1248 pages, with 466 illustrations. Cloth, \$6.00 net; Half Morocco, \$7.50 net.

SECOND EDITION

This new edition is designed expressly for the general practitioner. The methods given are practical and especially adapted for quick reference. The diagnostic methods are presented in a forceful, definite way by men who have had wide experience at the bedside and in the clinical laboratory.

The Medical Record

"The association in its authorship of a celebrated clinician and a well-known laboratory worker is most fortunate. It must long occupy a pre-eminent position."

Anders' Practice of Medicine

A Text-Book of the Practice of Medicine. By JAMES M. ANDERS, M. D., PH. D., LL. D., Professor of Medicine, University of Pennsylvania. Handsome octavo, 1336 pages, fully illustrated. Cloth, \$5.50 net; Half Morocco, \$7.00 net.

THE NEW (12th) EDITION

The success of this work is no doubt due to the extensive consideration given to Diagnosis and Treatment, under Differential Diagnosis the points of distinction of simulating diseases being presented in tabular form. In this new edition Dr. Anders has included all the most important advances in medicine, keeping the book within bounds by a judicious elimination of obsolete matter. A great many articles have also been rewritten.

Wm. E. Quine, M. D.,

Professor of Medicine and Clinical Medicine, College of Physicians and Surgeons, Chicago.

"I consider Anders' Practice one of the best single-volume works before the profession at this time, and one of the best text-books for medical students."

DaCosta's Physical Diagnosis

Physical Diagnosis. By JOHN C. DACOSTA, JR., M. D., Associate Professor of Medicine, Jefferson Medical College, Philadelphia. Octavo of 589 pages, with 243 original illustrations. Cloth, \$3.50 net

NEW (3d) EDITION

Dr. DaCosta's work is a thoroughly new and original one. Every method given has been carefully tested and proved of value by the author himself. Normal physical signs are explained in detail in order to aid the diagnostician in determining the abnormal. Both direct and differential diagnosis are emphasized. The cardinal methods of examination are supplemented by full descriptions of technic and the clinical utility of certain instrumental means of research.

Dr. Henry L. Elsner, *Professor of Medicine at Syracuse University.*

"I have reviewed this book, and am thoroughly convinced that it is one of the best ever written on this subject. In every way I find it a superior production."

Norris & Landis' Physical Diagnosis

Physical Diagnosis. Part I: By GEORGE WILLIAM NORRIS, A. B., M. D., Associate in Medicine at the University of Pennsylvania; Part II: By H. R. M. LANDIS, A. B., M. D., Director of Clinical and Sociological Department of the Phipps Institute, Philadelphia. Octavo of 800 pages, with 325 illustrations, mostly original.

STRONG ON INTERPRETATION

This work presents an admirable combination of the theory and applications of physical diagnosis. It is complete down to the last detail. The first part takes up the methods in themselves. Inspection, palpation, percussion, and auscultation are completely covered in the examination both of the lungs and of the heart. The latter is amplified by a chapter on the electrocardiograph by Dr. Edward B. Krumbhaar. The second part takes up the particular diseases of the bronchii, of the lungs, of the pleura, diaphragm, pericardium, heart and aorta, and shows you exactly how to determine the diagnosis by the symptoms and findings. You get here the application of the four methods to your daily clinical work.

Friedenwald and Ruhrah on Diet

Diet in Health and Disease. By JULIUS FRIEDENWALD, M. D., Professor of Diseases of the Stomach, and JOHN RUHRÄH, M. D., Professor of Diseases of Children, College of Physicians and Surgeons, Baltimore. Octavo of 857 pages. Cloth, \$4.00 net.

FOURTH EDITION

This new edition has been carefully revised, making it still more useful than the two editions previously exhausted. The articles on milk and alcohol have been rewritten, additions made to those on tuberculosis, the salt-free diet, and rectal feeding, and several tables added, including Winton's, showing the composition of diabetic foods.

George Dock, M. D.

Professor of Theory and Practice and of Clinical Medicine, Tulane University.

"It seems to me that you have prepared the most valuable work of the kind now available. I am especially glad to see the long list of analyses of different kinds of foods."

Carter's Diet Lists

DIET LISTS OF THE PRESBYTERIAN HOSPITAL OF NEW YORK CITY. Compiled, with notes, by HERBERT S. CARTER, M. D. 12mo of 129 pages. Cloth, \$1.00 net.

Here Dr. Carter has compiled all the diet lists for the various diseases and for convalescence as prescribed at the Presbyterian Hospital. Recipes are also included.

Kemp on Stomach, Intestines, and Pancreas

Diseases of the Stomach, Intestines, and Pancreas. By ROBERT COLEMAN KEMP, M. D., Professor of Gastro-intestinal Diseases at the New York School of Clinical Medicine. Octavo of 1096 pages, with 428 illustrations. Cloth, \$7.00 net; Half Morocco, \$8.50 net,

JUST OUT—NEW (3d) EDITION

The new edition of Dr. Kemp's successful work appears after a most searching revision. Several new subjects have been introduced, notably chapters on *Colon Bacillus Infection* and on *Diseases of the Pancreas*, the latter article being really an exhaustive monograph, covering over one hundred pages. The section on *Duodenal Ulcer* has been entirely rewritten. *Visceral Displacements* are given special consideration, in every case giving definite indications for surgical intervention when deemed advisable. There are also important chapters on the *Intestinal Complications of Typhoid Fever* and on *Diverticulitis*.

The Therapeutic Gazette

"The therapeutic advice which is given is excellent. Methods of physical and clinical examination are adequately and correctly described."

Gant on Diarrheas

Diarrheal, Inflammatory, Obstructive, and Parasitic Diseases of the Gastro-intestinal Tract. By SAMUEL G. GANT, M. D., LL.D., Professor of Diseases of Sigmoid Flexure, Colon, Rectum, and Anus, New York Post-graduate Medical School and Hospital. Octavo of 604 pages, 181 illustrations. Cloth, \$6.00 net; Half Morocco, \$7.50 net.

ILLUSTRATED

This new work is particularly full on the two practical phases of the subject—*diagnosis* and *treatment*. For instance: While the essential diagnostic points are given under each disease, a fuller description of diagnostic methods is given in a special chapter. The *differential diagnosis* of diarrheas of local and those of systemic disturbances is strongly brought out. There is a special chapter on *nervous diarrheas* and those originating from *gastrogenic* and *enterogenic dyspepsias*. You get methods of simultaneously controlling associated constipation and diarrhea. You get a complete *formulary*. The limitations of drugs are pointed out, and the indications and *technic* of all surgical procedures given.

Gant on Constipation and Obstruction

This work is medical, non-medical (mechanical), and surgical, the latter really being a complete work on rectocolonic surgery.

Octavo of 575 pages, with 250 illustrations. By SAMUEL G. GANT, M. D. Cloth, \$6.00 net.

Sollmann's Pharmacology

A Manual of Pharmacology: ITS APPLICATIONS TO THERAPEUTICS AND TOXICOLOGY. By TORALD SOLLMANN, M. D., Professor of Pharmacology and Materia Medica in the School of Medicine of Western Reserve University, Cleveland. Octavo of 901 pages, illustrated. Cloth, \$4.50 net.

JUST OUT—BASED ON THE 1916 U. S. PHARMACOPOEIA

MANUAL. This is the text or reference volume. Two sizes of type are used. The broad conceptions, the generalizations, and those detailed discussions of great and practical value to practitioner and student are set in the large type. The mass of minute details is set in the smaller type, with frequent side headings to facilitate quick reference. Throughout the work the *relation of pharmacology to the practice of medicine* is forcibly emphasized. The really important drugs—those drugs that you actually use in your practice—are discussed extensively, while those used less frequently are dismissed with less consideration. All the new remedies are included, with detailed instructions for their use: Vaccines, serums, salvarsan, neosalvarsan, pituitary extract, emetin—all those new remedies of the Pharmacopœia being so extensively discussed and employed. Every worthwhile development in the field of pharmacology is included.

LABORATORY GUIDE. The exercises in this *Laboratory Guide* present no difficulty in technic, and require little help from the instructor. They teach you how to *teach yourself*. Special stress is laid on facts with direct practical bearing. The experiments on animals are arranged in groups to illustrate various types or phenomena, to bring out the similarities and differences of the response of organs to pharmacologic agents, rather than to individual drugs. This arrangement articulates better with the student's experience in physiology and pathology.

A Laboratory Guide in Pharmacology. By TORALD SOLLMANN, M. D. Octavo of 355 pages, illustrated. Cloth, \$2.50 net.

Arny's Pharmacy

Just Out

Principles of Pharmacy. By HENRY V. ARNY, PH. D., Professor of Chemistry, New York College of Pharmacy. Octavo of 1056 pages, with 246 illustrations. Cloth, \$5.50 net; Half Morocco, \$7.00 net.

NEW (2d) EDITION

Professor Arny divides his book into seven parts: The first part deals with pharmaceutical processes, a striking feature being the clear discussion of the *arithmetic of pharmacy*; the second, with galenic preparations of the Pharmacopœia and those unofficial preparations of proved value; the third, with the inorganic chemicals, including the theories of chemistry; the fourth discusses the organic chemicals; the fifth is devoted to chemical testing, presenting a systematic grouping of *all the tests of the Pharmacopœia*; the sixth discusses the prescription from the time it is written until it is dispensed; the seventh is devoted to laboratory work, with *exercises in equation writing and chemical arithmetic*.

George Reimann, Ph. G., Secretary New York State Board of Pharmacy

"I would say that the book is certainly a great help to the student, and I think it ought to be in the hands of every person who is contemplating the study of pharmacy."

Bastedo's *Materia Medica* Pharmacology, Therapeutics, Prescription Writing

Materia Medica, Pharmacology, Therapeutics, and Prescription Writing. By W. A. BASTEDO, PH. D., M. D., Associate in Pharmacology and Therapeutics at Columbia University, New York. Octavo of 602 pages, illustrated. Cloth, \$3.50 net.

THREE PRINTINGS IN SIX MONTHS

Dr. Bastedo's discussion of his subject is very complete. As an illustration, take the pharmacologic action of the drug. It gives you the antiseptic action, the local action on the skin, mucous membranes, and the alimentary tract; where the drug is absorbed, if at all—and how rapidly. It gives you the systemic action on the circulatory organs, respiratory organs, nervous system, and sense organs. It tells you how the drug is changed in the body. It gives you the route of elimination and in what form. It gives you the action on the kidneys, bladder, urethra, skin, bowels, lungs, and mammary glands during elimination. It gives you the after-effects. It gives you the unexpected—the unusual—effects. It gives you the tolerance—habit formation. Could any discussion be more complete, more thorough?

Boston Medical and Surgical Journal

"Its aim throughout is therapeutic and practical, rather than theoretic and pharmacologic. The text is illustrated with sixty well-chosen plates and cuts. It should prove a useful contribution to the text-book literature on these subjects."

McKenzie on Exercise in Education and Medicine

Exercise in Education and Medicine. By R. TAIT MCKENZIE, B. A., M. D., Professor of Physical Education and Director of the Department, University of Pennsylvania. Octavo of 585 pages, with 478 original illustrations. Cloth, \$4.00 net.

NEW (2d) EDITION

D. A. Sargeant, M. D., *Director of Hemenway Gymnasium, Harvard University.*

"It cannot fail to be helpful to practitioners in medicine. The classification of athletic games and exercises in tabular form for different ages, sexes, and occupations is the work of an expert. It should be in the hands of every physical educator and medical practitioner."

Bonney's Tuberculosis

Second Edition

TUBERCULOSIS. By SHERMAN G. BONNEY, M. D., Professor of Medicine, Denver and Gross College of Medicine. Octavo of 955 pages, with 243 illustrations. Cloth, \$7.00 net; Half Morocco, \$8.50 net.

Maryland Medical Journal

"Dr. Bonney's book is one of the best and most exact works on tuberculosis, in all its aspects, that has yet been published."

Garrison's History of Medicine

History of Medicine. With Medical Chronology, Bibliographic Data, and Test Questions. By FIELDING H. GARRISON, M. D., Principal Assistant Librarian, Surgeon-General's Office, Washington, D. C. Cloth, \$6.00 net; Half Morocco, \$7.50 net.

REPRINTED IN THREE MONTHS—THE BAEDEKER OF MEDICAL HISTORY

The work begins with ancient and primitive medicine, and carries you in a most interesting and instructive way on through Egyptian medicine, Sumerian and Oriental medicine, Greek medicine, the Byzantine period; the Mohammedan and Jewish periods, the Medieval period, the period of the Renaissance, the Revival of learning and the Reformation; the Seventeenth Century (the age of individual scientific endeavor), the Eighteenth Century (the age of theories and systems), the Nineteenth Century (the beginning of organized advancement of science), the Twentieth Century (the beginning of organized preventive medicine). You get all the important facts in medical history; a *biographic dictionary*; an album of *medical portraits*; and a complete *medical chronology*.

Stevens' Therapeutics

Fifth Edition

A TEXT-BOOK OF MODERN MATERIA MEDICA AND THERAPEUTICS. By A. A. STEVENS, A. M., M. D., Lecturer on Physical Diagnosis in the University of Pennsylvania. Octavo of 675 pages. Cloth, \$3.50 net.

Dr. Stevens' Therapeutics is one of the most successful works on the subject ever published. In this new edition the work has undergone a very thorough revision, and now represents the very latest advances.

The Medical Record, New York

"Among the numerous treatises on this most important branch of medical practice, this by Dr. Stevens has ranked with the best."

Butler's Materia Medica

Sixth Edition

A TEXT-BOOK OF MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY. By GEORGE F. BUTLER, PH. G., M. D., Professor and Head of the Department of Therapeutics and Professor of Preventive and Clinical Medicine, Chicago College of Medicine and Surgery, Medical Department Valpariso University. Octavo of 702 pages, illustrated. Cloth, \$4.00 net; Half Morocco, \$5.50 net.

For this sixth edition Dr. Butler has entirely remodeled his work, a great part having been rewritten. All obsolete matter has been eliminated, and special attention has been given to the toxicologic and therapeutic effects of the newer compounds.

Medical Record, New York

"Nothing has been omitted by the author which, in his judgment, would add to the completeness of the text."

Tousey's Medical Electricity Röntgen Rays, and Radium

Medical Electricity, Röntgen Rays, and Radium. By SINCLAIR TOUSEY, M. D., Consulting Surgeon to St. Bartholomew's Hospital, New York. Octavo of 1219 pages, with 801 illustrations, 19 in colors. Cloth, \$7.50 net; Half Morocco, \$9.00 net.

SECOND EDITION, RESET

The revision for this edition was extremely heavy; new matter has increased the size of the book by some 100 pages. About 50 new illustrations have been added. The new matter added includes: Diathermy, sinusoidal currents, radiography with intensifying screens, röntgenotherapy, the Coolidge and similar Röntgen tubes and the author's method of dosage, and radium therapy are noted. The book has been enriched by including several of Machado's tabular classifications of electric methods, effects, and uses.

Throughout the entire work everything concerning electricity, *x*-rays, and radium in medicine, as well as phototherapy, is explained in detail—nothing is omitted. It tells you how to equip your office, and, more than that, how to use your apparatus, explaining away all difficulties. It tells you just how to apply these measures in the treatment of disease. The chapters on *dental radiography* are particularly valuable to those interested in dental work.

Deaderick & Thompson's Endemic Diseases of South

Endemic Diseases of the Southern States. By WILLIAM H. DEADERICK, M. D., Member American Society of Tropical Medicine; and LOYD THOMPSON, M. D., Charter Member American Association of Immunologists. Octavo of 546 pages, illustrated. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

THE ONLY WORK OF ITS KIND

This work records the experiences of two active practitioners and teachers right in the field and thoroughly familiar with these diseases. Those diseases of special importance are given unusual consideration. *Pellagra*, for instance, is given eight chapters for its full consideration, while *hookworm disease* covers nine chapters and *malaria* eight. You get the etiology, pathology, clinical history, diagnosis, prognosis, prophylaxis, and treatment of each disease, presented from every angle, always bearing in mind the practical aim of the work—the *application* of the knowledge in daily practice.
